m_{s} \equiv S_{z} / \hbar=-s,-s+1, \ldots, s-1, s
$$

Here $s$ is the quantum number of the square spin of the vector.
Since nucleon type has been defined to be completely equivalent to spin, essentially the same holds. A given nucleon energy state can still have different values of $T_{3}$ :

$$
\begin{equation*}
m_{T} \equiv T_{3}=-t_{T},-t_{T}+1, \ldots, t_{T}-1, t_{T} \tag{14.49}
\end{equation*}
$$

Here $t_{T}$ is the square nucleon-type quantum number of the state. The different values for $T_{3}$ above correspond to isobaric analog states for different nuclei. They are the same energy state, but for different nuclei.

You could say that isobaric analog states arise because "rotating" an energy state in the abstract $1,2,3$-space defined above does not make a difference. And the reason it does not make a difference is charge independence.

Based on the values of $T_{3}$ above, consider the possible values of $t_{T}$ for 14 nucleons. The value of $t_{T}$ cannot be greater than 7 . Otherwise there would be isobaric analog states with $T_{3}$ greater than 7 , and that is not possible for 14 nucleons. As far as the lowest possible value of $t_{T}$ is concerned, it varies with nucleus. As the expression above shows, the value of $\left|T_{3}\right|$ cannot be greater than $t_{T}$. So $t_{T}$ cannot be less than $\left|T_{3}\right|$. Since carbon-14 and oxygen-14 have $\left|T_{3}\right|=$ 1 , for these nuclei, $t_{T}$ cannot be less than 1 . However, nitrogen-14, with $T_{3}=$ 0 , also allows states with $t_{T}=0$.

It turns out that light nuclei in their ground state generally have the smallest value of $t_{T}$ consistent with their value of $T_{3}$. One way to get some idea of why that would be so is to look at the antisymmetrization requirements. A set of states with $t_{T}=7$ for 14 nucleons allows the state $T_{3}=7$, in which all 14 nucleons are protons. In that state, the wave function must be antisymmetric
when any nucleon is interchanged with any other. On the other hand, a $t_{T}=$ 0 state only needs to satisfy the antisymmetrization requirements for 7 protons and 7 neutrons. It does not have to be antisymmetric if a proton is exchanged with any one of the 7 neutrons. So antisymmetrization is less confining. In general, a state with $t_{T}$ greater than $\left|T_{3}\right|$ must work for more nuclei than one with $t_{T}=\left|T_{3}\right|$.
(Another argument, offered in literature, is essentially the reverse of the one that gives rise to the so-called "Hund rule" for atoms. Simply put, the Hund rule says that a couple of electrons maximize their spin, given the option between single-particle states of the same energy. The reason is that this allows electrons to stay farther apart, reducing their Coulomb repulsion, $\{$ A.34\}. This argument reverses for nucleons, since they normally attract rather than repel each other. However, surely this is a relatively minor effect? Consider 3 nucleons. For these, the highest value $t_{T}=\frac{3}{2}$ allows the possibility that all 3 are protons. Within a single-particle-state picture, only one can go into the lowest energy state; the second must go into the second lowest energy state, and the third in the third lowest. On the other hand, for say 2 protons and 1 neutron, the neutron can go into the lowest energy state with the first proton. So the lower value $t_{T}=\frac{1}{2}$ should normally have significantly less energy.)

For the deuteron $T_{3}=0$, so the lowest possible value of $t_{T}$ is 0 . Then according to the general rule above, the ground state of the deuteron should have $t_{T}=0$. That was already established above; it was the bound state not shared with the diproton and dineutron. Nitrogen-14 also has $T_{3}=0$, which means it too must have $t_{T}=0$ in its ground state. This lowest energy state cannot occur for carbon-14 or oxygen-14, because they have $\left|T_{3}\right|=1$. So nitrogen-14 should have less energy in its ground state than carbon-14 and oxygen-14. That seems at first surprising since nitrogen-14 has odd numbers of protons and neutrons, while carbon-14 and oxygen-14 have even numbers. Normally odd-odd nuclei are less tightly bound than even-even ones.

spin:
$-0 \quad-\frac{1}{2}-1$
$\begin{array}{lllllllllll}\frac{1}{2} & -1 & -\frac{3}{2} & -2 & -\frac{5}{2} & -3 & -\frac{7}{2} & -4 & -\frac{9}{2} & -5\end{array}$
Figure 14.46: Isobaric analog states. [pdf]

But it is true. Figure 14.46 shows the energy levels of carbon-14, nitrogen14, and oxygen-14. More precisely, it shows their binding energy, relative to the ground state value for nitrogen-14. In addition the von Weizsäcker value for the Coulomb energy has been subtracted to more clearly isolate the nuclear force effects. (The combined effect is simply to shift the normal spectra of carbon-14 and oxygen- 14 up by 2.83 , respectively 1.89 MeV .) It is seen that nitrogen- 14 is indeed more tightly bound in its ground state than carbon-14 and oxygen-14. Qualitatively, since nitrogen-14 does not have 8 nucleons of the same kind, it has an easier job with satisfying the antisymmetrization requirements.

Traces of the lower energy of light nuclei with $T_{3}=0$ can also be detected in figures like 14.4, and 14.5 through 14.8. In these figures $T_{3}=0$ straight above the $Z=N=2$ helium nucleus. Note in particular a distinct dark/light discontinuity in figures 14.5 through 14.8 along this vertical line. This discontinuity is quite distinct both from the magic numbers and from the average stability line that curves away from it.

Carbon-14 and oxygen-14 are mirror nuclei, so you would expect them to have pretty much the same sort of energy levels. Indeed, any oxygen-14 state, having $T_{3}=1$, must be part of a multiplet with $t_{T}$ at least 1 . Such a multiplet must have an equivalent state with $T_{3}=-1$, which means an equivalent carbon14 state. To the extent that the nuclear force is truly charge-independent, and the Coulomb effect has been properly removed, these two states should have the same energy. And indeed, the lowest four energy states of carbon-14 and oxygen- 14 have identical spin and parity and similar energies. Also, both eveneven nuclei have a $0^{+}$ground state, as even-even nuclei should. These ground states have $t_{T}=1$, the smallest possible.

Now each of these multiplets should also have a version with $T_{3}=0$, which means a nitrogen-14 state. So any state that carbon-14 and oxygen-14 have should also exist for nitrogen-14. For example, the ground states of carbon-14 and oxygen- 14 should also appear as a $0^{+}$state with $t_{T}=1$ in the nitrogen-14 spectrum. Indeed, if you inspect the energy levels for nitrogen-14 in figure 14.46, exactly halfway in between the carbon-14 and oxygen-14 ground state energies, there it is!

Ideally speaking, these three states should have the same height in the figure. But it would be difficult to remove the Coulomb effect completely. And charge independence is not exact either, even though it is quite accurate.

A similar $T_{3}=0$ state can readily be found for the first three excited levels of carbon-14 and oxygen-14. In each case there is a nitrogen-14 state with exactly the same spin and parity and $t_{T}=1$ right in between the matching carbon14 and oxygen- 14 levels. (To be sure, ENSDF does not list the $t_{T}$ values for carbon-14 above the ground state. But common sense says they must be the same as the corresponding states in nitrogen-14 and carbon-14. For the first excited state of carbon-14, this is confirmed in [50, p. 11].)

Figure 14.46 also shows that nitrogen-14 has a lot more low energy states
than carbon-14 or oxygen-14. Square nucleon type can explain that too: all the low-lying states of nitrogen-14 that are not shared with carbon-14 and oxygen-14 are $t_{T}=0$ states. These states are not possible for the other two nuclei.

Nothing is perfect, of course. The first state with nonzero $t_{T}$ in the nitrogen spectrum besides the mentioned four isobaric analog states is the $0^{-}, t_{T}=1$ state at 8.8 MeV , just below the $3^{-}$analog state. Carbon-14 has a $0^{-}$state immediately above the $3^{-}$state, but oxygen-14 has no obvious candidate.

Despite such imperfections, consideration of nucleon type is quite helpful for understanding the energy levels of light nuclei. And a lot of it carries over to heavier nuclei, [50, p. 12] and [36, p. 57]. While heavier nuclei have significant Coulomb energy, this long-range force is apparently often not that important here.

Now all that is needed is a good name. "Nucleon type" or "nucleon class" are not acceptable; they would give those hated outsiders and pesky students a general idea of what physicists were talking about. However, physicists noted that there is a considerable potential for confusion between nucleon type and spin, since both are described by the same mathematics. To maximize that potential for confusion, physicists decided that nucleon type should be called "spin."

Of course, physicists themselves still have to know whether they are talking about nucleon type or spin. Therefore some physicists called nucleon type "isobaric spin," because what differentiates isobars is the value of the net $T_{3}$. Other physicists talked about "isotopic spin," because physicists like to think of isotopes, and hey, isotopes have nucleon type too. Some physicists took the isowhatever spin to be $\frac{1}{2}$ for the proton, others for the neutron. However, that confused physicists themselves, so eventually it was decided that the proton has $\frac{1}{2}$. Also, a great fear arose that the names might cause some outsiders to suspect that the "spin" being talked about was not really spin. If you think about it, "isobaric angular momentum" or "isotopic angular momentum" does not make much sense. So physicists shortened the name to "isospin." Isospin means "equal spin" plain and simple; there is no longer anything to give the secret away that it is something completely different from spin. However, the confusion of having two different names for the same quantity was missed. Therefore, the alternate term " $i$-spin" was coined besides isospin. It too has nothing to give the secret away, and it restores that additional touch of confusion.

Isospin is conserved when only the nuclear force is relevant. As an example, consider the reaction in which a deuteron kicks an alpha particle out of an oxygen-16 nucleus:

$$
{ }_{8}^{16} \mathrm{O}+{ }_{1}^{2} \mathrm{H} \quad \rightarrow \quad{ }_{7}^{14} \mathrm{~N}+{ }_{2}^{4} \mathrm{He}
$$

The oxygen is assumed to be in the ground state. That is a $t_{T}=0$ state, in agreement with the fact that oxygen-16 is a light nucleus with $T_{3}=0$. The deuteron can only be in a $t_{T}=0$ state; that is the only bound state. The
alpha particle will normally be in the ground state, since it takes over 20 MeV to excite it. That ground state is a $t_{T}=0$ one, since it is a light $T_{3}=0$ nucleus. Conservation of isospin then implies that the nitrogen-14 must have $t_{T}$ $=0$ too. The nitrogen can come out excited, but it should not come out in its lowest excited state, the $0^{+} t_{T}=1$ state shared with carbon-14 and oxygen-14 in figure 14.46. Indeed, experiments show that this lowest excited state is only produced in negligible amounts compared to the surrounding states.

Selection rules for which nuclear decays occur can also be formulated based on isospin. If the electromagnetic force plays a significant part, $T_{3}$ but not $\vec{T}$ is conserved. The weak force does not conserve $T_{3}$ either, as beta decay shows. For example, the ground states of oxygen-14 and carbon-14 in figure 14.46 will betadecay to the ground state of nitrogen 14, changing both $T_{3}$ and $t_{T}$. (Oxygen-16 will also beta-decay to the corresponding isobaric analog state of nitrogen-14, a decay that is called "superallowed," because it is unusually fast. It is much faster than to the ground state, even though decay to the ground state releases more energy. Carbon-14 has too little energy to decay to the analog state.)

Despite the lack of isospin conservation, isospin turns out to be very useful for understanding beta and gamma decay. See for example the discussion of superallowed beta decays in chapter 14.19, and the isospin selection rules for gamma decay in section 14.20.2.

### 14.18.3 Draft: Additional points

There are other particles besides nucleons that are also pretty much the same except for electric charge, and that can also be described using isospin. For example, the positive, neutral, and negatively charged pions form an isospin triplet of states with $t_{T}=1$. Isospin was quite helpful in recognizing the existence of the more basic particles called quarks that make up baryons like nucleons and mesons like pions. In final analysis, the usefulness of isospin is a consequence of the approximate properties of these quarks.

Some sources incorrectly credit the concept of isospin to Heisenberg. But he did not understand what he was doing. Heisenberg did correctly guess that protons and neutrons might be described as two variants of the same particle. He then applied the only quantum approach for a two-state particle to it that he knew, that of spin. However, the mathematical machinery of spin is designed to deal with two-state properties that are preserved under rotations of an axis system, compare \{A.19\}. That is an inappropriate mathematical approach to describe nucleon type in the absence of charge independence. And at the time Heisenberg himself believed that the nuclear force was far from charge-independent.
(Because the nuclear force is in fact approximately charge-independent, unlike Heisenberg assumed, isospin is preserved under rotations of the abstract $1,2,3$ coordinate system as defined in the first subsection. Phrased more simply,
without charge independence, energy eigenfunctions would not have definite values of square isospin $t_{T}$. That would make isospin self-evidently "entirely useless," as Wigner pointed out. This point is not very clear from the example of two nucleons in empty space, as discussed above. That is because there the spatial wave function happens to be symmetric under particle exchange even without charge independence. But if you express the isospin states in the general wave function (14.41) in terms of the singlet and triplet states, you quickly see the problem.)

The recognition that isospin was meaningful only in the presence of charge independence, and the proposal that the nuclear force is indeed quite accurately charge-independent, was mostly due to Wigner, in part with Feenberg. Some initial steps had already been taken by other authors. In particular, Cassen \& Condon had already proposed to write wave functions in a form to include isospin,

$$
\psi=\psi\left(\vec{r}_{1}, S_{z 1}, T_{31}, \vec{r}_{2}, S_{z 2}, T_{32}, \ldots\right)
$$

and proposed symmetry under particle exchange in that form. This is the form of wave functions as written down earlier for the two-nucleon system. Still Wigner is considered the founding father of the study of isospin. His identification of isospin for complex nuclei as we know it today, as a preserved quantum number due to charge independence, is the foundation charter of nuclear isospin. Wigner is also the infernal idiot who decided that "nucleon type" should be called "spin."

See Wilkinson, [50, p. vi, 1-13], for a more extensive discussion of these historical issues. A very different history is painted by Henley in the next chapter in the same book. In this history, Heisenberg receives all the credit. Wigner does not exist. However, the author of this history implicitly admits that Heisenberg did think that the nuclear force was far from charge-independent. Maybe the author understood isospin too poorly to recognize that that is a rather big problem. Certainly there is no discussion. Or the author had a personal issue with Wigner and was willing to sacrifice his scientific integrity for it. Either way, the credibility of the author of this particular history is zero.

### 14.18.4 Draft: Why does this work?

It may seem astonishing that all this works. Why would nucleon type resemble spin? Spin is a vector in three-dimensional space, not a simple number. Why would energy eigenstates be unchanged under rotations in some weird abstract space?

The simplest and maybe best answer is that nature likes this sort of mathematics. Nature just loves creation and annihilation operators. But still, why would that lead to preserved lengths of vectors in an abstract spaces?

An answer can be obtained by looking a bit closer at square spin. Consider first two spin $1 / 2$ fermions. Compare the dot product of their spins to the operator
$\widehat{P}_{12}^{s}$ that exchanges their spins:

$$
\begin{aligned}
\widehat{\vec{S}}_{1} \cdot \widehat{\vec{S}}_{2}|00\rangle & =-\frac{3}{4} \hbar^{2}|00\rangle & \widehat{P}_{12}^{s}|00\rangle & =-|00\rangle \\
\widehat{\vec{S}}_{1} \cdot \widehat{\vec{S}}_{2}\left|1 m_{s}\right\rangle & =\frac{1}{4} \hbar^{2}\left|1 m_{s}\right\rangle & \widehat{P}_{12}^{s}\left|1 m_{s}\right\rangle & =\left|1 m_{s}\right\rangle
\end{aligned}
$$

The first set of relations is derived in $\{\mathrm{A} .10\}$. The second set can be verified by looking at the expressions of the spin states (5.26).

Comparing the two sets of relations, it is seen that the dot product of two spins is closely related to the operator that exchanges the two spins:

$$
\widehat{\vec{S}}_{1} \cdot \widehat{\vec{S}}_{2}=\frac{1}{4} \hbar^{2}\left(2 \widehat{P}_{12}^{s}-1\right)
$$

Now consider the square spin of a system of $I$ fermions. By definition

$$
\widehat{\vec{S}}^{2} \equiv\left(\sum_{i=1}^{I} \widehat{\vec{S}}_{i}\right) \cdot\left(\sum_{\underline{i}=1}^{I} \widehat{\vec{S}}_{\underline{i}}\right)=\sum_{i=1}^{I} \sum_{\underline{i}=1}^{I} \widehat{\vec{S}}_{i} \cdot \widehat{\vec{S}}_{\underline{i}}
$$

Split up the sum into terms that have $i$ and $\underline{i}$ equal, respectively not equal:

$$
\widehat{\vec{S}}^{2}=\sum_{i=1}^{I} \widehat{\vec{S}}_{i}^{2}+2 \sum_{i=1}^{I} \sum_{\underline{i}=i+1}^{I} \widehat{\vec{S}}_{i} \cdot \widehat{\vec{S}}_{\underline{i}}
$$

The first sum is just the square spin angular momentum of the individual fermions. The second sum can be written in terms of the exchange operators using the expression above. Doing so and cleaning up gives:

$$
\widehat{\vec{S}}^{2}=\hbar^{2}\left(I-\frac{1}{4} I^{2}\right)+\hbar^{2} \sum_{i=1}^{I} \sum_{\underline{i}=i+1}^{I} \widehat{P}_{i \underline{i}}^{s}
$$

Similarly then for isospin as defined in the first subsection,

$$
\widehat{\vec{T}}^{2}=\left(I-\frac{1}{4} I^{2}\right)+\sum_{i=1}^{I} \sum_{\underline{i}=i+1}^{I} \widehat{P}_{i \underline{i}}^{T}
$$

Square isospin by itself does not have direct physical meaning. However, the exchange operators do. In particular, charge independence means that exchanging nucleon types does not make a difference for the energy. That then means that $\widehat{\vec{T}}^{2}$ commutes with the Hamiltonian. That makes it a conserved quantity according to the rules of quantum mechanics, chapter 4.5.1 and/or \{A.19\}.

It may be noted that the exchange operators do not commute among themselves. That makes the symmetry requirements so messy. However, it is possible to restrict consideration to exchange operators of the form $\widehat{P}_{i i+1}$. See [14] for more.

Infinitesimal "rotations" of a state in 1,2,3 isospin state correspond to applying small multiples of the operators $\widehat{T}_{1}, \widehat{T}_{2}$ and $\widehat{T}_{3}$, compare $\{$ A.19\}. According to the definitions of $\widehat{T}_{1}$ and $\widehat{T}_{2}$, this corresponds to applying small multiples of the charge creation and annihilation operators. So it amounts to gradually changing protons into neutrons and vice-versa. As a simple example, a $180^{\circ}$ rotation around the 1 or 2 axis inverts the 3 -component of every nucleon. That turns every proton into a neutron and vice-versa.

### 14.19 Draft: Beta decay

### 14.19.1 Draft: Introduction

Beta decay is the decay mechanism that affects the largest number of nuclei. It is important in a wide variety of applications, such as betavoltaics and PET imaging.

In standard beta decay, or more specifically, beta-minus decay, a nucleus converts a neutron into a proton. The number of neutrons $N$ decreases by one unit, and the number of protons $Z$ increases by one. So the neutron excess decreases by two. Beta decay moves nuclei with too many neutrons closer to the stable range.

Unlike the neutron, the proton has a positive charge, so by itself, converting a neutron into a proton would create charge out of nothing. However, that is not possible as net charge is preserved in nature. In beta decay, the nucleus also emits a negatively charged electron, making the net charge that is created zero as it should.

But there is another problem with that. Now a neutron with spin $1 / 2$ is converted into a proton and an electron, each with spin $1 / 2$. That violates angular momentum conservation. (Regardless of any orbital angular momentum, the net angular momentum would change from half-integer to integer.) In beta decay, the nucleus also emits a second particle of spin $1 / 2$, thus keeping the net angular momentum half-integer. Fermi called that second particle the neutrino, since it was electrically neutral and so small that it was initially impossible to observe. In fact, even at the time of writing, almost a century later, the mass of the neutrino, though known to be nonzero, is too small to measure.

Nowadays the neutrino emitted in beta decay is more accurately identified as the electron antineutrino. An antineutrino is the antiparticle of an ordinary neutrino, just like the positron is the antiparticle of the electron. (Particles and antiparticles are exact opposites in all properties except mass, but including charge, allowing a particle and the corresponding antiparticle to annihilate each other, leaving only photons.)

The reason that an antineutrino is emitted rather than a neutrino is known as "conservation of lepton number." Leptons are elementary particles that do not
respond to the "strong force," including electrons and neutrinos. The net lepton number is defined as the number of leptons, minus the number of antileptons. It is found that this number is conserved in nature. So when in beta decay the nucleus emits an electron, a lepton, and an antineutrino, an antilepton, the lepton number stays unchanged as it should (like net angular momentum and net charge stay unchanged, as already noted).

The antineutrino does not affect the basics of beta decay, as it has no charge and virtually zero mass. However, the antineutrino does affect the detailed analysis; for one, the antineutrino can come out with a lot of kinetic energy, thus reducing the otherwise expected kinetic energy of the electron.

In beta decay, the new nucleus must be lighter than the original one. Classical mass conservation would say that the reduction in nuclear mass must equal the mass of the emitted electron plus the (negligible) mass of the antineutrino. However, Einstein's mass-energy relation implies that that is not quite right. Mass is equivalent to energy, and the rest mass reduction of the nucleus must also provide the kinetic energies of the electron and neutrino, as well as the (much smaller) one that the nucleus itself picks up during the decay by "recoil"

Still, the bottom line is that the nuclear mass reduction must be at least the rest mass of the electron (plus antineutrino). In energy units, it must be at least 0.511 MeV , the rest mass energy of the electron. The first subsection below will graphically examine which nuclei have enough energy to beta decay.

Beta-plus decay is the opposite of beta decay. In beta-plus decay, the nucleus converts a neutron into a proton instead of the other way around. To conserve charge, the nucleus can emit a positron, and with it, an electron neutrino to conserve angular momentum and lepton number.

However, while converting a proton into a neutron, the nucleus has a much easier way to conserve charge. Instead of emitting a positively charged positron, it can absorb a negatively charged electron from the atom it is in. The electron's charge then cancels that of the proton. To preserve angular momentum and lepton number, an electron neutrino is again emitted. This process is called "electron capture" (or also "K-capture" or "L-Capture" depending on the electron shell name from which the electron is swiped). Now the nuclear mass reduction does not need to provide the 0.512 MeV rest mass energy of a positron. Instead the nuclear mass can increase up to the 0.512 MeV rest mass energy of the electron that disappears.

So electron capture can occur in circumstances where positron creation is not possible. However, if the nuclear mass reduction is plenty for both electron capture and positron emission, the latter tends to dominate. The reason is the large quantum mechanical uncertainty in position of the low-energy atomic electron. This uncertainty dwarfs the size of the nucleus. It makes it very unlikely for the electron to be found inside the nucleus. A high-energy positron created by the nucleus itself can be created in any state, including high energy ones with short wave lengths.

Also note electron capture is of course not possible if somehow the nucleus has been stripped of all its atomic electrons, like might occur in space.

Electron capture is also called "inverse beta decay," because an electron being absorbed by a nucleus is much like a movie of an electron being emitted played backwards in time. But there are some problems with this idea. For one, the time-reversed movie would also have an electron antineutrino going into the nucleus, not an electron neutrino coming out.

Still, absorption of a particle is much like the emission of the corresponding antiparticle, at least as far as conservation laws other than energy are concerned. For example, capture of an electron adds one unit of negative charge, while emission of a positron removes one unit of positive charge. Either way, the nuclear charge becomes one unit more negative. In those terms, the notion of "inverse beta decay" may not be that far out, especially since the neutrino is a minor actor in the first place.

### 14.19.2 Draft: Energetics Data

As the introduction explained, in beta decay a nucleus converts a neutron into a proton, thus changing into a different nucleus. It can only occur if the nuclear mass reduction exceeds the 0.511 MeV rest mass energy of the electron emitted in the process.

Figures 14.47 through 14.50 show the nuclear mass reduction for beta decay as the vertical coordinate. The reduction exceeds the rest mass energy of the electron only above the horizontal center bands. The left half of each square indicates the nucleus before beta decay, the right half the one after the decay. The horizontal coordinate indicates the atomic numbers, with the values and element symbols as indicated. Neutron numbers are listed at the square itself. Lines connect pairs of nuclei with equal neutron excess.

If the left-half square is colored blue, beta decay is observed. Blue left-half squares are only found above the center bands, so the mass reduction is indeed at least the mass of the electron. However, some blue left-half squares are right on top of the band. Their beta decay should be very slow.

Note that some left-half squares above the band may not be blue. The color indicates the dominant decay process, so if the left-hand nucleus also experiences another decay mode in addition to beta decay, like alpha decay or beta-plus decay with another nucleus, and at a higher rate, its half square will not be blue. However, there should be no left-half squares above the band that are stable green.

Note here that even-even nuclei ${ }_{20}^{48} \mathrm{Ca}$ and ${ }_{40}^{96} \mathrm{Zr}$ are not stable, However, their beta decay is so extremely slow that double-beta decay dominates. Normal betadecay has never been observed for them. This is not just because the energy release is small, but more importantly because these transitions are strongly "forbidden" in the sense discussed in section 14.19.6.

Figure 14.47: Energy release in beta decay of even-odd nuclei. [pdf]

Figure 14.48: Energy release in beta decay of odd-even nuclei. [pdf]

Figure 14.50: Energy release in beta decay of even-even nuclei. [pdf]

In beta-plus decay, the nucleus converts a proton into a neutron instead of the other way around. To find the energy release in that process, the figures may be read the other way around. The nucleus before the decay is now the right hand one, and the decay is observed when the right-half square is red.

The energy release is now positive downward, and it is now below the center bands that the nuclear mass reduction is sufficient to produce the rest mass of a positron that can carry the proton' positive charge away. The positron, the anti-particle of the electron, has the same mass as the electron but opposite charge.

But note that red right-half squares extend to within the center bands. The reason is that instead of emitting a positron, the nucleus can capture an electron from the atomic electron cloud surrounding the nucleus. In that case, rather than having to come up with an electron mass worth of energy, the nucleus receives an infusion of that amount of energy. So the required energy goes down by two electron masses.

It follows that the left-hand nucleus will suffer beta decay if the square is above the top of the band, while the right-hand nucleus will suffer electron capture if the square is below the top of the band. Therefore at most one nucleus of each pair can be stable.

Note, once more, that color indicates the dominant decay mode. So righthalf squares below the top of the band do not have to be red; they just should not be stable green. This is especially relevant for the odd-odd nuclei in figures 14.49 and 14.50 . Odd-odd nuclei are unusually unstable, and the even-even nuclei they decay into are unusually stable. So it is quite likely that an odd-odd nuclei in the region of relatively stable nuclei finds that it has enough energy to both beta decay to the neighboring even-even nucleus of higher $Z$ and beta-plus decay / electron capture to the neighboring even-even nucleus of lower $Z$. Then, if one of the two processes is relatively slow, because the process is just above the top of the band in figure 14.49, or just below the top of the band in figure 14.50 , then the other process is likely to dominate. So the half square does not have the expected color. Left-hand squares just above the top of the band in figure 14.49 will be red, and right-hand squares just below the top of the band in figure 14.49 will be blue.

One example is ${ }_{19}^{40} \mathrm{~K}$ potassium-40, with 21 neutrons. It appears above the band in figure 14.49 , indicating that it suffers beta decay. But it also appears below the band in figure 14.50 , so that it also suffers electron capture and positron emission. In this case, beta decay dominates beta-plus decay and electron capture 9 to 1 . Recall that electron capture is relatively slow and the nucleus is just below the bottom of the band in figure 14.50, so beta-plus decay will be too.

### 14.19.3 Draft: Beta decay and magic numbers

The magic neutron numbers are quite visible in figures 14.47 through 14.50 . For example, diagonal bands at neutron numbers 50,82 , and 126 are prominent in all four figures. Consider for example figure 14.48. For the $50 / 49$ neutron nuclei, beta decay takes the tightly bound 50 th neutron to turn into a proton. That requires relatively large energy, so the energy release is reduced. For the neighboring 52/51 nuclei, beta decay takes the much less tightly bound 52nd neutron, and the energy release is correspondingly higher.

The magic proton numbers tend to show up as step-downs in the curves. For example, consider the nuclei at the vertical $Z=50$ line also in figure 14.48. In the $\mathrm{In} / \mathrm{Sn}$ (indium/tin) beta decay, the beta decay neutron becomes the tightly bound 50 th proton, and the energy release is correspondingly high. In the $\mathrm{Sb} / \mathrm{Te}$ (antimony/tellurium) decay, the neutron becomes the less tightly bound 52nd proton, and the energy release is lower.

When the neutron and proton magic number lines intersect, combined effects can be seen. One pointed out by Mayer in her Noble prize acceptance lecture $\llbracket 10 \rrbracket$ is the decay of argon-39. It has 18 protons and 21 neutrons. If you interpolate between the neighboring pairs of nuclei on the same neutron excess line in figure 14.47, you would expect argon-39 to be below the top of the center band, hence to be stable against beta decay. But the actual energy release for argon-39 is unusually high, and beta decay it does. Why is it unusually high? For the previous pairs of nuclei, beta decay converts a neutron in the neutron shell that ends at magic number 20 into a proton in the corresponding proton shell. For the suvsequent pairs, beta decay converts a neutron in the neutron shell that ends at magic number 28 to a proton in the corresponding proton shell. Only for argon-39, beta decay converts a neutron in the neutron shell that end at magic number 28 into a proton in the lower energy proton shell that ends at magic number 20. The lowering of the major shell releases additional energy, and the decay has enough energy to proceed.

In figures 14.47 and 14.48, the lowest line for the lightest nuclei is unusually smooth. These lines correspond to a neutron excess of 1 or -1 , depending on whether it is before or after the decay. The pairs of nuclei on these two lines are mirror nuclei. During beta decay the neutron that turns into a proton transfers from the neutron shells into the exact same position in the proton shells. Because of charge independence, the nuclear energy does not change. The Coulomb energy does change, but as a relatively small, long-range effect, it changes fairly gradually.

These lines also show that beta-plus decay and electron capture become energetically favored when the nuclei get heavier. That is to be expected since this are nuclei with almost no neutron excess. For the heavier ones, it is therefore energetically favorable to convert protons into neutrons, rather than the other way around.

### 14.19.4 Draft: Von Weizsäcker approximation

Since the von Weizsäcker formula of section 14.10.2 predicts nuclear mass, it can be used to predict whether beta-minus or beta-plus/electron capture will occur.

The mathematics is relatively simple, because the mass number $A$ remains constant during beta decay. For a given mass number, the von Weizsäcker formula is just a quadratic in $Z$. Like in the previous subsection, consider again pairs of nuclei with the same $A$ and one unit difference in $Z$. Set the mass difference equal to the electron mass and solve the resulting equation for $Z$ using simple algebra.

It is then seen that beta-minus decay, respectively beta-plus decay / electron capture occurs for a pair of nuclei depending whether the average $Z$ value is less, respectively greater, than

$$
\begin{equation*}
Z_{\mathrm{bd}}=A \frac{4 C_{a}+m_{\mathrm{n}}-m_{\mathrm{p}}-m_{\mathrm{e}}+C_{c} C_{z} A^{-1 / 3}}{8 C_{a}+2 C_{c} A^{2 / 3}} \tag{14.50}
\end{equation*}
$$

where the constants $C$. are as given in section 14.10 .2 . The nucleon pairing energy must be ignored in the derivation, so the result may be off by a pair of nuclei for even-even and odd-odd nuclei.

The result is plotted as the black curve in the decay graph figure 14.51. It gives the location where the change in nuclear mass is just enough for either beta-minus decay or electron capture to occur, with nothing to spare. The curve locates the stable nuclei fairly well. For light nuclei, the curve is about vertical, indicating there are equal numbers of protons and neutrons in stable nuclei. For heavier nuclei, there are more neutrons than protons, causing the curve to deviate to the right, the direction of increasing neutron excess.

Because of the pairing energy, stable even-even nuclei can be found well away from the curve. Conversely, stable odd-odd nuclei are hard to find at all. In fact, there are only four: hydrogen-2 (deuterium), lithium-6, boron-10, and nitrogen-14. For comparison, there are 150 stable even-even ones. For nuclei of odd mass number, it does not make much difference whether the number of protons is odd or the number of neutrons: there are 49 stable odd-even nuclei and 53 stable even-odd ones.
(There is also the bizarre excited ${ }^{180 \mathrm{~m}} \mathrm{Ta}$ nucleus that is stable, and is oddodd to boot. But that is an excited state and another story, which is discussed under gamma decay. The ground state ${ }_{73}{ }_{730} \mathrm{Ta}$ has a half life of only 8 hours, as a relatively heavy odd-odd nucleus should.)

As an example of the instability of odd-odd nuclei, consider the curious case of potassium-40, ${ }_{19}^{40} \mathrm{~K}$. It has both an odd number of protons, 19, and of neutrons, 21. Potassium- 40 is pretty much on top of the stable line, as evident from the fact that both its neighbors, odd-even isotopes potassium-39 and potassium-41, are stable. But potassium-40 itself is unstable. It does have

Figure 14.51: Examples of beta decay. [pdf]
a lifetime comparable to the age of the universe; long enough for significant quantities to accumulate. About $0.01 \%$ of natural potassium is potassium- 40 .

But decay it does. Despite the two billion year average lifetime, there are so many potassium- 40 nuclei in a human body that almost 5000 decay per second anyway. About $90 \%$ do so through beta decay and end up as the doubly-magic calcium-40. The other $10 \%$ decay by electron capture or positron emission and end up as even-even argon- 40 , with 18 protons and 22 neutrons. So potassium40 suffers all three beta decay modes, the only relatively common nucleus in nature that does.

Admittedly only $0.001 \%$ decays through positron emission. The nuclear mass difference of 0.99 MeV with argon- 40 is enough to create a positron, but not by much. Before a positron can be created, potassium is almost sure to have captured an electron already. For a nucleus like xenon-119 the mass difference with iodine-119 is substantially larger, 4.5 MeV , and about 4 in 5 xenon-119 nuclei decay by positron emission, and the fifth by electron capture.

It is energetically possible for the potassium- 40 decay product calcium- 40 to decay further into argon-40, by capturing two electrons from the atom. Energetically possible means that this does not require addition of energy, it liberates energy, so it can occur spontaneously. Note that calcium- 40 would have to capture two electrons at the same time; capturing just one electron would turn it into potassium-40, and that requires external energy addition. In other words, calcium-40 would have to skip over the intermediate odd-odd potassium 40 . While it is possible, it is believed that calcium-40 is stable; if it decays at all, its half-life must be more than 5.9 zettayear ( $5.910^{21}$ year).

But some even-even nuclei do decay through "double beta-minus" decay. For example, germanium- 76 with 32 protons and 44 neutrons will in a couple of zettayear emit two electrons and so turn into even-even selenium-76, skipping over odd-odd arsenic-76 in the process. However, since the entire lifetime of the universe is much less than the blink of an eye compared to a zettayear, this does not get rid of much germanium-76. About $7.5 \%$ of natural germanium is germanium-76.

The reduced stability of odd-odd nuclei is the main reason that technetium ( Tc ) and promethium ( Pm ) can end up with no stable isotopes at all while their immediate neighbors have many. Both technetium and promethium have an odd-odd isotope sitting right on top of the separating line between beta-minus and beta-plus decay; technetium-98 respectively promethium-146. Because of the approximation errors in the von Weizsäcker formula, they are not quite on the theoretical curve in figure 14.51. However, examination of the experimental nuclear masses shows the excess mass reduction for beta-minus decay and electron capture to be virtually identical for these odd-odd nuclei. And in fact promethium-146 does indeed decay both ways. Technetium- 98 could too, but does not; it finds it quicker to create an electron than to capture one from the surrounding atom.

Because the theoretical stable line slopes towards the right in figure 14.51, only one of the two odd-even isotopes next to technetium-98 should be unstable, and the same for the ones next to promethium-146. However, the energy liberated in the decay of these odd-even nuclei is only a few hundred keV in each case, far below the level for which the von Weizsäcker formula is anywhere meaningful. For technetium and promethium, neither neighboring isotope is stable. This is a qualitative failure of the von Weizsäcker model. But it is rare; it happens only for these two out of the lowest 82 elements. Few books even mention it is a fundamental failure of the formula.

### 14.19.5 Draft: Kinetic Energies

The kinetic energy of nuclear decay products is important to understand the correct nature of the decay.

Historically, one puzzling observation in beta decay was the kinetic energies with which the electrons came out. When the beta decay of a collection of nuclei of a given type is observed, the electrons come out with a range of kinetic energies. In contrast, in the alpha decay of a collection of nuclei of a given type, all alpha particles come out with pretty much the exact same kinetic energy.

Consider the reason. The total kinetic energy release in the decay of a given nucleus is called the " $Q$ value." Following Einstein's famous relation $E=m c^{2}$, the $Q$ value in alpha decay is given by the reduction in the net rest mass energy during the decay:

$$
\begin{equation*}
Q=m_{\mathrm{N} 1} c^{2}-m_{\mathrm{N} 2} c^{2}-m_{\alpha} c^{2} \tag{14.51}
\end{equation*}
$$

where 1 indicates the nucleus before the decay and 2 the nucleus after the decay.
Since energy must be conserved, the reduction in rest mass energy given by the $Q$-value is converted into kinetic energy of the decay products. Classical analysis makes that:

$$
Q=\frac{1}{2} m_{\mathrm{N} 2} v_{\mathrm{N} 2}^{2}+\frac{1}{2} m_{\alpha} v_{\alpha}^{2}
$$

This assumes that the initial nucleus is at rest, or more generally that the decay is observed in a coordinate system moving with the initial nucleus. Linear momentum must also be conserved:

$$
m_{\mathrm{N} 1} \vec{v}_{\mathrm{N} 1}=m_{\mathrm{N} 2} \vec{v}_{\mathrm{N} 2}+m_{\alpha} \vec{v}_{\alpha}
$$

but since the velocity of the initial nucleus is zero,

$$
m_{\mathrm{N} 2} \vec{v}_{\mathrm{N} 2}=-m_{\alpha} \vec{v}_{\alpha}
$$

Square both sides and divide by $2 m_{\mathrm{N} 2}$ to get:

$$
\frac{1}{2} m_{\mathrm{N} 2} v_{\mathrm{N} 2}^{2}=\frac{m_{\alpha}}{m_{\mathrm{N} 2}} \frac{1}{2} m_{\alpha} v_{\alpha}^{2}
$$

Now, excluding the special case of beryllium-8, the mass of the alpha particle is much smaller than that of the final nucleus. So the expression above shows that the kinetic energy of the final nucleus is much less than that of the alpha particle. The alpha particle runs away with almost all the kinetic energy. Its kinetic energy is almost equal to $Q$. Therefore it is always the same for a given initial nucleus, as claimed above. In the special case that the initial nucleus is beryllium-8, the final nucleus is also an alpha particle, and each alpha particle runs away with half the kinetic energy. But still, each alpha particle always comes out with a single value for its kinetic energy, in this case $\frac{1}{2} Q$.

In beta decay, things would be pretty much the same if just an electron was emitted. The electron too would come out with a single kinetic energy. The fact that it did not led Pauli to propose that another small particle also comes out. That particle could carry away the rest of the kinetic energy. It had to be electrically neutral like a neutron, because the nuclear charge change is already accounted for by the charge taken away by the electron. The small neutral particle was called the "neutrino" by Fermi. The neutrino was also required for angular momentum conservation: a proton and an electron each with spin $1 / 2$ have net spin 0 or 1 , not $1 / 2$ like the original neutron.

The neutrino that comes out in beta-minus decay is more accurately called an electron antineutrino and usually indicated by $\bar{\nu}$. The bar indicates that it is counted as an antiparticle.

The analysis of the kinetic energy of the decay products changes because of the presence of an additional particle. The $Q$-value for beta decay is

$$
\begin{equation*}
Q=m_{\mathrm{N} 1} c^{2}-m_{\mathrm{N} 2} c^{2}-m_{\mathrm{e}} c^{2}-m_{\bar{\nu}} c^{2} \tag{14.52}
\end{equation*}
$$

However, the rest mass energy of the neutrino can safely be ignored. At the time of writing, numbers less than a single eV are bandied around. That is immeasurably small compared to the nuclear rest mass energies which are in terms of GeV . In fact, physicists would love the neutrino mass to be nonnegligible: then they could figure out what is was!

As an aside, it should be noted that the nuclear masses in the $Q$ values are nuclear masses. Tabulated values are invariably atomic masses. They are different by the mass of the electrons and their binding energy. Other books therefore typically convert the $Q$-values to atomic masses, usually by ignoring the electronic binding energy. But using atomic masses in a description of nuclei, not atoms, is confusing. It is also a likely cause of mistakes. (For example, [31, fig. 11.5] seems to have mistakenly used atomic masses to relate isobaric nuclear energies.)

It should also be noted that if the initial and/or final nucleus is in an excited state, its mass can be computed from that of the ground state nucleus by adding the excitation energy, converted to mass units using $E=m c^{2}$. Actually, nuclear masses are usually given in energy units rather than mass units, so no conversion is needed.

Because the amount of kinetic energy that the neutrino takes away varies, so does the kinetic energy of the electron. One extreme case is that the neutrino comes out at rest. In that case, the given analysis for alpha decay applies pretty much the same way for beta decay if the alpha is replaced by the electron. This gives the maximum kinetic energy at which the electron can come out to be $Q$. (Unlike for the alpha particle, the mass of the electron is always small compared to the nucleus, and the nucleus always ends up with essentially none of the kinetic energy.) The other extreme is that the electron comes out at rest. In that case, it is the neutrino that pretty much takes all the kinetic energy. Normally, both electron and neutrino each take their fair share of kinetic energy. So usually the kinetic energy of the electron is somewhere in between zero and $Q$.

A further modification to the analysis for the alpha particle must be made. Because of the relatively small masses of the electron and neutrino, they come out moving at speeds close to the speed of light. Therefore the relativistic expressions for momentum and kinetic energy must be used, chapter 1.1.2.

Consider first the extreme case that the electron comes out at rest. The relativistic energy expression gives for the kinetic energy of the neutrino:

$$
\begin{equation*}
T_{\bar{\nu}}=\sqrt{\left(m_{\bar{\nu}} c^{2}\right)^{2}+(p c)^{2}}-m_{\bar{\nu}} c^{2} \tag{14.53}
\end{equation*}
$$

where $c$ is the speed of light and $p$ the momentum. The nucleus takes only a very small fraction of the kinetic energy, so $T_{\bar{\nu}} \approx Q$. Also, whatever the neutrino rest mass energy $m_{\bar{\nu}} c^{2}$ may be exactly, it is certainly negligibly small. It follows that $T_{\bar{\nu}} \approx Q \approx p c$.

The small fraction of the kinetic energy that does end up with the nucleus may now be estimated, because the nucleus has the same magnitude of momentum $p$. For the nucleus, the nonrelativistic expression may be used:

$$
\begin{equation*}
T_{\mathrm{N} 2}=\frac{p^{2}}{2 m_{\mathrm{N} 2}}=p c \frac{p c}{2 m_{\mathrm{N} 2} c^{2}} \tag{14.54}
\end{equation*}
$$

The final fraction is very small because the energy release $p c \approx Q$ is in MeV while the nuclear mass is in GeV . Therefore the kinetic energy of the nucleus is indeed very small compared to that of the neutrino. If higher accuracy is desired, the entire computation may now be repeated, starting from the more accurate value $T_{\bar{\nu}}=Q-T_{\mathrm{N} 2}$ for the kinetic energy of the neutrino.

The extreme case that the neutrino is at rest can be computed in much the same way, except that the rest mass energy of the electron is comparable to $Q$ and must be included in the computation of $p c$. If iteration is not desired, an exact expression for $p c$ can be derived using a bit of algebra:

$$
p c=\sqrt{\frac{\left[E^{2}-\left(E_{\mathrm{N} 2}+E_{\mathrm{e}}\right)^{2}\right]\left[E^{2}-\left(E_{\mathrm{N} 2}-E_{\mathrm{e}}\right)^{2}\right]}{4 E^{2}}} \quad E=E_{\mathrm{N} 2}+E_{\mathrm{e}}+Q
$$

where $E_{\mathrm{N} 2}=m_{\mathrm{N} 2} c^{2}$ and $E_{\mathrm{e}}=m_{\mathrm{e}} c^{2}$ are the rest mass energies of the final nucleus and electron. The same formula may be used in the extreme case that the electron is at rest and the neutrino is not, by replacing $E_{\mathrm{e}}$ by the neutrino rest mass, which is to all practical purposes zero.

In the case of beta-plus decay, the electron becomes a positron and the electron antineutrino becomes an electron neutrino. However, antiparticles have the same mass as the normal particle, so there is no change in the energetics. (There is a difference if it is written in terms of atomic instead of nuclear masses.) In case of electron capture, it must be taken into account that the nucleus receives an infusion of mass equal to that of the captured electron. The $Q$-value becomes

$$
\begin{equation*}
Q=m_{\mathrm{N} 1} c^{2}+m_{\mathrm{e}} c^{2}-m_{\mathrm{N} 2} c^{2}-m_{\bar{\nu}} c^{2}-E_{\mathrm{B}, \mathrm{ce}} \tag{14.56}
\end{equation*}
$$

where $E_{\mathrm{B}, \mathrm{ce}}$ is the electronic binding energy of the captured electron. Because this is an inner electron, normally a K or L shell one, it has quite a lot of binding energy, too large to be ignored. After the electron capture, an electron farther out will drop into the created hole, producing an X-ray. If that electron leaves a hole behind too, there will be more X-rays. The energy in these $X$-rays subtracts from that available to the neutrino.

The binding energy may be ballparked from the hydrogen ground state energy, chapter 4.3 , by simply replacing $e^{2}$ in it by $e^{2} Z$. That gives:

$$
\begin{equation*}
E_{\mathrm{B}, \mathrm{ce}} \sim 13.6 Z^{2} \mathrm{eV} \tag{14.57}
\end{equation*}
$$

The ballparks for electron capture in figure 14.54 use

$$
\begin{equation*}
E_{\mathrm{B}, \mathrm{ce}} \sim \frac{1}{2}(\alpha Z)^{2} m_{\mathrm{e}} c^{2}\left(1+\frac{1}{4}(\alpha Z)^{2}\right) \tag{14.58}
\end{equation*}
$$

in an attempt to partially correct for relativistic effects, which are significant for heavier nuclei. Here $\alpha \approx 1 / 137$ is the so-called fine structure constant. The second term in the parentheses is the relativistic correction. Without that term, the result is the same as (14.57). See addendum \{A.39\} for a justification.

### 14.19.6 Draft: Forbidden decays

Energetics is not all there is to beta decay. Some decays are energetically fine but occur extremely slowly or not at all. Consider calcium-48 in figure fig:betdec2e. The square is well above the center band, so energy-wise there is no problem at all for the decay to scandium-48. But it just does not happen. The half life of calcium-48 is $6410^{18}$ years, more than three billion times the entire lifetime of the universe. And when decay does happen, it is due to double beta decay; as of 2016, normal beta decay of calcium-48 has never been observed.

The big problem is angular momentum conservation. As an even-even nucleus, calcium- 48 has zero spin, while scandium- 48 has spin 6 in its ground
state. To conserve angular momentum during the decay, the electron and the antineutrino must therefore take six units of spin along. But to the extend that the nuclear size can be ignored, the electron and antineutrino come out of a mathematical point. That means that they come out with zero orbital angular momentum. They have half a unit of spin each, and there is no way to produce six units of net spin from that. The decay is forbidden by angular momentum conservation.

Of course, calcium-48 could decay to an excited state of scandium-48. Unfortunately, only the lowest two excited states are energetically possible, and these have spins 5 and 4 . They too are forbidden.

### 14.19.6.1 Draft: Allowed decays

To understand what beta decays are forbidden, the first step is to examine what decays are allowed.

Consider the spins of the electron and antineutrino. They could combine into a net spin of zero. If they do, it is called a "Fermi decay." Since the electron and antineutrino take no spin away, in Fermi decays the nuclear spin cannot change.

The only other possibility allowed by quantum mechanics is that the spins of electron and antineutrino combine into a net spin of one; that is called a "Gamow-Teller decay." The rules of quantum mechanics for the addition of angular momentum vectors imply:

$$
\begin{equation*}
\left|j_{\mathrm{N} 1}-j_{\mathrm{e} \bar{\nu}}\right| \leqslant j_{\mathrm{N} 2} \leqslant j_{\mathrm{N} 1}+j_{\mathrm{e} \bar{\nu}} \tag{14.59}
\end{equation*}
$$

where $j_{\mathrm{N} 1}$ indicates the spin of the nucleus before the decay, $j_{\mathrm{N} 2}$ the one after it, and $j_{\mathrm{e} \bar{\nu}}$ is the combined angular momentum of electron and antineutrino. Since $j_{\mathrm{e} \bar{\nu}}=1$ for allowed Gamow-Teller decays, spin can change one unit or stay the same. There is one exception; if the initial nuclear spin is zero, the final spin cannot be zero but must be one. Transitions from spin zero to zero are only allowed if they are Fermi ones. But they are allowed.

Putting it together, the angular momentum can change by up to one unit in an allowed beta decay. Also, if there is no orbital angular momentum, the parities of the electron and antineutrino are even, so the nuclear parity cannot change. In short

$$
\text { allowed: } \quad\left|\Delta j_{\mathrm{N}}\right| \leqslant 1 \quad \Delta \pi_{\mathrm{N}}=\text { no }
$$

(14.60)
where $\Delta$ indicates the nuclear change during the decay, $j_{\mathrm{N}}$ the spin of the nucleus, and $\pi_{\mathrm{N}}$ its parity.

One simple example of an allowed decay is that of a single neutron into a proton. Since this is a $1 / 2^{+}$to $1 / 2^{+}$decay, both Fermi and Gamow-Teller decays
occur. The neutron has a half-life of about ten minutes. It can be estimated that the decay is $18 \%$ Fermi and $82 \%$ Gamow-Teller, [31, p. 290].

Some disclaimers are in order. Both the discussion above and the following one for forbidden decays are nonrelativistic. But neutrinos are very light particles that travel at very close to the speed of light. For such relativistic particles, orbital angular momentum and spin get mixed-up. That is much like they get mixed-up for the photon. That was such a headache in describing electromagnetic transitions in chapter 7.4.3. Fortunately, neutrinos turn out to have some mass. So the given arguments apply at least under some conditions, even if such conditions are never observed.

A much bigger problem is that neutrinos and antineutrinos do not conserve parity. That is discussed in more detail a later subsection, Above, this book simply told you a blatant lie when it said that the electron-antineutrino system, (or the positron-neutrino system in beta-plus decay), comes off with zero parity. A system involving a single neutrino or antineutrino does not have definite parity. And parity is not conserved in the decay process anyway. But the initial and final nuclear states do have definite parity (to within very high accuracy). Fortunately, it turns out that you get the right answers for the change in nuclear parity if you simply assume that the electron and antineutrino come off with the parity given by their "orbital" angular momentum.

No you cannot have your money back. You did not pay any.
A relativistic description of neutrinos can be found in \{A.44\}.

### 14.19.6.2 Draft: Forbidden decays allowed

As noted at the start of this subsection, beta decay of calcium-48 requires a spin change of at least 4 and that is solidly forbidden. But forbidden is not quite the same as impossible. There is a small loophole. A nucleus is not really a mathematical point, it has a nonzero size.

Classically that would not make a difference, because the orbital angular momentum would be much too small to make up the deficit in spin. A rough ballpark of the angular momentum of, say, the electron would be $p R$, with $p$ its linear momentum and $R$ the nuclear radius. Compare this with the quantum unit of angular momentum, which is $\hbar$. The ratio is

$$
\frac{p R}{\hbar}=\frac{p c R}{\hbar c}=\frac{p c R}{197 \mathrm{MeV} \mathrm{fm}}
$$

with $c$ the speed of light. The product $p c$ is comparable to the energy release in the beta decay and can be ballparked as on the order of 1 MeV . The nuclear radius ballparks to 5 fm . As a result, the classical orbital momentum is just a few percent of $\hbar$.

But quantum mechanics says that the orbital momentum cannot be a small fraction of $\hbar$. Angular momentum is quantized to values $\sqrt{l(l+1)} \hbar$ where $l$ must
be an integer. For $l=0$ the angular momentum is zero, for $l=1$ the angular momentum is $\sqrt{2} \hbar$. There is nothing in between. An angular momentum that is a small fraction of $\hbar$ is not possible. Instead, what is small in quantum mechanics is the probability that the electron has angular momentum $l=1$. If you try long enough, it may happen.

In particular, $p R / \hbar$ gives a rough ballpark for the quantum amplitude of the $l=1$ state. (The so-called Fermi theory of beta decay, \{A.45\}, can be used to justify this and other assumptions in this section.) The probability is the square magnitude of the quantum amplitude, so the probability of getting $l=1$ is roughly $(p R / \hbar)^{2}$ smaller than getting $l=0$. That is about 3 or 4 orders of magnitude less. It makes decays that have $l=1$ that many orders of magnitude slower than allowed decays, all else being the same. But if the decay is energetically possible, and allowed decays are not, it will eventually happen. (Assuming of course that some completely different decay like alpha decay does not happen first.)

Decays with $l=1$ are called "first-forbidden decays." The electron and neutrino can then take up to 2 units of angular momentum away through their combined orbital angular momentum and spin. So the nuclear spin can change up to two units. Orbital angular momentum has negative parity if $l$ is odd, so the parity of the nucleus must change during the decay. Therefore the possible changes in nuclear spin and parity are:

$$
\begin{equation*}
\text { first-forbidden: } \quad\left|\Delta j_{\mathrm{N}}\right| \leqslant 2 \quad \Delta \pi_{\mathrm{N}}=\text { yes } \tag{14.61}
\end{equation*}
$$

That will not do for calcium-48, because at least 4 units of spin change is needed. In "second-forbidden decays," the electron and neutrino come out with a net orbital angular momentum $l=2$. Second forbidden decays are another 3 or 4 order of magnitude slower still than first forbidden ones. The nuclear parity remains unchanged like in allowed decays. Where both allowed and second forbidden decays are possible, the allowed decay should be expected to have occurred long before the second forbidden one has a chance. Therefore, the interesting second-forbidden cases cases are those that are not allowed ones:

$$
\begin{equation*}
\text { second-forbidden: } \quad\left|\Delta j_{\mathrm{N}}\right|=2 \text { or } 3 \quad \Delta \pi_{\mathrm{N}}=\text { no } \tag{14.62}
\end{equation*}
$$

In third forbidden decays, $l=3$. The transitions that become possible that were not in first forbidden ones are:

$$
\begin{equation*}
\text { third-forbidden: } \quad\left|\Delta j_{N}\right|=3 \text { or } 4 \quad \Delta \pi_{N}=\text { yes } \tag{14.63}
\end{equation*}
$$

These transitions are still another 3 or 4 orders of magnitude slower than second forbidden ones. And they do not work for calcium-48, as both the calcium-48 ground state and the three reachable scandium-48 states all have equal, positive, parity.

Beta decay of calcium-48 is possible through fourth-forbidden transitions:

$$
\begin{equation*}
\text { fourth-forbidden: } \quad\left|\Delta j_{\mathrm{N}}\right|=4 \text { or } 5 \quad \Delta \pi_{\mathrm{N}}=\text { no } \tag{14.64}
\end{equation*}
$$

This allows decay to either the $5^{+}$and $4^{+}$excited states of scandium-48. However, fourth forbidden decays are generally impossibly slow.

### 14.19.6.3 Draft: The energy effect

There is an additional effect slowing down the beta decay of the $0^{+}$calcium-48 ground state to the $5^{+}$excited scandium-48 state. The energy release, or $Q-$ value, of the decay is only about 0.15 MeV .

One reason that is bad news, (or good news, if you like calcium-48), is because it makes the momentum of the electron and neutrino correspondingly small. The ratio $p R / \hbar$ is therefore quite small at about 0.01 . And because this is a fourth forbidden decay, the transition is slowed down by a ballpark $\left((p R / \hbar)^{-2}\right)^{4}$; that means a humongous factor $10^{16}$ for $p R / \hbar=0.01$. If a 1 MeV allowed beta decay may take on the order of a day, you can see why calcium-48 is effectively stable against beta decay.

Figure 14.52: The Fermi integral. It shows the effects of energy release and nuclear charge on the beta decay rate of allowed transitions. Other effects exists. [pdf]

There is another, smaller, effect. Even if the final nucleus is the $5^{+}$excited scandium-48 state, with a single value for the magnetic quantum number, there is still more than one final state to decay to. The reason is that the relative amounts of energy taken by the electron and neutrino can vary. Additionally, their directions of motion can also vary. The actual net decay rate is an integral of the individual decay rates to all these different states. If the $Q$-value is low, there are relatively few states available, and this reduces the total decay rate too. The amount of reduction is given by the so-called "Fermi integral" shown in figure 14.52. A decay with a $Q$ value of about 0.15 MeV is slowed down by roughly a factor thousand compared to one with a $Q$ value of 1 MeV .

The Fermi integral shows beta plus decay is additionally slowed down, because it is more difficult to create a positron at a strongly repelling positively charged nucleus. The relativistic Fermi integral also depends on the nuclear radius, hence a bit on the mass number. Figure 14.52 used a ballpark value of the mass number for each $Z$ value, $\{\mathrm{A} .45\}$.

The Fermi integral applies to allowed decays, but the general idea is the same for forbidden decays. In fact, half-lives $\tau_{1 / 2}$ are commonly multiplied by the Fermi integral $f$ to produce a "comparative half-life," or " $f t$-value" that is relatively insensitive to the details of the decay besides the degree to which it is forbidden. The $f t$-value of a given decay can therefore be used to ballpark to what extent the decay is forbidden.

You see how calcium-48 can resist beta-decay for $6410^{18}$ years. (Zirconium96 with a half-life of $2410^{18}$ years has similar resistance to plain beta decay.)

### 14.19.7 Draft: Data and Fermi theory

Figure 14.53 shows nuclei that decay primarily through beta-minus decay in blue. Nuclei that decay primarily through electron capture and beta-plus decay are shown in red. The sizes of the squares indicate the decay rates. For reference, the stable and double-beta decay nuclei are shown as full-size green squares.

Note the tremendous range of decay rates. It corresponds to half-lives ranging from milliseconds to $10^{17}$ years. This is much like the tremendous range of half-lives in alpha decay. Decays lasting more than about twenty years are shown as a minimum-size dot in figure 14.53; many would be invisible shown on the true scale.

The decay rates in figure 14.53 are color coded according to a guesstimated value for how forbidden the decay is. Darker red or blue indicate more forbidden decays. Note that more forbidden decays tend to have much lower decay rates. (Lightly colored squares indicate nuclei for which the degree to which the decay is forbidden could not be guesstimated by the automated procedures used.)

Figure 14.54 shows the decay rates normalized with a theoretical guesstimate for them. Note the greatly reduced range of variation that the guesstimate achieves, crude as it may be. One major success story is for forbidden decays.

Figure 14.53: Beta decay rates. [pdf][con]

Figure 14.54: Beta decay rates as fraction of a ballparked value. [pdf][con]

These are often so slow that they must be shown as minimum-size dots in figure 14.53 to be visible. However, in figure 14.54 they join the allowed decays as fullsize squares. Consider in particular the three slowest decays among the data set. The slowest of all is vanadium-50, with a half-life of $15010^{15}$ year, followed by cadmium-113 with $810^{15}$ year, followed by indium-115 with $44110^{12}$ year. (Tellurium-123 has only a lower bound on its half life listed and is not included.) These decay times are long enough that all three isotopes occur naturally. In fact, almost all naturally occurring indium is the "unstable" isotope indium-115. Their dots in figure 14.53 become full squares in figure 14.54 .

Another eye-catching success story is ${ }_{1}^{3} \mathrm{H}$, the triton, which suffers beta decay into ${ }_{2}^{3} \mathrm{He}$, the stable helion. The decay is allowed, but because of its miniscule energy release, or $Q$-value, it takes 12 years anyway. Scaled with the ballpark, this slow decay too becomes a full size square.

The ballparks were obtained from the "Fermi theory" of beta decay, as discussed in detail in addendum \{A.45\}. Unlike the relatively simple theory of alpha decay, the Fermi theory is elaborate even in a crude form. Taking betaminus decay as an example, the Fermi theory assumes a pointwise interaction between the wave functions of the neutron that turns into a proton and those of the electron/antineutrino pair produced by the decay. (Quantum mechanics allows the neutron before the decay to interact with the electron and neutrino that would exist if it had already decayed. That is a "twilight" effect, as discussed in chapter 5.3 and more specifically in addendum \{A.24\} for gamma decay.) The strength of the interaction is given by empirical constants.

Note that for many nuclei no ballparks were found. One major reason is that the primary decay mechanism is not necessarily to the ground state of the final nucleus. If decay to the ground state is forbidden, decay to a less-forbidden excited state may dominate. Therefore, to correctly estimate the decay rate for a given nucleus requires detailed knowledge about the excited energy states of the final nucleus. The energies of these excited states must be sufficiently accurately known, and they may not be. In particular, for a few nuclei, the energy release of the decay, or $Q$-value, was computed to be negative even for the ground state. This occurred for the electron capture of ${ }_{67}^{163} \mathrm{Ho},{ }_{78}^{193} \mathrm{Pt},{ }_{80}^{194} \mathrm{Hg}$, ${ }_{82}^{202} \mathrm{~Pb}$, and ${ }_{82}^{205} \mathrm{~Pb}$, and for the beta decay of ${ }_{75}^{187} \mathrm{Re}$ and ${ }_{94}^{241} \mathrm{Pu}$. According to the Fermi theory, the decay cannot occur if the $Q$-value is negative. However, the $Q$-values in question are much smaller than the estimated electronic binding energy (14.8). In fact they are comparable to the difference in electronic binding energy between initial and final nucleus or less. Since the binding energy is just an estimate, the computed $Q$-values, and therefore the guesstimated decay rate, should not be trusted.

In addition to the energy of the excited states, their spins and parities must also be accurately known. The reason is that they determine to what level the decay is forbidden, hence slowed down. The computer program that produced figures 14.53 and 14.54 assumed conservatively that if no unique value for spin
and/or parity was given, it might be anything. Also, while there was obviously no way for the program to account for any excited states whose existence is not known, the program did allow for the possibility that there might be additional excited states above the highest energy level known. This is especially important well away from the stable line where the excited data are often sparse or missing altogether. All together, for about one third of the nuclei processed, the uncertainty in the ballparked decay rate was judged too large to be accepted. For the remaining nuclei, the level to which the decay was forbidden was taken from the excited state that gave the largest contribution to the decay rate.

The Fermi ballparks were constructed such that the true decay rate should not be significantly more than the ballparked one. In general they met that requirement, although for about $1 \%$ of the nuclei, the true decay rate was more ten times the ballparked ones, reaching up to 370 times for ${ }_{100}^{253} \mathrm{Fm}$. All these cases were for first-forbidden decays with relatively low $Q$-values. Since they included both beta minus and electron capture decays, a plausible explanation may be poor $Q$-values. However, for forbidden decays, the correction of the electron/ positron wave function for the effect of the nuclear charge is also suspect.

Note that while the true decay rate should not be much more than the ballparked one, it is very possible for it to be much less. The ballpark does not consider the details of the nuclear wave function, because that is in general prohibitively difficult. The ballpark simply hopes that if a decay is not strictly forbidden by spin or parity at level $l$, the nuclear wave function change will not for some other reason make it almost forbidden. But in fact, even if the decay is theoretically possible, the part of the Hamiltonian that gives rise to the decay may produce a nuclear wave function that has little probability of being the right one. In that case the decay is slowed down proportional to that probability.

As an example, compare the decay processes of scandium-41 and calcium47. Scandium-41, with 21 protons and 20 neutrons, decays into its mirror twin calcium- 41 , with 20 protons and 21 neutrons. The decay is almost all due to beta-plus decay to the ground state of calcium-41. According to the shell model, the lone proton in the $4 \mathrm{f}_{7 / 2}$ proton shell turns into a lone neutron in the $4 \mathrm{f}_{7 / 2}$ neutron shell. That means that the nucleon that changes type is already in the right state. The only thing that beta decay has to do is turn it from a proton into a neutron. And that is in fact all that the decay Hamiltonian does in the case of Fermi decay. Gamow-Teller decays also change the spin. The nucleon does not have to be moved around spatially. Decays of this type are called "superallowed." (More generally, superallowed decays are defined as decays between isobaric analog states, or isospin multiplets. Such states differ only in nucleon type. In other words, they differ only in the net isospin component $T_{3}$.) Superallowed decays proceed at the maximum rate possible. Indeed the decay of scandium- 41 is at 1.6 times the ballparked value.

All the electron capture / beta-plus decays of the nuclei immediately to the
left of the vertical $Z=N$ line in figures 14.53 and 14.54 are between mirror nuclei, and all are superallowed. They are full-size squares in figure 14.54. Superallowed beta-minus decays occur for the triton mentioned earlier, as well as for a lone neutron.

But now consider the beta-minus decay process of calcium- 47 to scandium47. Calcium- 47 has no protons in the $4 \mathrm{f}_{7 / 2}$ proton shell, but it has 7 neutrons in the $4 f_{7 / 2}$ neutron shell. That means that it has a 1-neutron "hole" in the $4 \mathrm{f}_{7 / 2}$ neutron shell. Beta decay to scandium- 47 will turn one of the 7 neutrons into a lone proton in the $4 \mathrm{f}_{7 / 2}$ proton shell.

At least one source claims that in the odd-particle shell model "all odd particles are treated equivalently," so that we might expect that the calcium- 47 decay is superallowed just like the scandium-41 one. That is of course not true. The odd-particle shell model does emphatically not treat all odd particles equivalently. It only says that, effectively, an even number of nucleons in the shell pair up into a state of zero net spin, leaving the odd particle to provide the net spin and electromagnetic moments. That does not mean that the seventh $4 \mathrm{f}_{7 / 2}$ neutron can be in the same state as the lone proton after the decay. In fact, if the seventh neutron was in the same state as the lone proton, it would blatantly violate the antisymmetrization requirements, chapter 5.7. Whatever the state of the lone proton might be, 7 neutrons require 6 more independent states. And each of the 7 neutrons must occupy all these 7 states equally. It shows. The nuclear wave function of calcium- 47 produced by the decay Hamiltonian matches up very poorly with the correct final wave function of scandium- 47 . The true decay rate of calcium- 47 is therefore about 10000 times smaller than the ballpark.

As another example, consider the beta-plus decay of oxygen-14 to nitrogen14. Their isobaric analog states were identified in figure 14.46. Decay to the ground state is allowed by spin and parity, at a ballparked decay rate of $0.23 / \mathrm{s}$. However, the true decay proceeds at a rate $0.01 / \mathrm{s}$, which just happens to be 1.6 times the ballparked decay rate to the $0^{+}$excited isobaric analog state. One source notes additionally that over $99 \%$ of the decay is to the analog state. So decay to the ground state must be contributing less than a percent to the total decay. And that is despite the fact that decay to the ground state is allowed too and has the greater $Q$-value. The effect gets even clearer if you look at the carbon-14 to nitrogen-14 beta-minus decay. Here the decay to the isobaric analog state violates energy conservation. The decay to the ground state is allowed, but it is more than 10000 times slower than ballpark.

Superallowed decays like the one of oxygen-14 to the corresponding isobaric analog state of nitrogen-14 are particularly interesting because they are $0^{+}$to $0^{+}$decays. Such decays cannot occur through the Gamow-Teller mechanism, because in Gamow-Teller decays the electron and neutrino take away one unit of angular momentum. That means that decays of this type can be used to study the Fermi mechanism in isolation.

The horror story of a poor match up between the nuclear wave function produced by the decay Hamiltonian and the final nuclear wave function is lutetium176. Lutetium-176 has a $7^{-}$ground state, and that solidly forbids decay to the $0^{+}$hafnium-176 ground state. However, hafnium has energetically allowed $6^{+}$ and $8^{+}$excited states that are only first-forbidden. Therefore you would not really expect the decay of lutetium- 176 to be particularly slow. But the spin of the excited states of hafnium is due to collective nuclear rotation, and these states match up extremely poorly with the ground state of lutetium-176 in which the spin is intrinsic. The decay rate is a stunning 12 orders of magnitude slower than ballpark. While technically the decay is only first-forbidden, lutetium is among the slowest decaying unstable nuclei, with a half-life of almost $4010^{12}$ year. As a result, it occurs in significant quantities naturally. It is commonly used to determine the age of meteorites. No other ground state nucleus gets anywhere close to that much below ballpark. The runner up is neptunium-236, which is 8 orders of magnitude below ballpark. Its circumstances are similar to those of lutetium-176.

The discussed examples show that the Fermi theory does an excellent job of predicting decay rates if the differences in nuclear wave functions are taken into account. In fact, if the nuclear wave function can be accurately accounted for, like in $0^{+}$to $0^{+}$superallowed decays, the theory will produce decay rates to 3 digits accurate, [31, table 9.2]. The theory is also able to give accurate predictions for the distribution of velocities with which the electrons or positrons come out. Data on the velocity distributions can in fact be used to solidly determine the level to which the decay is forbidden by plotting them in socalled "Fermi-Kurie plots." These and many other details are outside the scope of this book.

### 14.19.8 Draft: Parity violation

For a long time, physicists believed that the fundamental laws of nature behaved the same when seen in the mirror. The strong nuclear force, electromagnetism, and gravity all do behave the same when seen in the mirror. However, in 1956 Lee and Yang pointed out that the claim had not been tested for the weak force. If it was untrue there, it could explain why what seemed to be a single type of K-meson could decay into end products of different parity. The symmetry of nature under mirroring leads to the law of conservation of parity, chapter 7.3. However, if the weak force is not the same under mirroring, parity can change in weak processes, and therefore, the decay products could have any net parity, not just that of the original K-meson.

Wu and her coworkers therefore tested parity conservation for the beta decay of cobalt-60 nuclei. These nuclei were cooled down to extremely low temperatures to cut down on their thermal motion. That allowed their spins to be aligned with a magnetic field, as in the left of figure 14.55. It was then observed

Figure 14.55: Parity violation. In the beta decay of cobalt-60, left, the electron preferentially comes out in the direction that a left-handed screw rotating with the nuclear spin would move. Seen in the mirror, right, that becomes the direction of a right-handed screw.
that the electrons preferentially came out in the direction of motion of a lefthanded screw rotating with the nuclear spin. Since a left-handed screw turns into a right-handed one seen in the mirror, it followed that indeed the weak force is not the same seen in the mirror. The physics in the mirror is not the correct physics that is observed.

Since the weak force is weak, this does not affect parity conservation in other circumstances too much. Formally it means that eigenfunctions of the Hamiltonian are not eigenfunctions of the parity operator. However, nuclear wave functions still have a single parity to very good approximation; the amplitude of the state of opposite parity mixed in is of the order of $10^{-7}$, [31, p. 313]. The probability of measuring the opposite parity is the square of that, much smaller still. Still, if a decay is absolutely forbidden when parity is strictly preserved, then it might barely be possible to observe the rare decays allowed by the component of the wave function of opposite parity.

An additional operation can be applied to the mirror image in 14.55 to turn it back into a physically correct decay. All particles can be replaced by their antiparticles. This operation is called "charge conjugation," because among other things it changes the sign of the charge for each charged particle. In physics, you are always lucky if a name gets some of it right. Some of the particles involved may actually be charged, and "conjugation" is a sophisticated-sounding term to some people. It is also a vague term that quite conceivably could be taken to mean "reversal of sign" by people naive enough to consider "conjugation" sophisticated. Charge conjugation turns the electrons going around in the loops of the electromagnet in figure 14.55 into positrons, so the current reverses direction. That must reverse the sign of the magnetic field if the physics is right. But so will the magnetic moment of anticobalt-60 nucleus change sign, so it stays aligned with the magnetic field. And physicist believe the positrons will preferentially come out of anticobalt-60 nuclei along the motion of a right-handed
screw
Besides this combined charge conjugation plus parity (CP) symmetry of nature, time symmetry is also of interest here. Physical processes should remain physically correct when run backwards in time, the same way you can run a movie backwards. It turns out that time symmetry too is not completely absolute, and neither is CP symmetry for that matter. However, if all three operations, charge conjugation (C), mirroring (P), and time inversion (T), together are applied to a physical process, the resulting process is believed to always be physically correct. There is a theorem, the CPT theorem, that says so under relatively mild assumptions.

### 14.20 Draft: Gamma Decay

Nuclear reactions and decays often leave the final nucleus in an quantum state of elevated energy. Such an excited state may lower its energy by emitting a photon of electromagnetic radiation. That is called gamma decay. It is a common way to evolve to the ground state.

Gamma decay is in many respect similar to alpha and beta decay discussed in earlier sections. However, the type of nucleus does not change in gamma decay. Both the atomic and mass number of the nucleus stay the same. (Of course, an excited nuclear state can suffer alpha or beta decay instead of gamma decay. That however is not the subject of this section.)

Gamma decay of excited nuclei is the direct equivalent of the decay of excited electron states in atoms. The big difference between gamma decay and the radiation emitted by the electrons in atoms is energy. The energy of the photons emitted by nuclei is typically even higher than that of the X-ray photons emitted by inner electrons. Therefore the radiation emitted by nuclei is generally referred to as "gamma rays."

Both atomic radiation and nuclear gamma decay were analyzed in considerable detail in chapter 7.4 through 7.8 and addenda $\{$ A. 20$\}$ through $\{\mathrm{A} .25\}$. There is no point in repeating all that here. Instead this section will merely summarize the key points and discuss some actual observations.

However, the existing data on gamma decay is enormous. Consider NuDat 2, a standard data base. At the time of writing, it contains over 3100 nuclei. Almost every nucleus but the deuteron has many excited energy levels; there are over 160000 in NuDat 2. Gamma decays can proceed between different states, and NuDat 2 contains over 240000 of them. There is no way that this book can cover all that data. The coverage given in this section will therefore be anecdotal or random rather than comprehensive.

However, based on a simple model, at least ballpark transition rates will be established. These are called the Weisskopf units. They are commonly used as reference values, to give some context to the measured transition rates.

One big limitation of gamma decay is for nuclear states of zero spin. A state of zero spin cannot transition to another state of zero spin by emitting a photon. As discussed in chapter 7.4, this violates conservation of angular momentum.

But there are other ways that a nucleus can get rid of excess energy besides emitting an electromagnetic photon. One way is by kicking an atomic electron out of the surrounding atom. This process is called "internal conversion" because the electron is outside the nucleus. It allows transitions between states of zero spin.

For atoms, two-photon emission is a common way to achieve decays between states of zero angular momentum. However, for nuclei this process is less important because internal conversion usually works so well.

Internal conversion is also important for other transitions. Gamma decay is slow between states that have little difference in energy and/or a big difference in spin. For such decays, internal conversion can provide a faster alternative.

If the excitation energy is high, it is also possible for the nucleus to create an electron and positron pair from scratch. Since the quantum uncertainty in position of the pair is far too large for them to be confined within the small nucleus, this is called "internal pair creation."

### 14.20.1 Draft: Energetics

The reduction in nuclear energy during gamma decay is called the $Q$-value. This energy comes out primarily as the energy of the photon, though the nucleus will also pick up a bit of kinetic energy, called the recoil energy.

Recoil energy will usually be ignored, so that $Q$ gives the energy of the photon. The photon energy is related to its momentum and frequency through the relativistic mass-energy and Planck-Einstein relations:

$$
\begin{equation*}
Q=E_{\mathrm{N} 1}-E_{\mathrm{N} 2}=p c=\hbar \omega \tag{14.65}
\end{equation*}
$$

Typical tabulations list nuclear excitation energies as energies, rather than as nuclear masses. Unfortunately, the energies are usually in eV instead of SI units.

In internal conversion, the nucleus does not emit a photon, but kicks an electron out of the surrounding atomic electron cloud. The nuclear energy reduction goes into kinetic energy of the electron, plus the binding energy required to remove the electron from its orbit:

$$
\begin{equation*}
Q=E_{\mathrm{N} 1}-E_{\mathrm{N} 2}=T_{\mathrm{e}}+E_{\mathrm{B}, \mathrm{e}} \tag{14.66}
\end{equation*}
$$

### 14.20.2 Draft: Forbidden decays

The decay rate in gamma decay is to a large extent dictated by what is allowed by conservation of angular momentum and parity. The nucleus is almost a mathematical point compared to the wave length of a typical photon emitted
in gamma decay. Therefore, it is difficult for the nucleus to give the photon additional orbital angular momentum. That is much like what happens in alpha and beta decay.

The photon has one unit of spin. If the nucleus does not give it additional orbital angular momentum, the total angular momentum that the photon carries off is one unit. That means that the nuclear spin cannot change by more than one unit.
(While this is true, the issue is actually somewhat more subtle than in the decay types discussed previously. For a photon, spin and orbital angular momentum are intrinsically linked. Because of that, a photon always has some orbital angular momentum. That was discussed in chapter 7.4.3 and in detail in various addenda such as $\{\mathrm{A} .21\}$. However, the inherent orbital angular momentum does not really change the story. The bottom line remains that it is unlikely for the photon to be emitted with more than one unit of net angular momentum.)

The nuclear spin can also stay the same, instead of change by one unit, even if a photon with one unit of angular momentum is emitted, In classical terms the one unit of angular momentum can go into changing the direction of the nuclear spin instead of its magnitude, chapter 7.4.2. However, this only works if the nuclear spin is nonzero.

Parity must also be preserved, chapter 7.4. Parity is even, or 1 , if the wave function stays the same when the positive direction of all three Cartesian axes is reversed. Parity is odd, or -1 , if the wave function changes sign. Parities of separate sources are multiplied together to combine them. That is unlike for angular momentum, where separate angular momenta are added together.

In the normal, or "allowed," decays the photon is emitted with odd parity. Therefore, the nuclear parity must reverse during the transition, chapter 7.4.2.
(To be picky, the so-called weak force does not preserve parity. This creates a very small uncertainty in nuclear parities. That then allows a very small probability for transitions in which the apparent parity is not conserved. But the probability for this is so small that it can almost always be ignored.)

Allowed transitions are called electric transitions because the nucleus interacts mainly with the electric field of the photon. More specifically, they are called "electric dipole transitions" for reasons originating in classical electromagnetics, chapter 7.7.2. For practical purposes, a dipole transition is one in which the photon is emitted with one unit of net angular momentum.

Transitions in which the nuclear spin change is greater than one unit, or in which the nuclear parity does not change, or in which the spin stays zero, are called "forbidden." Despite the name, most such decays will usually occur given enough time. However they are generally much slower.

One way that forbidden transitions can occur is that the nucleus interacts with the magnetic field instead of the electric field. This produces what are called magnetic transitions. Magnetic transitions tend to be noticeably slower
than corresponding electric ones. In magnetic dipole transitions, the photon has one unit of net angular momentum just like in electric dipole transitions. However, the photon now has even parity. Therefore magnetic dipole transitions allow the nuclear parity to stay the same.

Transitions in which the nuclear spin changes by more than one unit are possible through emission of a photon with additional orbital angular momentum. That allows a net angular momentum of the photon greater than one. But at a price. Each unit of additional net angular momentum slows down the typical decay rate by roughly 5 orders of magnitude.

The horror story is tantalum-180m. There are at the time of writing 256 ground state nuclei that are classified as stable. And then there is the excited nucleus tantalum-180m. Stable nuclei should be in their ground state, because states of higher energy decay into lower energy ones. But tantalum-180m has never been observed to decay. If it decays at all, it has been established that its half life cannot be less than $10^{15}$ year. The universe has only existed for roughly $10^{10}$ years, and so tantalum- 180 m occurs naturally.

Figure 14.56: Energy levels of tantalum-180. [pdf]
The tantalum-180 ground state shows no such idiocy. It is unstable as any self-respecting heavy odd-odd nucleus should be. In fact it disintegrates within about 8 hours through both electron capture and beta-minus decay at comparable rates. But tantalum- 180 m is an excited state with a humongous spin of 9 . Figure 14.56 shows the excited energy levels of tantalum-180; tantalum-180m is the second excited energy level. It can only decay to the $1^{+}$ground state and to an $2^{+}$excited state. It has very little energy available to do either. The decay would require the emission of a photon with at least seven units of orbital angular momentum, and that just does not happen in a thousand years. Nor in a petayear.

You might think that tantalum-180m could just disintegrate directly through electron capture or beta decay. But those processes have the same problem. There is just no way for tantalum-180m to get rid of all that spin without emitting particles with unlikely large orbital angular momentum. So tantalum-

180 m will live forever, spinning too fast to reach the sweet oblivion of the quick death that waits below.

Electric transitions are often generically indicated as $\mathrm{E} \ell$ and magnetic ones as $\mathrm{M} \ell$. Here $\ell$ indicates the net angular momentum of the photon. That is the maximum nuclear spin change that the transition can achieve. So electric dipole transitions are E1, and magnetic dipole transitions are M1. Names have also been given to the higher multipole orders. For example, $\ell=2$ transitions are quadrupole ones, $\ell=3$ octupole, $\ell=4$ hexadecapole, $\ell=5$ triakontadipole, $\ell$ $=6$ hexacontatetrapole, etcetera. (If you are wondering, the prefixes in these names are powers of two, expressed in a mixture of Latin and Greek.)

For electric transitions, the nuclear parity changes when $\ell$ is odd. For magnetic transitions, it changes when $\ell$ is even. The transition rules are summarized in table 14.4.

|  | maximum spin change | nuclear parity change |
| :---: | :---: | :---: |
| $\mathrm{E} \ell:$ | $\ell$ | if $\ell$ is odd |
| $\mathrm{M} \ell:$ | $\ell$ | if $\ell$ is even |

Table 14.4: Nuclear spin and parity changes in electromagnetic multipole transitions.

That leaves transitions from nuclear spin 0 to nuclear spin 0 . Such transitions cannot occur through emission of a photon, period. For such transitions, conservation of angular momentum would require that the photon is emitted without angular momentum. But a photon cannot have zero net angular momentum. You might think that the spin of the photon could be canceled through one unit of orbital angular momentum. However, because the spin and orbital angular momentum of a photon are linked, it turns out that this is not possible, \{A.21\}.

Decay from an excited state with spin zero to another state that also has spin zero is possible through internal conversion or internal pair production. In principle, it could also be achieved through two-photon emission, but that is a very slow process that has trouble competing with the other two.

One other approximate conservation law might be mentioned here, isospin. Isospin is conserved by nuclear forces, and its charge component is conserved by electromagnetic forces, section 14.18. It can be shown that to the extent that isospin is conserved, certain additional selection rules apply. These involve the quantum number of square isospin $t_{T}$, which is the isospin equivalent of
the azimuthal quantum number for the spin angular momentum of systems of fermions. Warburton \& Weneser [48] give the following rules:

1. Electromagnetic transitions are forbidden unless $\Delta t_{T}=0$, or $\pm 1$. (Here " $\Delta$ " means the difference between the initial and final nuclear states).
2. Corresponding $\Delta t_{T}= \pm 1$ transitions in conjugate nuclei are identical in all properties. ("Conjugate" means that the two nuclei have the numbers of protons and neutrons swapped. "Corresponding" transitions means transitions between equivalent levels, as discussed in section 14.18.)
3. Corresponding E1 transitions in conjugate nuclei - whether $\Delta t_{T}=$ 0 or $\pm 1$ - have equal strengths.
4. $\Delta t_{T}=0$ E1 transitions in self-conjugate nuclei are forbidden. (Selfconjugate nuclei have the same number of protons as neutrons.)
5. Corresponding $\Delta t_{T}=0 \mathrm{M} 1$ transitions in conjugate nuclei are expected to be of approximately equal strength, within, say, a factor of two if the transitions are of average strength or stronger.
6. $\Delta t_{T}=0 \mathrm{M} 1$ transitions in self-conjugate nuclei are expected to be weaker by a factor of 100 than the average M1 transition strength.
7. $\Delta t_{T}=0 \mathrm{M} \ell$ transitions in conjugate nuclei are expected to be of approximately equal strength if the transitions are of average strength or stronger.
8. $\Delta t_{T}=0 \mathrm{M} \ell$ transitions in self-conjugate nuclei are expected to be appreciably weaker than average.
The last four rules involve an additional approximation besides the assumption that isospin is conserved.

In a nutshell, expect that the transitions will be unexpectedly slow if the isospin changes by more than one unit. Expect the same for nuclei with equal numbers of protons and neutrons if the isospin does not change at all and it is an E1 or magnetic transition.

As an example, [31, p. 390], consider the decay of the $1^{-}$isobaric analog state common to carbon-14, nitrogen-14, and oxygen-14 in figure 14.46. This state has $t_{T}=1$. For oxygen-14, it is the lowest excited state. Its decay to the $t_{T}=1,0^{+}$, ground state is an E1 transition that is allowed by the spin, parity, and isospin selection rules. And indeed, the $1^{-}$excited state decays rapidly to the ground state; the half-life is about 0.000012 fs (femtoseconds). That is even faster than the Weisskopf ballpark for a fully allowed decay, subsection 14.20.4, which gives about 0.009 fs here. But for nitrogen-14, the equivalent transition is not allowed because of rule 4 above. Nitrogen-14 has 7 protons and 7 neutrons. And indeed, the partial half life of this transition is 2.7 fs . That is very much longer. Based on rule 3 above, it is expected that the decay rate of the $1^{-}$state in carbon-14 is similar to the one in oxygen-14. Unfortunately, experimentally it has only been established that its half-life is less than 7 fs .

Some disclaimers are appropriate for this example. As far as the oxygen transition is concerned, the NuDat $2 \llbracket 12 \rrbracket$ data do not say what the dominant decay process for the oxygen-14 state is. Nor what the final state is. So it might be another decay process that dominates. The next higher excited state, with 0.75 MeV more energy, decays $100 \%$ through proton emission. And two orders of magnitude faster than Weisskopf does seem a lot, figure 14.63.

As far as the nitrogen transition is concerned, the decay processes are listed in NuDat 2. The decay is almost totally due to proton emission, not gamma decay. The actual half-life of this state is 0.00002 fs ; the 2.7 fs mentioned above is computed using the given decay branching ratios. The 2.7 fs is way above the 0.006 fs Weisskopf estimate, but that is quite common for E1 transitions.

It may be more reasonable to compare the forbidden nitrogen 8 MeV to 2.3 MeV transition to the allowed 8 MeV to ground state, and 8 MeV to 4 MeV transitions. They are all three E1 transitions. Corrected for the differences in energy release, the forbidden transition is 20 times slower than the one to the ground state, and 25 times slower than the one to the 4 MeV state. So apparently, being forbidden seems to slow down this transition by a factor of roughly 20 . It is significant, though it is not that big on the scale of figure 14.63.

As another example, the nitrogen transition from the $1^{-} 5.7 \mathrm{MeV} t_{T}=0$ state to the $t_{T}=0$ ground state is also forbidden, while the transition to the $0^{+} t_{T}=1$ state is now permitted. And indeed, the decay to the ground state is about ten times slower, when corrected for energy release, [31, p. 391].

More comprehensive data may be found in [48].

### 14.20.3 Draft: Isomers

An "isomer" is a long lasting excited state of a nucleus. Usually, an excited nucleus that does not disintegrate through other means will drop down to lower energies through the emission of photons in the gamma ray range. It will then end up back in the ground state within a typical time in terms of fs, or about $10^{-15}$ second.

But sometimes a nucleus gets stuck in a metastable state that takes far longer to decay. Such a state is called an isomeric state. Krane [31, p. 174] ballparks the minimum lifetime to be considered a true isomeric state at roughly $10^{-9} \mathrm{~s}$, Bertulani [5, p. 244] gives $10^{-15} \mathrm{~s}$, and NuDat $2 \llbracket 12$ 』 uses $10^{-1} \mathrm{~s}$ with qualification in their policies and $10^{-9} \mathrm{~s}$ in their glossary. Don't you love standardization? In any case, this book will not take isomers serious unless they have a lifetime comparable to $10^{-9}$ second. Why would an excited state that cannot survive for a millisecond be given the same respect as tantalum-180m, which shows no sign of kicking the bucket after $10^{15}$ years?

But then, why would any excited state be able to last very much more than the typical $10^{-15} \mathrm{~s}$ gamma decay time in the first place? The main reason is angular momentum conservation. It is very difficult for a tiny object like
a nucleus to give a photon much angular momentum. Therefore, transitions between states of very different angular momentum will be extremely slow, if they occur at all. Such transitions are highly "forbidden," or using a better term, "hindered."

If an excited state has a very different spin than the ground state, and there are no states in between the two that are more compatible, then that excited state is stuck. But why would low spin states be right next to high spin states? The main reason is found in the shell model, and in particular figure 14.15. According to the shell model, just below the magic numbers of 50,82 , and 126 , high spin states are pushed into regions of low spin states by the so-called spin-orbit interaction. That is a recipe for isomerism if there ever was one.

Therefore, it should be expected that there will be many isomers below the magic numbers of 50,82 , and 126 . And that these isomers will have the opposite parity of the ground state, because the high spin states are pushed into low spin states of opposite parity.

And so it is. Figure 14.57 shows the half-lifes of the longest-lasting exited states of even $Z$ and odd $N$ nuclei. The groups of isomers below the magic neutron numbers are called the "islands of isomerism." The difference in spin from the ground state is indicated by the color. A difference in parity is indicated by a minus sign. Half-lives over $10^{14} \mathrm{~s}$ are shown as full-size squares.

Figure 14.58 shows the islands for odd $Z$, even $N$ nuclei.
For odd-odd nuclei, figure 14.59, the effects of proton and neutron magic numbers get mixed up. Proton and neutron excitations may combine into larger spin changes, providing one possible explanation for the isomers of light nuclei without parity change.

Besides tantalum-180m, which lives forever, also note bismuth-210m in figure 14.59. Bismuth- 210 m has the same spin $9^{-}$as tantalum- 180 m , but it does manage to decay after about 3 million years. But it does so through alphadecay, rather than gamma-decay,

For even-even nuclei, figure 14.60, there is very little isomeric activity.

### 14.20.4 Draft: Weisskopf estimates

Gamma decay rates can be ballparked using the so-called "Weisskopf estimates:"

| $\lambda^{\mathrm{E} \ell}=C_{\mathrm{E} \ell} A^{2 \ell / 3} Q^{2 \ell+1}$ |  |  |  |  |  | $\lambda^{\mathrm{M} \ell}=C_{\mathrm{M} \ell} A^{(2 \ell-2) / 3} Q^{2 \ell+1}$ |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\ell$ | 1 | 2 | 3 | 4 | 5 |  |  |  |  |
| $C_{\mathrm{E} \ell}:$ | 1.0 | $10^{14}$ | 7.3 | $10^{7}$ | 34 | 1.1 |  |  |  |
| $C_{\mathrm{M} \ell}:$ | 3.1 | $10^{13}$ | 2.2 | $10^{-5}$ | 10 | 3.4 |  |  |  |

Here the decay rates are per second, $A$ is the mass number, and $Q$ is the energy release of the decay in MeV . Also $\ell$ is the maximum nuclear spin change possible for that transition. As discussed in subsection 14.20.2, electric transitions

Figure 14.57: Half-life of the longest-lived even-odd isomers. [pdf][con]

Figure 14.58: Half-life of the longest-lived odd-even isomers. [pdf][con]

Figure 14.59: Half-life of the longest-lived odd-odd isomers. [pdf][con]

Figure 14.60: Half-life of the longest-lived even-even isomers. [pdf][con]
require that the nuclear parity flips over when $\ell$ is odd, and magnetic ones that it flips over when $\ell$ is even. In the opposite cases, the nuclear parity must stay the same. If there is more than one decay process involved, add the individual decay rates.

The estimates are plotted in figure 14.61. For magnetic transitions the better Moszkowski estimates are shown in figure 14.62. (Internal conversion is discussed in subsection 14.20.6, where the ballparks are given.)

A complete derivation and discussion of these estimates can be found $\{\mathrm{A} .25\}$. Note that many sources have errors in their formulae and/or graphs or use nonSI units, $\{$ A.25.9\}. The correct formulae in SI units are in $\{$ A.25.8\}.

These estimates are derived under the assumption that only a single proton changes states in the transition. They also assume that the multipole order is the lowest possible, given by the change in nuclear spin. And that the final state of the proton has angular momentum $1 / 2$. Some correction factors are available to allow for different multipole orders and different final angular momenta, \{A.25.8\}. There are also correction factors to allow for the fact that really the proton and the rest of the nucleus move around their common center of gravity Similar correction factors can allow for the case that a single neutron instead of a proton makes the transition. See $\{\mathrm{A} .25 .8\}$ for more.

The initial and final proton states assumed in the estimates are further very simple, $\{$ A. 25.8$\}$. They are like a shell model state with a simplified radial dependence. Corrections exist for that radial dependence too. But the way the estimates are mostly used in practice is as a reference. The actual decay rate in a transition is compared to the Weisskopf or Moszkowski estimates. These estimates are therefore used as "units" to express decay rates in.

If there is a big difference, it gives hints about the nature of the transition process. For example, the actual decay rate is often orders of magnitude smaller than the estimate. That can indicate that the state produced by the decay Hamiltonian has only a small probability of being the correct final nuclear state. In other words, there may be a "poor match-up" or "little overlap" between the initial and final nuclear states. It is implicit in the simple proton states used in the estimates that the state produced by the decay Hamiltonian has a good chance of being right. But actual E1 transitions can easily be three or more orders of magnitude slower than estimate, as shown in the next subsection. That is similar to what was observed for the ballparks for beta decays given in section 14.19.7. One reason may be that some of these transitions are approximately forbidden by isospin conservation.

Conversely, the observed transition rate may be several orders of magnitude more rapid than the estimate. That may indicate that a lot of nucleons are involved in the transition. Their contributions can add up. This is frequently related to shape changes in nonspherical nuclei. For example, E2 transitions, which are particularly relevant to deformed nuclei, may easily be orders of magnitude faster than estimate.

Figure 14.61: Weisskopf ballpark half-lifes for electromagnetic transitions versus energy release. Broken lines include ballparked internal conversion. [pdf]

Figure 14.62: Moszkowski ballpark half-lifes for magnetic transitions versus energy release. Broken lines include ballparked internal conversion. [pdf]

Interestingly, M4 transitions tend to be quite close to the mark. Recall that the shell model puts the highest spin states of one harmonic oscillator shell right among the lowest spin states of the next lower shell, 14.15. Transitions between these states involve a parity change and a large change in spin, leading to E3 and M4 transitions. They resemble single-particle transitions as the Weisskopf and Moszkowski estimates assume. The estimates tend to work well for them. One possible reason that they do not end up that much below ballpark as E1 transitions may be that these are heavy nuclei. For heavy nuclei the restrictions put on by isospin may be less confining.

Finally, what other books do not point out is that there is a problem with electrical transitions in the islands of isomerism. There is serious concern about the correctness of the very Hamiltonian used in such transitions, \{N.14\}. This problem does not seem to affect magnetic multipole transitions in the nonrelativistic approximation.

Another problem not pointed out in various other books is for magnetic transitions. Consider the shell model states, figure 14.15. They allow many transitions inside the bands that by their unit change in angular momentum and unchanged parity are M1 transitions. However, these states have a change in orbital angular momentum equal to two units. The single-particle model on which the Weisskopf and Moszkowski estimates are based predicts zero transition rate
for such M1 transitions. It does not predict the Moszkowski or Weisskopf values given above and in the figures. In general, the predicted single-particle transition rates are zero unless the multipole order $\ell$ satisfies, $\{$ A. 25.8$\}$

$$
\left|l_{1}-l_{2}\right| \leqslant \ell \leqslant l_{1}+l_{2}
$$

where $l_{1}$ and $l_{2}$ are the initial and final orbital azimuthal quantum numbers. Fortunately this is only an issue for magnetic transitions, \{A.25.8\}.

Note that the single-particle model does give a nontrivial prediction for say an $2 p_{1 / 2}$ to $2 p_{3 / 2}$ M1 transition. That is despite the fact that the simplified Hamiltonian on which it is based would predict zero transition rate for the model system. For say a $4 p_{3 / 2}$ to 2 p transition, the Weisskopf and Moszkowski units also give a nontrivial prediction. That, however, is due to the incorrect radial estimate (A.187). The correct single-particle model on which they are based would give this transition rate as zero. Fortunately, transitions like $4 p_{3 / 2}$ to 2 p are not likely to be much of a concern.

### 14.20.5 Draft: Comparison with data

This subsection compares the theoretical Weisskopf and Moszkowski estimates of the previous section with actual data. The data are from NuDat 2, $\llbracket 12 \rrbracket$. The plotted values are a broad but further quite random selection of data of apparently good quality. A more precise description of the data selection procedure is in $\{\mathrm{N} .34\}$. Internal conversion effects, as discussed in subsection 14.20.6, have been mathematically removed using the conversion constants given by NuDat 2. Computed decay rates were checked against the decay rates in W.u. as given by NuDat 2 .

Figures 14.63 and 14.64 show the results. What is plotted is the half life, scaled to an (harmonic) average nucleus size. In particular,

$$
\mathrm{E} \ell: \quad \tau_{1 / 2, \mathrm{red}}=\tau_{1 / 2}\left(\frac{A}{32}\right)^{2 \ell / 3} \quad \mathrm{M} \ell: \quad \tau_{1 / 2, \mathrm{red}}=\tau_{1 / 2}\left(\frac{A}{32}\right)^{2(\ell-1) / 3}
$$

The horizontal coordinate in the figures indicates the energy release $Q$.
The multipole levels are color coded. The Weisskopf values are shown as broken lines. The solid lines are an attempt at a "best guess" based on the single-particle model. For the electric transitions, they simply use the empirical radial factor $\{$ A. 25.8$\}$ (A.187). For the magnetic transitions, the best guess was based on the more accurate Moszkowski estimates. The empirical radial factor was again used. The momentum factor $\{$ A.25.8\} (A.189) at minimum multipole order was averaged between the proton and neutron values. The $g$ values in those factors were in turn averaged between their free space and theoretical values.

Figure 14.63: Comparison of electric gamma decay rates with theory. [pdf]

Figure 14.64: Comparison of magnetic gamma decay rates with theory. [pdf]

Symbol size indicates the nucleus size. Symbol shape indicates whether the numbers of protons and neutrons are even or odd. A minus sign indicates that the initial parity is odd; otherwise it is even. The final parity follows from the multipole order and type. An open symbol center indicates that the multipole level $\ell$ is higher than needed in the transition. More precisely, it indicates that it is higher than the change in nuclear spin.

Please, your mouth is hanging open. It makes you look very goofy. You can almost pretend that the magnetic data are not really as bad as they look, if you cover up those numbers along the vertical axis with your arm.

There is no doubt that if engineers got data like that, they would conclude that something is terribly and fundamentally wrong. Physicists however poohpooh the problems.

First of all, physics textbooks typically only present the M4 data graphically like this. Yes, the M4 transitions are typically "only" an order of magnitude or so off. According to the figures here, this "good" agreement happens only for the M4 data. Have a look at the E1 and E2 data. They end up pretty much in the same humongous cloud of scattered data. In physics textbooks you do not really see it, as these data are presented in separate histograms. And for some reason, in those histograms the E2 transitions are typically only half an order of magnitude above estimate, rather than 2.5 orders. (The E1 transitions in those histograms are similar to the data presented here.)

Consider now a typical basic nuclear textbook for physicist. According to the book, disagreements of several orders of magnitude from theory can happen. The difference between "can happen" and "are normal" is not defined. The book further explains: "In particular, experimental disintegration rates smaller than the ones predicted by [the Weisskopf estimates] can mean that [the Weisskopf radial factor $\{$ A.25.8\} (A.187)] is not very reasonable and that the small overlap of the [initial and final nuclear wave functions] decreases the values of $\lambda$. ."

However, the "best guess" E1 line in figure 14.63 uses a better radial estimate. It is not exactly enough to get anywhere near the typical data.

And "poor overlap" is an easy cop-out since nuclear wave functions are not known. For example, it does not explain why some multipole orders like E1 have a very poor overlap of wave functions, and others do not.

Transition rates many orders of magnitude smaller than theory must have a good reason. Random deviations from theory are not a reasonable explanation. Having a transition rate typically four orders of magnitude smaller than a reasonable theoretical estimate is like routinely hitting the bull's eye of a 10 cm target to within a mm . There must be something causing this.

But what might that be? Conservation of angular momentum and parity are already fully accounted for. To be sure, conservation of isospin is not. However, isospin is an approximate symmetry. It is not accurate enough to explain reductions by 4 or 5 orders of magnitude. The two examples mentioned in subsection 14.20.2 managed just 1 order of magnitude slow down. And not
all E1 transitions are forbidden anyway. And light nuclei, for which isospin conservation is presumably more accurate, seem no worse than heavier ones in figure 14.63. Actually, the two best data are small nuclei.

To be sure, the above arguments implicitly assume that a bull's eye is hit by an incredibly accurate cancelation of opposite terms in the so-called matrix element that describes transitions. There is an alternate possibility. The final nuclear wave function could be zero where the initial one is nonzero and vice versa. In that case, the integrand in the matrix element is everywhere zero, and no accurate cancellations are needed.

But consider now the top half of figure 14.65. Here mixed E1 +M 2 transitions are plotted. These transitions take sometimes place through the electric dipole mechanism and sometimes through the magnetic quadrupole one. Note that there are three very fast M2 transitions, the first, fourth, and tenth. These transitions occur at rates of 49,58 , respectively 21 times faster than the best guess based on the single-particle model. So the initial and final wave functions must unavoidably "overlap" very well. But how then to explain that the corresponding electric rates are 31000,7800 , and 200 times slower than best guess? The initial and final wave functions are the same. While there is a different operator sandwiched in between, $\{\mathrm{A} .25\}$, the picture still becomes that one operator apparently achieves a bull's eye of perfect cancellation. There should be an explanation.

The example textbook also notes: "Experimental values higher than predicted by [the Weisskopf estimates] can mean, on the other hand, that the transition involves the participation of more than one nucleon or even a collective participation of the whole nucleus." The textbook notes in particular that the reason that most E2 transitions are faster than theory is due to the fact that these transitions are common among collective bands, especially rotational bands in deformed nuclei.

This is a well established argument. In principle 50 protons transitioning could indeed explain why many E2 transitions in figure 14.63 end up on the order of a rough factor $50^{2}$ faster than theory.

But there are again some problems. For one, the mixed E1 + M2 transitions discussed earlier are not among states in the same rotational bands. The nuclear parity flips over in them. But the mentioned examples showed that several M2 transitions were also much faster than single-particle theory. While that might still be due to collective motion, it does not explain why the E1 transitions then were so slow.

Consider also the bottom of figure 14.65. Here mixed M1 +E 2 transitions are plotted. Note that the E2 transitions are again much faster than theory, with few exceptions. But how then to explain that the M1 transitions between the same initial and final states are much slower than theory? More of these miraculously accurate cancellations? There are quite a few transitions at the higher energies where the M1 transition proceeds slower than the E2 one, despite

Figure 14.65: Comparisons of decay rates between the same initial and final states.
the difference in multipole order.
It is true that the orbital effect is relatively minor in magnetic transitions of minimal multipole order, $\{\mathrm{A} .25 .8\}$. But the transitions given by black symbols with open centers in the bottom of figure 14.65 are not of minimal multipole order. And in any case, "relatively minor" gets nowhere near to explaining differences of four or five orders of magnitude in relative decay rates.

The same problem exists for the idea that the special nature of transitions within rotational bands might somehow be responsible. Surely the idea of rotational bands is not be far accurate enough to explain the humongous differences? And some of the worst offenders in figure 14.65 are definitely not between states in the same rotational band. Those are again the ones where the black symbol has an open center; the nuclear spin does not change in those transitions.

There are 65 randomly chosen E1 transitions plotted in figure 14.63. Out of these 65 , only one manages to achieve the "best guess" theoretical transition rate. That is a boron-10 transition. (You may have to strain your eyes to see it, it is such a small nucleus. It is right on top of the best-guess line, just before 1 MeV .) On the other hand, one transition is slower than best guess by more than 8 orders of magnitude, and another three are slower by more than 7 orders of magnitude.

Compare that with the 67 E2 transitions. Only one manages the three orders of magnitude slower than best guess that is so ho-hum for E1 transitions. That transition is a $2340 \mathrm{keV} 29 / 2^{+}$to $2063 \mathrm{keV} 25 / 2^{2}+{ }_{85}^{205} \mathrm{At}$ one. The amount of spin that is involved here is not exactly run-of-the mill. Note also that the three runners-up for being far above the E2 line are E1 transitions, rather than E2 ones...

Also, why do E3 transitions act much like E1 transitions in the first half of the energy range and like E2 ones over the second half? It seems weird.

The example textbook concludes: "In figure [...] one notes very good agreement between theoretical values and experimental ones for M4. This behavior is typical for transitions of high multipolarity." Based on figures 14.63 and 14.64, it seems very optimistic to call M4 transitions "typical" for high multipolarity.

Needless to say, then, the author of this book finds the discussion of measured gamma decay versus theory in standard nuclear text books grossly inadequate, and highly unconvincing where it is given at all. If you feel the same way, see note $\{\mathrm{N} .36\}$ for one alternative idea.

### 14.20.6 Draft: Internal conversion

In internal conversion, a nucleus gets rid of excitation energy by kicking an atomic electron out of the atom. This is most important for transitions between states of zero spin. For such transitions, the normal gamma decay process of emitting a photon is not possible since a photon cannot be emitted with zero angular momentum. However, the ejected electron, called the "conversion
electron," can keep whatever angular momentum it has. (For practical purposes, that is zero. Electrons that are not in s states have negligible probabilility of being found inside the nucleus.) Transitions in which no angular momentum is emitted by the nucleus are called E0 transitions.

A ballpark decay rate for E0 internal conversion can be found in Blatt \& Weisskopf [7, 8, p. 621]. Where else. Converted to look similar to the gamma decay Weisskopf estimate (A.190), it reads

$$
\begin{equation*}
\lambda_{\text {Blatt\&Weisskopf }}^{\mathrm{E} 0} \sim \alpha \omega(k R)^{4} \frac{2}{25} \alpha(\alpha Z)^{3}\left(\frac{2 m_{\mathrm{e}} c^{2}}{Q}\right)^{9 / 2} \quad \omega \equiv \frac{Q}{\hbar} \quad k \equiv \frac{Q}{\hbar c} \tag{14.68}
\end{equation*}
$$

Here $\alpha=e^{2} / 4 \pi \epsilon_{0} \hbar c \approx 1 / 137$ is the fine structure constant and $Q$ is the energy release. Further $m_{\mathrm{e}} c^{2}$ is the rest mass energy of the electron, which is about half an MeV . The initial and final parities need to be the same.

Note that the first three factors in the expression above look much like an E2 electric transition. However, the next three factors are very small, though less so for heavy nuclei. On the other hand the final factor can be very large if the energy release $Q$ is much less than an MeV . So E0 internal conversion is relatively speaking most effective for low-energy transitions in heavy nuclei.

Putting in the numbers gives the equivalent of (14.67) as

$$
\begin{equation*}
\lambda^{\mathrm{E} 0}=3.8 Z^{3} A^{4 / 3} Q^{1 / 2} \tag{14.69}
\end{equation*}
$$

Once again, the energy release should be in MeV and then the decay rate will be per second. Note that absolutely speaking the decay rate does in fact increase with the energy release, but very weakly.

Table 14.5 shows how the estimate stands up to scrutiny. The listed E0 transitions are all those for which NuDat 2, 【12】, gives useful and unambiguous data. All these turn out to be $0^{+}$to $0^{+}$transitions.

The second-last column in the table shows a scaled half life. It is scaled to some (harmonic) average nucleus size $Z=16, A=32$. In particular

$$
\tau_{1 / 2, \text { red }} \equiv \tau_{1 / 2} \frac{Z^{3}}{16^{3}} \frac{A^{4 / 3}}{32^{4 / 3}}
$$

The final column shows what the scaled half life should be according to the theoretical estimate above. Note that, excluding the final three nuclei, the agreement is not too bad, as they come. What is an order of magnitude or so between friends? After the previous subsections everything would look accurate.

However, the final three nuclei decay much more rapidly than internal conversion predicts. A second decay process occurs here: electron-positron pair creation. This requires that the nuclear energy release $Q$ is at least large enough to provide the rest mass energy of the electron and positron. That is a bit over a MeV . However, as the table suggests, to get a significant effect, more energy

| Nucleus | $Q$ | $\tau_{1 / 2}$ <br> $\mu s$ | $\tau_{1 / 2, \text { red }}$ <br> $\mu s$ | I.C. Theory <br> $\mu s$ |
| :--- | :--- | :--- | :---: | :---: |
| ${ }_{80}^{184} \mathrm{Hg}$ | 0.375 | 0.00062 | 0.80 | 0.72 |
| ${ }_{36}^{72} \mathrm{Kr}$ | 0.671 | 0.0263 | 0.88 | 0.54 |
| ${ }_{32}^{72} \mathrm{Ge}$ | 0.691 | 0.4442 | 10. | 0.53 |
| ${ }_{42}^{98} \mathrm{Mo}$ | 0.735 | 0.0218 | 1.8 | 0.51 |

| ${ }_{16}^{16} \mathrm{O}$ | 6.048 | 0.00007 | 0.000003 | 0.18 |

Table 14.5: Half lifes for E0 transitions.
is needed. There should be enough additional energy to give the electron and positron relativistically nontrivial kinetic energies.

In transitions other than between states of zero spin, normal gamma decay is possible. But even in those decays, internal conversion and pair production may compete with gamma decay. They are especially important in highly forbidden gamma decays.

The so-called "internal conversion coefficient" $\alpha_{\ell}$ gives the internal conversion rate of a transition as a fraction of its gamma decay rate:

$$
\begin{equation*}
\alpha_{\ell}=\frac{\lambda_{\mathrm{IC}}}{\lambda_{\gamma}} \tag{14.70}
\end{equation*}
$$

The following ballpark values for the internal conversion coefficient in electric and magnetic transitions can be derived ignoring relativistic effects and electron binding energy:

$$
\alpha_{\mathrm{E} \ell}=\frac{1}{n^{3}} \frac{\ell}{\ell+1} \alpha(\alpha Z)^{3}\left(\frac{2 m_{\mathrm{e}} c^{2}}{Q}\right)^{\ell+5 / 2} \quad \alpha_{\mathrm{M} \ell}=\frac{1}{n^{3}} \alpha(\alpha Z)^{3}\left(\frac{2 m_{\mathrm{e}} c^{2}}{Q}\right)^{\ell+3 / 2}
$$

Here, once again, $\ell$ is the multipole order of the decay, $Q$ the nuclear energy release, and $\alpha \approx 1 / 137$ the fine structure constant. Further $n$ is the principal quantum number of the atomic shell that the conversion electron comes from, Note the brilliance of using the same symbol for the internal conversion coefficients as for the fine structure constant. This book will use subscripts to keep them apart.

The above estimates are very rough. They are routinely off by a couple of orders of magnitude. However, they do predict a few correct trends. Internal conversion is relatively more important compared to gamma decay if the energy release $Q$ of the decay is low, if the multipolarity $\ell$ is high, and if the nucleus is heavy. Ejection from the $n=1 \mathrm{~K}$ shell tends to dominate ejection from the other shells, but not to a dramatic amount.
(You might wonder why the earlier ballpark for E0 transitions looks mathematically like an $\ell=2$ rate, instead of some $\ell=0$ one. The reason is that E0 transitions do not create an electromagnetic field outside the nucleus, compare for example chapter 7.4.3. So the interaction with the electron is limited to the interior of the nucleus. That reduces the magnitude of the interaction greatly.)

Internal conversion is especially useful for investigating nuclei because the conversion coefficients are different for electric and magnetic transitions. Therefore, detailed decay measurements can shed light on the question whether a given transition is an electric or a magnetic one. Since they also depend strongly on the multipole order, they also help establish that. To be sure, the estimates above are not by far accurate enough to do these things. But much more accurate values have been computed using relativistic theories and tabulated.

Internal pair formation supplements internal conversion, [7, 8, p. 622]. The pair formation rate is largest where the internal conversion rate is smallest. That is in the region of low atomic number and high transition energies.

One very old reference incorrectly states that internal conversion happens when a gamma ray emitted by the nucleus knocks a surrounding electron out of the atom. Such a process, the photoelectric effect, is in principle possible, but its probability would be negligibly small. Note in particular that in many decays, almost no gamma rays are emitted but lots of conversion electrons. (While the interaction between the nucleus and the conversion electron is of course caused by photons, these are virtual photons. They would not come out of the nucleus even if you stripped away the atomic electrons.)

It may be noted that "internal conversion" is not unique to nuclei. Energetic atomic electron transitions can also get rid of their energy by ejection of another electron. The ejected electrons are called "Auger electrons." They are named after the physicist Auger, who was the first man to discover the process. (Some unscrupulous woman, Lise Meitner, had discovered and published it earlier, selfishly attempting to steal Auger's credit, \{N.35\}). In fact, internal conversion can give rise to additional Auger electrons as other electrons rush in to fill the internal converion electron hole. And so can electron capture.

## Part IV

Supplementary Information

## Appendix A

## Addenda

This appendix describes a number of additional topics. They did not seem important enough to warrant including them in the main text. An addition is always a distraction; at the minimum you have to worry about whether you need to worry about it. However, many of the topics below are covered in well-known other texts. Obviously many other authors disagree about their importance. If they turn out to be right, you can find it here.

## A. 1 Classical Lagrangian mechanics

Lagrangian mechanics is a way to simplify complicated dynamical problems. This note gives a brief overview. For details and practical examples you will need to consult a good book on mechanics.

## A.1.1 Introduction

As a trivial example of how Lagrangian mechanics works, consider a simple molecular dynamics simulation. Assume that the forces on the particles are given by a potential that only depends on the positions of the particles.

The difference between the net kinetic energy and the net potential energy is called the "Lagrangian." For a system of particles as considered here it takes the form

$$
\mathcal{L}=\sum_{j} \frac{1}{2} m_{j}\left|\vec{v}_{j}\right|^{2}-V\left(\vec{r}_{1}, \vec{r}_{2}, \ldots\right)
$$

where $j$ indicates the particle number and $V$ the potential of the attractions between the particles and any external forces.

It is important to note that in Lagrangian dynamics, the Lagrangian must mathematically be treated as a function of the velocities and positions of the particles. While for a given motion, the positions and velocities are in turn a
function of time, time derivatives must be implemented through the chain rule, i.e. by means of total derivatives of the Lagrangian.

The "canonical momentum" $p_{j, i}^{c}$ of particle $j$ in the $i$ direction, (with $i=1$, 2 , or 3 for the $x, y$, or $z$ components respectively), is defined as

$$
p_{j, i}^{\mathrm{c}} \equiv \frac{\partial \mathcal{L}}{\partial v_{j, i}}
$$

For the Lagrangian above, this is simply the normal momentum $m v_{j, i}$ of the particle in the $i$-direction.

The Lagrangian equations of motion are

$$
\frac{\mathrm{d} p_{j, i}^{\mathrm{c}}}{\mathrm{~d} t}=\frac{\partial \mathcal{L}}{\partial r_{j, i}}
$$

This is simply Newton's second law in disguise: the left hand side is the time derivative of the linear momentum of particle $j$ in the $i$-direction, giving mass times acceleration in that direction; the right hand side is the minus the spatial derivative of the potential, which gives the force in the $i$ direction on particle $j$. Obviously then, use of Lagrangian dynamics does not help here.

## A.1.2 Generalized coordinates

One place where Lagrangian dynamics is very helpful is for macroscopic objects. Consider for example the dynamics of a Frisbee. Nobody is going to do a molecular dynamics computation of a Frisbee. What you do is approximate the thing as a "solid body," (or more accurately, a rigid body). The position of every part of a solid body can be fully determined using only six parameters, instead of the countless position coordinates of the individual atoms. For example, knowing the three position coordinates of the center of gravity of the Frisbee and three angles is enough to fully fix it. Or you could just choose three reference points on the Frisbee: giving three position coordinates for the first point, two for the second, and one for the third is another possible way to fix its position.

Such parameters that fix a system are called "generalized coordinates." The word generalized indicates that they do not need to be Cartesian coordinates; often they are angles or distances, or relative coordinates or angles. The number of generalized coordinates is called the number of degrees of freedom. It varies with the system. A bunch of solid bodies moving around freely will have six per solid body; but if there are linkages between them, like the bars in your car's suspension system, it reduces the number of degrees of freedom. A rigid wheel spinning around a fixed axis has only one degree of freedom, and so does a solid pendulum swinging around a fixed axis. Attach a second pendulum to its end, maybe not in the same plane, and the resulting compound pendulum has two degrees of freedom.

If you try to describe such systems using plain old Newtonian mechanics, it can get ugly. For each solid body you can apply that the sum of the forces must equal mass times acceleration of the center of gravity, and that the net moment around the center of gravity must equal the rate of change of angular momentum, which you then presumably deduce using the principal axis system.

Instead of messing with all that complex vector algebra, Lagrangian dynamics allows you to deal with just a single scalar, the Lagrangian. If you can merely figure out the net kinetic and potential energy of your system in terms of your generalized coordinates and their time derivatives, you are in business.

If there are linkages between the members of the system, the benefits magnify. A brute-force Newtonian solution of the three-dimensional compound pendulum would involve six linear momentum equations and six angular ones. Yet the thing has only two degrees of freedom; the angular orientations of the individual pendulums around their axes of rotation. The reason that there are twelve equations in the Newtonian approach is that the support forces and moments exerted by the two axes add another 10 unknowns. A Lagrangian approach allows you to just write two equations for your two degrees of freedom; the support forces do not appear in the story. That provides a great simplification.

## A.1.3 Lagrangian equations of motion

This section describes the Lagrangian approach to dynamics in general. Assume that you have chosen suitable generalized coordinates that fully determine the state of your system. Call these generalized coordinates $q_{1}, q_{2}, \ldots$ and their time derivatives $\dot{q}_{1}, \dot{q}_{2}, \ldots$ The number of generalized coordinates $K$ is the number of degrees of freedom in the system. A generic canonical coordinate will be indicated as $q_{k}$.

Now find the kinetic energy $T$ and the potential energy $V$ of your system in terms of these generalized coordinates and their time derivatives. The difference is the Lagrangian:

$$
\begin{aligned}
& \mathcal{L}\left(q_{1}, q_{2}, \ldots, q_{K}, \dot{q}_{1}, \dot{q}_{2}, \ldots, \dot{q}_{K}, t\right) \\
& \quad \equiv T\left(q_{1}, q_{2}, \ldots, q_{K}, \dot{q}_{1}, \dot{q}_{2}, \ldots, \dot{q}_{K}, t\right)-V\left(q_{1}, q_{2}, \ldots, q_{K}, t\right)
\end{aligned}
$$

Note that the potential energy depends only on the position coordinates of the system, but the kinetic energy also depends on how fast they change with time. Dynamics books give lots of helpful formulae for the kinetic energy of the solid members of your system, and the potential energy of gravity and within springs.

The canonical momenta are defined as

$$
\begin{equation*}
p_{k}^{\mathrm{c}} \equiv \frac{\partial \mathcal{L}}{\partial \dot{q}_{k}} \tag{A.1}
\end{equation*}
$$

for each individual generalized coordinate $q_{k}$. The equations of motion are

$$
\begin{equation*}
\frac{\mathrm{d} p_{k}^{\mathrm{c}}}{\mathrm{~d} t}=\frac{\partial \mathcal{L}}{\partial q_{k}}+Q_{k} \tag{A.2}
\end{equation*}
$$

There is one such equation for each generalized coordinate $q_{k}$, so there are exactly as many equations as there are degrees of freedom. The equations are second order in time, because the canonical momenta involve first order time derivatives of the $q_{k}$.

The $Q_{k}$ terms are called generalized forces, and are only needed if there are forces that cannot be modeled by the potential $V$. That includes any frictional forces that are not ignored. To find the generalized force $Q_{k}$ at a given time, imagine that the system is displaced slightly at that time by changing the corresponding generalized coordinate $q_{k}$ by an infinitesimal amount $\delta q_{k}$. Since this displacement is imaginary, it is called a "virtual displacement." During such a displacement, each force that is not modelled by $V$ produces a small amount of "virtual work." The net virtual work divided by $\delta q_{k}$ gives the generalized force $Q_{k}$. Note that frictionless supports normally do not perform work, because there is no displacement in the direction of the support force. Also, frictionless linkages between members do not perform net work, since the forces between the members are equal and opposite. Similarly, the internal forces that keep a solid body rigid do not perform work.

The bottom line is that normally the $Q_{k}$ are zero if you ignore friction. However, any collisions against rigid constraints have to be modeled separately, just like in normal Newtonian mechanics. For an infinitely rigid constraint to absorb the kinetic energy of an impact requires infinite force, and $Q_{k}$ would have to be an infinite spike if described normally. Of course, you could instead consider describing the constraint as somewhat flexible, with a very high potential energy penalty for violating it. Then make sure to use an adaptive time step in any numerical integration.

It may be noted that in relativistic mechanics, the Lagrangian is not the difference between potential and kinetic energy. However, the Lagrangian equations of motion (A.1) and (A.2) still apply.

The general concept that applies both nonrelativistically and relativistically is that of "action." The action $\mathcal{S}$ is defined as the time integral of the Lagrangian:

$$
\begin{equation*}
\mathcal{S} \equiv \int_{t_{1}}^{t_{2}} \mathcal{L} \mathrm{~d} t \tag{A.3}
\end{equation*}
$$

Here $t_{1}$ and $t_{2}$ are suitably chosen starting and ending times that enclose the time interval of interest. The action is unchanged by infinitesimal imaginary displacements of the system. It turns out that that is all that is needed for the Lagrangian equations of motion to apply.

See $\{D .3 .1\}$ for a derivation of the above claims.

## A.1.4 Hamiltonian dynamics

For a system with $K$ generalized coordinates the Lagrangian approach provides one equation for each generalized coordinate $q_{k}$. These $K$ equations involve second order time derivatives of the $K$ unknown generalized coordinates $q_{k}$. However, if you consider the time derivatives $\dot{q}_{k}$ as $K$ additional unknowns, you get $K$ first order equations for these $2 K$ unknowns. An additional $K$ equations are:

$$
\frac{\mathrm{d} q_{k}}{\mathrm{~d} t}=\dot{q}_{k}
$$

These are no longer trivial because they now give the time derivatives of the first $K$ unknowns in terms of the second $K$ of them. This trick is often needed when using canned software to integrate the equations, because canned software typically only does systems of first order equations.

However, there is a much neater way to get $2 K$ first order equations in $2 K$ unknowns, and it is particularly close to concepts in quantum mechanics. Define the "Hamiltonian" as

$$
\begin{equation*}
H\left(q_{1}, q_{2}, \ldots, q_{K}, p_{1}^{\mathrm{c}}, p_{2}^{\mathrm{c}}, \ldots, p_{K}^{\mathrm{c}}, t\right) \equiv \sum_{k=1}^{K} \dot{q}_{k} p_{k}^{\mathrm{c}}-\mathcal{L}\left(q_{1}, q_{2}, \ldots, q_{K}, \dot{q}_{1}, \dot{q}_{2}, \ldots, \dot{q}_{K}, t\right) \tag{A.4}
\end{equation*}
$$

In the right hand side expression, you must rewrite all the time derivatives $\dot{q}_{k}$ in terms of the canonical momenta

$$
p_{k}^{\mathrm{c}} \equiv \frac{\partial \mathcal{L}}{\partial \dot{q}_{k}}
$$

because the Hamiltonian must be a function of the generalized coordinates and the canonical momenta only. (In case you are not able to readily solve for the $\dot{q}_{k}$ in terms of the $p_{k}^{c}$, things could become messy. But in principle, the equations to solve are linear for given values of the $q_{k}$.)

In terms of the Hamiltonian, the equations of motion are

$$
\begin{equation*}
\frac{\mathrm{d} q_{k}}{\mathrm{~d} t}=\frac{\partial H}{\partial p_{k}^{\mathrm{c}}} \quad \frac{\mathrm{~d} p_{k}^{\mathrm{c}}}{\mathrm{~d} t}=-\frac{\partial H}{\partial q_{k}}+Q_{k} \tag{A.5}
\end{equation*}
$$

where the $Q_{k}$, if any, are the generalized forces as before.
If the Hamiltonian does not explicitly depend on time and the generalized forces are zero, these evolution equations imply that the Hamiltonian does not change with time at all. For such systems, the Hamiltonian is the conserved total energy of the system. In particular for a nonrelativistic system, the Hamiltonian is the sum of the kinetic and potential energies, provided that the position of the system only depends on the generalized coordinates and not also explicitly on time.

See \{D.3.2 for a derivation of the above claims.

## A.1.5 Fields

The previous subsections discussed discrete mechanical objects like molecules, Frisbees, and pendulums. However, the Lagrangian and Hamiltonian formalisms can be generalized to fields like the electromagnetic field. That is mainly important for advanced physics like quantum field theories; these are not really covered in this book. But since it does appear in one advanced addendum, \{A. 22$\}$, this subsection will summarize the main points.

The simplest classical field is the electrostatic potential $\varphi$. However, there may be more than one potential in a system. For example, in electrodynamics there are also vector potentials. So the generic potential will be indicated as $\varphi_{\alpha}$, where the index $\alpha$ indicates what particular potential it is. A single potential $\varphi_{\alpha}$ is still characterized by infinitely many variables: there is a value of the potential at each position.

In addition there may be discrete variables. Electromagnetics would be pretty boring if you would not have some charged particles around. A generic coordinate of such a particle will be indicated as $q_{k}$. For example, if there is just one charged particle, $q_{1}, q_{2}$, and $q_{3}$ could represent the $x, y$, and $z$ components of the position of the particle. If there are more particles, just keep increasing $k$.

Under the above conditions, the Lagrangian will involve an integral:

$$
\mathcal{L}=\mathcal{L}_{0}+\int £ \mathrm{~d}^{3} \vec{r}
$$

Here $£$ is called the "Lagrangian density." It is essentially a Lagrangian per unit volume. The integral is over all space.

The first part $\mathcal{L}_{0}$ is as before. It will depend on the discrete variables and their time derivatives:

$$
\mathcal{L}_{0}=\mathcal{L}_{0}\left(\ldots ; q_{k}, \dot{q}_{k} ; \ldots\right)
$$

The dot indicates the time derivative of the variable.
The Lagrangian density $£$ will depend on both the fields and the discrete coordinates:

$$
£=£\left(\ldots ; \varphi_{\alpha}, \varphi_{\alpha_{t}}, \varphi_{\alpha_{x}}, \varphi_{\alpha_{y}}, \varphi_{\alpha_{z}} ; \ldots ; q_{k} ; \dot{q}_{k} ; \ldots\right)
$$

Here the subscripts on the field indicate partial derivatives:

$$
\varphi_{\alpha_{t}}=\frac{\partial \varphi_{\alpha}}{\partial t} \quad \varphi_{\alpha_{x}}=\frac{\partial \varphi_{\alpha}}{\partial x} \quad \varphi_{\alpha_{y}}=\frac{\partial \varphi_{\alpha}}{\partial y} \quad \varphi_{\alpha_{z}}=\frac{\partial \varphi_{\alpha}}{\partial z}
$$

In principle, there is no reason why the Lagrangian could not contain higher order derivatives, but fortunately you do not see such things in quantum field theories.

This brings up one practical point. Consider a contribution such as the potential energy of a particle called P with charge $\bar{q}_{\mathrm{P}}$ in an electrostatic field $\varphi$. Assuming that the particle is a point charge, that potential energy is $\bar{q}_{\mathrm{P}} \varphi_{\mathrm{P}}$ where $\varphi_{\mathrm{P}}$ is the potential evaluated at the position $\vec{r}_{\mathrm{P}}$ of the particle. But potentials evaluated at a point are problematic. You would really want the potentials to always appear inside integrals. To achieve that, you can assume that the particle is not really a point charge. That its charge is spread out just a little bit around the nominal position $\vec{r}_{\mathrm{p}}$. In that case, the potential energy takes the form:

$$
\int \bar{q}_{\mathrm{P}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{P}}\right) \varphi(\vec{r} ; t) \mathrm{d}^{3} \vec{r} \approx \bar{q}_{\mathrm{P}} \varphi\left(\vec{r}_{\mathrm{P}} ; t\right)
$$

Here $\delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{P}}\right)$ is some chosen function that is zero except within some small distance $\varepsilon$ of $\vec{r}_{\mathrm{P}}$, and that integrates to one. Because this function is zero except very close to $\vec{r}_{p}$, you can approximate $\varphi(\vec{r} ; t)$ by $\varphi\left(\vec{r}_{\mathrm{r}} ; t\right)$ and then take it out of the integral. That gives the original expression for the potential energy. But the integral is easier to use in the Lagrangian. Its integrand becomes part of the Lagrangian density. And you can always take the limit $\varepsilon \rightarrow 0$ at the end of the day to get point charges.

The Lagrangian equations for the discrete parameters are exactly the same as before, but of course now the Lagrangian includes the integral, $\{$ D.3.3\}:

$$
\begin{equation*}
\frac{\mathrm{d}}{\mathrm{~d} t}\left(\frac{\partial \mathcal{L}_{0}}{\partial \dot{q}_{k}}+\int \frac{\partial £}{\partial \dot{q}_{k}} \mathrm{~d}^{3} \vec{r}\right)=\frac{\partial \mathcal{L}_{0}}{\partial q_{k}}+\int \frac{\partial £}{\partial q_{k}} \mathrm{~d}^{3} \vec{r} \tag{A.6}
\end{equation*}
$$

There is one such equation for each discrete parameter $q_{k}$, valid at any time.
The Lagrangian equations for the field are based on the Lagrangian density instead of the Lagrangian itself. That is why you really want to have the terms involving the field as integrals. The equations are

$$
\begin{equation*}
\frac{\partial}{\partial t}\left(\frac{\partial £}{\partial \varphi_{\alpha_{t}}}\right)+\frac{\partial}{\partial x}\left(\frac{\partial £}{\partial \varphi_{\alpha_{x}}}\right)+\frac{\partial}{\partial y}\left(\frac{\partial £}{\partial \varphi_{\alpha_{y}}}\right)+\frac{\partial}{\partial z}\left(\frac{\partial £}{\partial \varphi_{\alpha_{z}}}\right)=\frac{\partial £}{\partial \varphi_{\alpha}} \tag{A.7}
\end{equation*}
$$

There is one such equation for each field $\varphi_{\alpha}$, valid at any position and time.
The canonical momenta are now

$$
\begin{equation*}
p_{k}^{\mathrm{c}} \equiv \frac{\partial \mathcal{L}_{0}}{\partial \dot{q}_{k}}+\int \frac{\partial £}{\partial \dot{q}_{k}} \mathrm{~d}^{3} \vec{r} \quad \pi_{\alpha}^{\mathrm{c}} \equiv \frac{\partial £}{\partial \varphi_{\alpha_{t}}} \tag{A.8}
\end{equation*}
$$

Note that the field momentum $\pi_{\alpha}^{\mathrm{c}}$ is per unit volume.
The Hamiltonian is

$$
\begin{equation*}
H=\sum_{k} p_{k}^{\mathrm{c}} \dot{q}_{k}+\sum_{\alpha} \int \pi_{\alpha}^{\mathrm{c}} \varphi_{\alpha_{t}} \mathrm{~d}^{3} \vec{r}-\mathcal{L} \tag{A.9}
\end{equation*}
$$

The time derivatives $\dot{q}_{k}$ and $\varphi_{\alpha_{t}}$ must again be expressed in terms of the corresponding canonical momenta.

Hamilton's equations for discrete variables are as before:

$$
\begin{equation*}
\frac{\mathrm{d} q_{k}}{\mathrm{~d} t}=\frac{\partial H}{\partial p_{k}^{\mathrm{c}}} \quad \frac{\mathrm{~d} p_{k}^{\mathrm{c}}}{\mathrm{~d} t}=-\frac{\partial H}{\partial q_{k}} \tag{A.10}
\end{equation*}
$$

The equations for the fields are a bit tricky. If there are no discrete variables, there is no problem. Then the Hamiltonian can be written in terms of a Hamiltonian density $h$ as

$$
H=\int h \mathrm{~d}^{3} \vec{r}
$$

In that case Hamilton's equations are

$$
\frac{\partial \varphi_{\alpha}}{\partial t}=\frac{\partial h}{\partial \pi_{\alpha}^{\mathrm{c}}} \quad \frac{\partial \pi_{\alpha}^{\mathrm{c}}}{\partial t}=-\frac{\partial h}{\partial \varphi_{\alpha}}+\frac{\partial}{\partial x}\left(\frac{\partial h}{\partial \varphi_{\alpha_{x}}}\right)+\frac{\partial}{\partial y}\left(\frac{\partial h}{\partial \varphi_{\alpha_{y}}}\right)+\frac{\partial}{\partial z}\left(\frac{\partial h}{\partial \varphi_{\alpha_{z}}}\right)
$$

Unfortunately, if there are discrete parameters, products of integrals will appear. Then there is no Hamiltonian density. So the only thing you can do do is differentiate the full Hamiltonian $H$ instead of a Hamiltonian density $h$. At the end of every differentiation, you will then need to drop an $\int$ and a $d^{3} \vec{r}$. In particular, differentiate the Hamiltonian $H$ until you have to start differentiating inside an integral, like, say,

$$
\frac{\partial}{\partial \varphi_{\alpha}} \int £ \mathrm{~d}^{3} \vec{r}
$$

At that time, make the substitution

$$
\frac{\partial}{\partial \varphi_{\alpha}} \int £ \mathrm{~d}^{3} \vec{r} \quad \Longrightarrow \quad \frac{\partial £}{\partial \varphi_{\alpha}}
$$

This will produce the right answer, although the left hand side above is mathematically complete nonsense.

See \{D.3.3\} for a justification of this procedure and the other claims in this subsection.

## A. 2 An example of variational calculus

The problem to solve in addendum $\{$ A. 22.1$\}$ provides a simple example of variational calculus.

The problem can be summarized as follows. Given is the following expression for the net energy of a system:

$$
\begin{equation*}
E=\frac{\epsilon_{1}}{2} \int(\nabla \varphi)^{2} \mathrm{~d}^{3} \vec{r}-\int \sigma_{\mathrm{p}} \varphi \mathrm{~d}^{3} \vec{r} \tag{1}
\end{equation*}
$$

Here the operator $\nabla$ is defined as

$$
\nabla \equiv \hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z} \quad \Longrightarrow \quad \nabla \varphi \equiv \hat{\imath} \frac{\partial \varphi}{\partial x}+\hat{\jmath} \frac{\partial \varphi}{\partial y}+\hat{k} \frac{\partial \varphi}{\partial z}
$$

The integrals are over all space, or over some other given region. Further $\epsilon_{1}$ is assumed to be a given positive constant and $\sigma_{\mathrm{p}}=\sigma_{\mathrm{p}}(\vec{r})$ is a given function of the position $\vec{r}$. The function $\varphi=\varphi(\vec{r})$ will be called the potential and is not given. Obviously the energy depends on what this potential is. Mathematicians would say that $E$ is a "functional," a number that depends on what a function is.

The energy $E$ will be minimal for some specific potential $\varphi_{\min }$. The objective is now to find an equation for this potential $\varphi_{\min }$ using variational calculus.

To do so, the basic idea is the following: imagine that you start at $\varphi_{\min }$ and then make an infinitesimally small change $\mathrm{d} \varphi$ to it. In that case there should be no change $\mathrm{d} E$ in energy. After all, if there was an negative change in $E$, then $E$ would decrease. That would contradict that $\varphi_{\min }$ produces the lowest energy of all. If there was an positive infinitesimal change in $E$, then a change in potential of opposite sign would give a negative change in $E$. Again that produces a contradiction to what is given.

The typical physicist would now work out the details as follows. The slightly perturbed potential is written as

$$
\varphi(\vec{r})=\varphi_{\min }(\vec{r})+\delta \varphi(\vec{r})
$$

Note that the d in $\mathrm{d} \varphi$ has been renotated as $\delta$. That is because everyone does so in variational calculus. The symbol does not make a difference, the idea remains the same. Note also that $\delta \varphi$ is a function of position; the change away from $\varphi_{\text {min }}$ is normally different at different locations. You are in fact allowed to choose anything you like for the function $\delta \varphi$, as long as it is sufficiently small and it is zero at the limits of integration.

Now just take differentials like you typically do it in calculus or physics. If in calculus you had some expression like $f^{2}$, you would say $\mathrm{d} f^{2}=2 f \mathrm{~d} f$. (For example, if $f$ is a function of a variable $t$, then $\mathrm{d} f^{2} / \mathrm{d} t=2 f \mathrm{~d} f / \mathrm{d} t$. But physicists usually do not bother with the $\mathrm{d} t$; then they do not have to worry what exactly $f$ is a function of.) Similarly

$$
\delta(\nabla \varphi)^{2}=2(\nabla \varphi) \cdot \delta(\nabla \varphi)
$$

where

$$
\delta \nabla \varphi=\nabla\left(\varphi_{\min }+\delta \varphi\right)-\nabla\left(\varphi_{\min }\right)=\nabla \delta \varphi
$$

so

$$
\delta(\nabla \varphi)^{2}=2(\nabla \varphi) \cdot(\nabla \delta \varphi)
$$

For a change starting from $\varphi_{\text {min }}$ :

$$
\delta(\nabla \varphi)^{2}=2\left(\nabla \varphi_{\min }\right) \cdot(\nabla \delta \varphi)
$$

(Note that $\varphi$ by itself gets approximated as $\varphi_{\min }$, but $\delta \varphi$ is the completely arbitrary change that can be anything.) Also,

$$
\delta\left(\sigma_{\mathrm{p}} \varphi\right)=\sigma_{\mathrm{p}} \delta \varphi
$$

because $\sigma_{\mathrm{p}}$ is a given constant at every position.
Total you get for the change in energy that must be zero

$$
\begin{equation*}
0=\delta E=\frac{\epsilon_{1}}{2} \int 2\left(\nabla \varphi_{\min }\right) \cdot(\nabla \delta \varphi) \mathrm{d}^{3} \vec{r}-\int \sigma_{\mathrm{p}} \delta \varphi \mathrm{~d}^{3} \vec{r} \tag{2}
\end{equation*}
$$

A conscientious mathematician would shudder at the above manipulations. And for good reason. Small changes are not good mathematical concepts. There is no such thing as "small" in mathematics. There are just limits where things go to zero. What a mathematician would do instead is write the change in potential as a some multiple $\lambda$ of a chosen function $\varphi_{\mathrm{c}}$. So the changed potential is written as

$$
\varphi(\vec{r})=\varphi_{\min }(\vec{r})+\lambda \varphi_{\mathrm{c}}(\vec{r})
$$

The chosen function $\varphi_{\mathrm{c}}$ can still be anything that you want that vanishes at the limits of integration. But it is not assumed to be "small." So now no mathematical nonsense is written. The energy for this changed potential is

$$
E=\frac{\epsilon_{1}}{2} \int\left[\nabla\left(\varphi_{\min }+\lambda \varphi_{\mathrm{c}}\right)\right]^{2} \mathrm{~d}^{3} \vec{r}-\int \sigma_{\mathrm{p}}\left(\varphi_{\min }+\lambda \varphi_{\mathrm{c}}\right) \mathrm{d}^{3} \vec{r}
$$

Now this energy is a function of the multiple $\lambda$. And that is a simple numerical variable. The energy must be smallest at $\lambda=0$, because $\varphi_{\text {min }}$ gives the minimum energy. So the above function of $\lambda$ must have a minimum at $\lambda=0$. That means that it must have a zero derivative at $\lambda=0$. So just differentiate the expression with respect to $\lambda$. (You can differentiate as is, or simplify first and bring $\lambda$ outside the integrals.) Set this derivative to zero at $\lambda=0$. That gives the same result (2) as derived by physicists, except that $\varphi_{\mathrm{c}}$ takes the place of $\delta \varphi$. The result is the same, but the derivation is nowhere fishy.

This derivation will return to the notations of physicists. The next step is to get rid of the derivatives on $\delta \varphi$. Note that

$$
\int\left(\nabla \varphi_{\min }\right) \cdot(\nabla \delta \varphi) \mathrm{d}^{3} \vec{r}=\iiint \frac{\partial \varphi_{\min }}{\partial x} \frac{\partial \delta \varphi}{\partial x}+\frac{\partial \varphi_{\min }}{\partial y} \frac{\partial \delta \varphi}{\partial y}+\frac{\partial \varphi_{\min }}{\partial z} \frac{\partial \delta \varphi}{\partial z} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z
$$

The way to get rid of the derivatives on $\delta \varphi$ is by integration by parts. Integration by parts pushes a derivative from one factor on another. Here you see the real reason why the changes in potential must vanish at the limits of integration. If
they did not, integrations by parts would bring in contributions from the limits of integration. That would be a mess.

Integrations by parts of the three terms in the integral in the $x, y$, and $z$ directions respectively produce

$$
\int\left(\nabla \varphi_{\min }\right) \cdot(\nabla \delta \varphi) \mathrm{d}^{3} \vec{r}=\iiint-\frac{\partial^{2} \varphi_{\min }}{\partial x^{2}} \delta \varphi-\frac{\partial^{2} \varphi_{\min }}{\partial y^{2}} \delta \varphi-\frac{\partial^{2} \varphi_{\min }}{\partial z^{2}} \delta \varphi \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z
$$

In vector notation, that becomes

$$
\int\left(\nabla \varphi_{\min }\right) \cdot(\nabla \delta \varphi) \mathrm{d}^{3} \vec{r}=-\int\left(\nabla^{2} \varphi_{\min }\right) \delta \varphi \mathrm{d}^{3} \vec{r}
$$

Substituting that in the change of energy (2) gives

$$
0=\delta E=\int\left(-\epsilon_{1} \nabla^{2} \varphi_{\min }-\sigma_{\mathrm{p}}\right) \delta \varphi \mathrm{d}^{3} \vec{r}
$$

The final step is to say that this can only be true for whatever change $\delta \varphi$ you take if the parenthetical expression is zero. That gives the final looked-for equation for $\varphi_{\text {min }}$ :

$$
\begin{equation*}
-\epsilon_{1} \nabla^{2} \varphi_{\min }-\sigma_{\mathrm{p}}=0 \tag{3}
\end{equation*}
$$

To justify the above final step, call the parenthetical expression $f$ for short. Then the variational statement above is of the form

$$
\int f \delta \varphi \mathrm{~d}^{3} \vec{r}=0
$$

where $\delta \varphi$ can be arbitrarily chosen as long as it is zero at the limits of integration. It is now to be shown that this implies that $f$ is everywhere zero inside the region of integration.
(Note here that whatever function $f$ is, it should not contain $\delta \varphi$. And there should not be any derivatives of $\delta \varphi$ anywhere at all. Otherwise the above statement is not valid.)

The best way to see that $f$ must be zero everywhere is first assume the opposite. Assume that $f$ is nonzero at some point P . In that case select a function $\delta \varphi$ that is zero everywhere except in a small vicinity of P , where it is positive. (Make sure the vicinity is small enough that $f$ does not change sign in it.) Then the integral above is nonzero; in particular, it will have the same sign as $f$ at P . But that is a contradiction, since the integral must be zero. So the function $f$ cannot be nonzero at a point P ; it must be zero everywhere.
(There are more sophisticated ways to do this. You could take $\delta \varphi$ as a positive multiple of $f$ that fades away to zero away from point P . In that case the integral will be positive unless $f$ is everywhere zero. And sign changes in $f$ are no longer a problem.)

## A. 3 Galilean transformation

The Galilean transformation describes coordinate system transformations in nonrelativistic Newtonian physics. This note explains these transformation rules. Essentially the same analysis also applies to Lorentz transformations between observers using arbitrarily chosen coordinate systems. The small difference will be indicated.

Consider two observers $A^{\prime}$ and $\mathrm{B}^{\prime}$ that are in inertial motion. In other words, they do not experience accelerating forces. The two observers move with a relative velocity of magnitude $V$ relative to each other. Observer A' determines the time of events using a suitable clock. This clock displays the time $t_{\mathrm{A}^{\prime}}$ as a single number, say as the number of seconds since a suitably chosen reference event. To specify the position of events, observer A' uses a Cartesian coordinate system $\left(x_{\mathrm{A}^{\prime}}, y_{\mathrm{A}^{\prime}}, z_{\mathrm{A}^{\prime}}\right)$ that is at rest compared to him. The origin of the coordinate system is chosen at a suitable location, maybe the location of the reference event that is used as the zero of time.

Observer B' determines time using a clock that indicates a time $t_{B^{\prime}}$. This time might be zero at a different reference event than the time $t_{\mathrm{A}^{\prime}}$. To specify the position of events, observer B' uses a Cartesian coordinate system ( $x_{\mathrm{B}^{\prime}}, y_{\mathrm{B}^{\prime}}, z_{\mathrm{B}^{\prime}}$ ) that is at rest compared to her. The origin of this coordinate system is different from the one used by observer A'. For one, the two origins are in motion compared to each other with a relative speed $V$.

The question is now, what is the relationship between the times and positions that these two observers attach to arbitrary events.

To answer this, it is convenient to introduce two additional observers A and B. Observer A is at rest compared to observer A'. However, she takes her zero of time and the origin of her coordinate system from observer B'. In particular, the location and time that A associates with her origin at time zero is also the origin at time zero for observer B':

$$
\left(x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}, t_{\mathrm{A}}\right)=(0,0,0,0) \quad \Longleftrightarrow \quad\left(x_{\mathrm{B}^{\prime}}, y_{\mathrm{B}^{\prime}}, z_{\mathrm{B}^{\prime}}, t_{\mathrm{B}^{\prime}}\right)=(0,0,0,0)
$$

The other additional observer, B , is at rest compared to B '. Like observer A, observer B uses the same origin and zero of time as observer B':

$$
\left(x_{\mathrm{B}}, y_{\mathrm{B}}, z_{\mathrm{B}}, t_{\mathrm{B}}\right)=(0,0,0,0) \quad \Longleftrightarrow \quad\left(x_{\mathrm{B}^{\prime}}, y_{\mathrm{B}^{\prime}}, z_{\mathrm{B}^{\prime}}, t_{\mathrm{B}^{\prime}}\right)=(0,0,0,0)
$$

Observer B orients her coordinate system like A does.
That makes the relationship between A and B just like A and B as discussed for the Lorentz transform, figure 1.2. However, the classical Galilean transformation is much simpler than the Lorentz transformation. It is

$$
\begin{equation*}
t_{\mathrm{B}}=t_{\mathrm{A}} \quad x_{\mathrm{B}}=x_{\mathrm{A}}-V t_{\mathrm{A}} \quad y_{\mathrm{B}}=y_{\mathrm{A}} \quad z_{\mathrm{B}}=z_{\mathrm{A}} \tag{A.11}
\end{equation*}
$$

Note however that these classical formulae are only an approximation. They can only be used if the relative velocity $V$ between the observers is much smaller
than the speed of light. In fact, if you take the limit $c \rightarrow \infty$ of the Lorentz transformation (1.6), you get the Galilean transformation above.

The question still is how to relate the times and locations that observer A' attaches to events to those that observer $\mathrm{B}^{\prime}$ does. To answer that, it is convenient to do it in stages. First relate the times and locations that A' attaches to events to the ones that A does. Then use the formulae above to relate the times and locations that A attaches to events to the ones that B does. Or, if you want the relativistic transformation, at this stage use the Lorentz transformation (1.6). Finally, relate the times and locations that B attaches to events to the ones that B ' does.

Consider then now the relationship between the times and locations that A' attaches to events and the ones that A does. Since observer A and A' are at rest relative to each other, they agree about differences in time between events. However, A' uses a different zero for time. Therefore, the relation between the times used by the two observers is

$$
t_{\mathrm{A}}=t_{\mathrm{A}^{\prime}}-\tau_{\mathrm{AA}^{\prime}}
$$

Here $\tau_{\mathrm{AA}^{\prime}}$ is the time that observer $\mathrm{A}^{\prime}$ associates with the reference event that observer A uses as time zero. It is a constant, and equal to $-\tau_{\mathrm{A}^{\prime} \mathrm{A}}$. The latter can be seen by simply setting $t_{\mathrm{A}^{\prime}}$ zero in the formula above.

To specify the location of events, both observers A' and A use Cartesian coordinate systems. Since the two observers are at rest compared to each other, they agree on distances between locations. However, their coordinate systems have different origins. And they are also oriented under different angles. That makes the unit vectors $\hat{\imath}, \hat{\jmath}$, and $\hat{k}$ along the coordinate axes different. In vector form the relation between the coordinates is then:

| $x_{\mathrm{A}} \hat{\imath}_{\mathrm{A}}+y_{\mathrm{A}} \hat{\jmath}_{\mathrm{A}}+z_{\mathrm{A}} \hat{k}_{\mathrm{A}}=\left(x_{\mathrm{A}^{\prime}}-\xi_{\mathrm{AA}^{\prime}}\right) \hat{\imath}_{\mathrm{A}^{\prime}}+\left(y_{\mathrm{A}^{\prime}}-\eta_{\mathrm{AA}^{\prime}}\right) \hat{\jmath}_{\mathrm{A}^{\prime}}+\left(z_{\mathrm{A}^{\prime}}-\zeta_{\mathrm{AA}^{\prime}}\right) \hat{k}_{\mathrm{A}^{\prime}}$ |
| :--- |
| (A.12) |

Here $\xi_{\mathrm{AA}^{\prime}}, \eta_{\mathrm{AA}^{\prime}}$, and $\theta_{\mathrm{AA}^{\prime}}$ are the position coordinates that observer A' associates with the origin of the coordinate system of A . By putting ( $x_{\mathrm{A}^{\prime}}, y_{\mathrm{A}^{\prime}}, z_{\mathrm{A}^{\prime}}$ ) to zero in the expression above, you can relate this to the coordinates that A attaches to the origin of A'.

The above equations can be used to find the coordinates of A in terms of those of A. To do so, you will need to know the components of the unit vectors used by A' in terms of those used by A. In other words, you need to know the dot products in

$$
\begin{aligned}
& \hat{\imath}_{\mathrm{A}^{\prime}}=\left(\hat{\imath}_{\mathrm{A}^{\prime}} \cdot \hat{\imath}_{\mathrm{A}}\right) \hat{\imath}_{\mathrm{A}}+\left(\hat{\imath}_{\mathrm{A}^{\prime}} \cdot \hat{\jmath}_{\mathrm{A}}\right) \hat{\jmath}_{\mathrm{A}}+\left(\hat{\imath}_{\mathrm{A}^{\prime}} \cdot \hat{k}_{\mathrm{A}}\right) \hat{k}_{\mathrm{A}} \\
& \hat{\jmath}_{\mathrm{A}^{\prime}}=\left(\hat{\jmath}_{\mathrm{A}^{\prime}} \cdot \hat{\imath}_{\mathrm{A}}\right) \hat{\imath}_{\mathrm{A}}+\left(\hat{\jmath}_{\mathrm{A}^{\prime}} \cdot \hat{\jmath}_{\mathrm{A}}\right) \hat{\jmath}_{\mathrm{A}}+\left(\hat{\jmath}_{\mathrm{A}^{\prime}} \cdot \hat{k}_{\mathrm{A}}\right) \hat{k}_{\mathrm{A}} \\
& \hat{k}_{\mathrm{A}^{\prime}}=\left(\hat{k}_{\mathrm{A}^{\prime}} \cdot \hat{\imath}_{\mathrm{A}}\right) \hat{\imath}_{\mathrm{A}}+\left(\hat{k}_{\mathrm{A}^{\prime}} \cdot \hat{\jmath}_{\mathrm{A}}\right) \hat{\jmath}_{\mathrm{A}}+\left(\hat{k}_{\mathrm{A}^{\prime}} \cdot \hat{k}_{\mathrm{A}}\right) \hat{k}_{\mathrm{A}}
\end{aligned}
$$

Then these relations allow you to sum the $\hat{\imath}_{\mathrm{A}}$ components in the right hand side of (A.12) to give $x_{\mathrm{A}}$. Similarly the $\hat{\jmath}_{\mathrm{A}}$ components sum to $y_{\mathrm{A}}$ and the $\hat{k}_{\mathrm{A}}$ components to $z_{\mathrm{A}}$.

Note also that if you know these dot products, you also know the ones for the inverse transformation, from A to A'. For example,

$$
\left(\hat{\imath}_{\mathrm{A}} \cdot \hat{\imath}_{\mathrm{A}^{\prime}}\right)=\left(\hat{\imath}_{\mathrm{A}^{\prime}} \cdot \hat{\imath}_{\mathrm{A}}\right) \quad\left(\hat{\imath}_{\mathrm{A}} \cdot \hat{\jmath}_{\mathrm{A}^{\prime}}\right)=\left(\hat{\jmath}_{\mathrm{A}^{\prime}} \cdot \hat{\imath}_{\mathrm{A}}\right) \quad \text { etcetera }
$$

(In terms of linear algebra, the dot products form a $3 \times 3$ matrix. This matrix is called "unitary," or as a real matrix also more specifically "orthonormal," since it preserves distances between locations. The matrix for the reverse transform is found by taking a transpose.)

The relationship between observers B and $B^{\prime}$ is a simplified version of the one between observers $A$ and $A^{\prime}$. It is simpler because $B$ and $B^{\prime}$ use the same zero of time and the same origin. Therefore the formulae can be obtained from the ones given above by replacing A' and A by B and B' and dropping the terms related to time and origin shifts.

## A. 4 More on index notation

Engineering students are often much more familiar with linear algebra than with tensor algebra. So it may be worthwhile to look at the Lorentz transformation from a linear algebra point of view. The relation to tensor algebra will be indicated. If you do not know linear algebra, there is little point in reading this addendum.

A contravariant four-vector like position can be pictured as a column vector that transforms with the Lorentz matrix $\Lambda$. A covariant four-vector like the gradient of a scalar function can be pictured as a row vector that transforms with the inverse Lorentz matrix $\Lambda^{-1}$ :

$$
\stackrel{\rightharpoonup}{r}_{\mathrm{B}}=\Lambda \stackrel{\rightharpoonup}{r}_{\mathrm{A}} \quad(\stackrel{\rightharpoonup}{\nabla} f)_{\mathrm{B}}^{\mathrm{T}}=(\stackrel{\rightharpoonup}{\nabla} f)_{\mathrm{A}}^{\mathrm{T}} \Lambda^{-1}
$$

In linear algebra, a superscript $T$ transforms columns into rows and vice-versa. Since you think of the gradient by itself as a column vector, the T turns it into a row vector. Note also that putting the factors in a product in the correct order is essential in linear algebra. In the second equation above, the gradient, written as a row, premultiplies the inverse Lorentz matrix.

In tensor notation, the above expressions are written as

$$
x_{\mathrm{B}}^{\mu}=\lambda^{\mu}{ }_{\nu} x_{\mathrm{A}}^{\nu} \quad \partial_{\mu, \mathrm{B}} f=\partial_{\nu, \mathrm{A}} f\left(\lambda^{-1}\right)^{\nu}{ }_{\mu}
$$

The order of the factors is now no longer a concern; the correct way of multiplying follows from the names of the indices.

The key property of the Lorentz transformation is that it preserves dot products. Pretty much everything else follows from that. Therefore the dot product must now be formulated in terms of linear algebra. That can be done as follows:

$$
\stackrel{\rightharpoonup}{r}_{1} \cdot \stackrel{\rightharpoonup}{r}_{2} \equiv \stackrel{\rightharpoonup}{r}_{1}^{\mathrm{T}} G \stackrel{\rightharpoonup}{r}_{2} \quad \text { where } \quad G=\left(\begin{array}{cccc}
-1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{array}\right)
$$

The matrix $G$ is called the "Minkowski metric." The effect of $G$ on $\vec{r}_{2}$ is to flip over the sign of the zeroth, time, entry. Looking at it another way, the effect of $G$ on the preceding $\vec{r}_{1}^{\mathrm{T}}$ is to flip over the sign of its zeroth entry. Either way, $G$ provides the minus sign for the product of the time coordinates in the dot product.

In tensor notation, the above expression must be written as

$$
\stackrel{\rightharpoonup}{r}_{1} \cdot \stackrel{\rightharpoonup}{r}_{2} \equiv x_{1}^{\mu} g_{\mu \nu} x_{2}^{\nu}
$$

In particular, since space-time positions have superscripts, the metric matrix $G$ needs to be assigned subscripts. That maintains the convention that a summation index appears once as a subscript and once as a superscript.

Since dot products are invariant,

$$
\overleftrightarrow{r}_{1 \mathrm{~A}}^{\mathrm{T}} G \stackrel{\rightharpoonup}{r}_{2 \mathrm{~A}}=\stackrel{\rightharpoonup}{r}_{1 \mathrm{~B}}^{\mathrm{T}} G \stackrel{\rightharpoonup}{r}_{2 \mathrm{~B}}=\stackrel{\rightharpoonup}{r}_{1 \mathrm{~A}}^{\mathrm{T}} \Lambda^{T} G \Lambda \stackrel{\rightharpoonup}{r}_{2 \mathrm{~A}}
$$

Here the final equality substituted the Lorentz transformation from A to B. Recall that if you take a transpose of a product, the order of the factors gets inverted. If the expression to the far left is always equal to the one to the far right, it follows that

$$
\begin{equation*}
\Lambda^{\mathrm{T}} G \Lambda=G \tag{A.13}
\end{equation*}
$$

This must be true for any Lorentz transform. In fact, many sources define Lorentz transforms as transforms that satisfy the above relationship. Therefore, this relationship will be called the "defining relation." It is very convenient for doing the various mathematics. However, this sort of abstract definition does not really promote easy physical understanding.

And there are a couple of other problems with the defining relation. For one, it allows Lorentz transforms in which one observer uses a left-handed coordinate system instead of a right-handed one. Such an observer observes a mirror image of the universe. Mathematically at least. A Lorentz transform that switches from a normal right-handed coordinate system to a left handed one, (or vice-versa), is called "improper." The simplest example of such an improper transformation is $\Lambda=-G$. That is called the "parity transformation." Its effect is to flip over all spatial position vectors. (If you make a picture of
it, you can see that inverting the directions of the $x, y$, and $z$ axes of a righthanded coordinate system produces a left-handed system.) To see that $\Lambda=-G$ satisfies the defining relation above, note that $G$ is symmetric, $G^{\mathrm{T}}=G$, and its own inverse, $G G=I$.

Another problem with the defining relation is that it allows one observer to use an inverted direction of time. Such an observer observes the universe evolving to smaller values of her time coordinate. A Lorentz transform that switches the direction of time from one observer to the next is called "nonorthochronous." (Ortho indicates correct, and chronous time.) The simplest example of a nonorthochronous transformation is $\Lambda=G$. That transformation is called "timereversal." Its effect is to simply replace the time $t$ by $-t$. It satisfies the defining relation for the same reasons as the parity transformation.

As a result, there are four types of Lorentz transformations that satisfy the defining relation. First of all there are the normal proper orthochronous ones. The simplest example is the unit matrix $I$, corresponding to the case that the observers A and B are identical. Second, there are the improper ones like $-G$ that switch the handedness of the coordinate system. Third there are the nonorthochronous ones like $G$ that switch the correct direction of time. And fourth, there are improper nonorthochronous transforms, like $-G G=-I$, that switch both the handedness and the direction of time.

These four types of Lorentz transforms form four distinct groups. You cannot gradually change from a right-handed coordinate system to a left-handed one. Either a coordinate system is right-handed or it is left-handed. There is nothing in between. By the same token, either a coordinate system has the proper direction of time or the exactly opposite direction.

These four groups are reflected in mathematical properties of the Lorentz transforms. Lorentz transform matrices have determinants that are either 1 or -1 . That is easily seen from taking determinants of both sides of the defining equation (A.13), splitting the left determinant in its three separate factors. Also, Lorentz transforms have values of the entry $\lambda^{0}{ }_{0}$ that are either greater or equal to 1 or less or equal to -1 . That is readily seen from writing out the ${ }_{0}{ }_{0}$ entry of (A.13).

Proper orthochronous Lorentz transforms have a determinant 1 and an entry $\lambda^{0}{ }_{0}$ greater or equal to 1 . That can readily be checked for the simplest example $\Lambda=I$. More generally, it can easily be checked that $\lambda_{0}{ }_{0}$ is the time dilatation factor for events that happen right in the hands of observer A. That is the physical reason that $\lambda^{0}{ }_{0}$ must always be greater or equal to 1 . Transforms that have $\lambda^{0}{ }_{0}$ less or equal to -1 flip over the correct direction of time. So they are nonorthochronous. Transforms that switch over the handedness of the coordinate system produce a negative determinant. But so do nonorthochronous transforms. If a transform flips over both handedness and the direction of time, it has a time dilatation less or equal to -1 but a positive determinant.

For reasons given above, if you start with some proper orthochronous Lorentz
transform like $\Lambda=I$ and gradually change it, it stays proper and orthochronous. But in addition its determinant stays 1 and its time-dilatation entry stays greater or equal to 1 . The reasons are essentially the same as before. You cannot gradually change from a value of 1 or above to a value of -1 or below if there is nothing in between.

One consequence of the defining relation (A.13) merits mentioning. If you premultiply both sides of the relation by $G^{-1}$, you immediately see that

$$
\begin{equation*}
\Lambda^{-1}=G^{-1} \Lambda^{T} G \tag{A.14}
\end{equation*}
$$

This is the easy way to find inverses of Lorentz transforms. Also, since $G^{2}=$ $I, G^{-1}=G$. However, it cannot hurt to leave the expression as written. There are other applications in tensor algebra in which $G^{-1}$ is not equal to $G$.

As already illustrated above, what multiplications by $G$ do is flip over the sign of some entries. So to find an inverse of a Lorentz transform, just flip over the right entries. To be precise, flip over the entries in which one index is 0 and the other is not.

The above observations can be readily converted to tensor notation. First an equivalent is needed to some definitions used in tensor algebra but not normally in linear algebra. The "lowered covector" to a contravariant vector like position will be defined as

$$
\stackrel{r}{r}^{\mathrm{L}} \equiv \stackrel{\rightharpoonup}{r}^{\mathrm{T}} G
$$

In words, take a transpose and postmultiply with the metric $G$. The result is a row vector while the original is a column vector.

Note that the dot product can now be written as

$$
\vec{r}_{1} \cdot \stackrel{\rightharpoonup}{r}_{2}=\stackrel{\rightharpoonup}{r}_{1}^{\mathrm{L}} \stackrel{\rightharpoonup}{r}_{2}
$$

Note also that lowered covectors are covariant vectors; they are row vectors that transform with the inverse Lorentz transform. To check that, simply plug in the Lorentz transformation of the original vector and use the expression for the inverse Lorentz transform above.

Similarly, the "raised contravector" to a covariant vector like a gradient will be defined as

$$
(\stackrel{\rightharpoonup}{\nabla} f)^{\mathrm{TR}} \equiv G^{-1} \vec{\nabla} f
$$

In words, take a transpose and premultiply by the inverse metric. The raised contravector is a contravariant vector. Forming a raised contravector of a lowered covector gives back the original vector. And vice-versa. (Note that metrics are symmetric matrices in checking that.)

In tensor notation, the lowered covector is written as

$$
x_{\mu}=x^{\nu} g_{\nu \mu}
$$

Note that the graphical effect of multiplying by the metric tensor is to "lower" the vector index.

Similarly, the raised contravector to a covector is

$$
\partial^{\mu} f=\left(g^{-1}\right)^{\mu \nu} \partial_{\nu} f
$$

It shows that the inverse metric can be used to "raise" indices. But do not forget the golden rule: raising or lowering an index is much more than cosmetic: you produce a fundamentally different vector.
(That is not true for so-called "Cartesian tensors" like purely spatial position vectors. For these the metric $G$ is the unit matrix. Then raising or lowering an index has no real effect. By the way, the unit matrix is in tensor notation $\delta^{\mu}{ }_{\nu}$. That is called the Kronecker delta. Its entries are 1 if the two indices are equal and 0 otherwise.)

Using the above notations, the dot product becomes as stated in chapter 1.2.5,

$$
x_{1, \mu} x_{2}^{\mu}
$$

More interestingly, consider the inverse Lorentz transform. According to the expression given above $\Lambda^{-1}=G^{-1} \Lambda^{\mathrm{T}} G$, so:

$$
\left(\lambda^{-1}\right)^{\mu}{ }_{\nu}=\left(g^{-1}\right)^{\mu \alpha} \lambda^{\beta}{ }_{\alpha} g_{\beta \nu}
$$

(A transpose of a matrix, in this case $\Lambda$, swaps the indices.) According the index raising/lowering conventions above, in the right hand side the heights of the indices of $\Lambda$ are inverted. So you can define a new matrix with entries

$$
\lambda_{\nu}{ }^{\mu} \equiv\left(\lambda^{-1}\right)^{\mu}{ }_{\nu}
$$

But note that the so-defined matrix is not the Lorentz transform matrix:

$$
\lambda_{\nu}{ }^{\mu} \neq \lambda^{\mu}{ }_{\nu}
$$

It is a different matrix. In particular, the signs on some entries are swapped.
(Needless to say, various supposedly authoritative sources list both matrices as $\lambda_{\nu}^{\mu}$ for that exquisite final bit of confusion. It is apparently not easy to get subscripts and superscripts straight if you use some horrible product like MS Word. Of course, the simple answer would be to use a place holder in the empty position that indicates whether or not the index has been raised or lowered. For example:

$$
\lambda_{\nu R}^{L \mu} \neq \lambda_{N \nu}^{\mu N}
$$

However, this is not possible because it would add clarity.)
Now consider another very confusing result. Start with

$$
G^{-1} G G^{-1}=G^{-1} \quad \Longrightarrow \quad\left(g^{-1}\right)^{\mu \alpha} g_{\alpha \beta}\left(g^{-1}\right)^{\beta \nu}=\left(g^{-1}\right)^{\mu \nu}
$$

According to the raising conventions, that can be written as

$$
\begin{equation*}
g^{\mu \nu} \equiv\left(g^{-1}\right)^{\mu \nu} \tag{A.15}
\end{equation*}
$$

Does this not look exactly as if $G=G^{-1}$ ? That may be true in the case of Lorentz transforms and the associated Minkowski metric. But for more general applications of tensor algebra it is most definitely not true. Always remember the golden rule: names of tensors are only meaningful if the indices are at the right height. The right height for the indices of $G$ is subscripts. So $g^{\mu \nu}$ does not indicate an entry of $G$. Instead it turns out to represent an entry of $G^{-1}$.

So physicists now have two options. They can write the entries of $G^{-1}$ in the understandable form $\left(g^{-1}\right)^{\mu \nu}$. Or they can use the confusing, error-prone form $g^{\mu \nu}$. So what do you think they all do? If you guessed option (b), you are making real progress in your study of modern physics.

Often the best way to verify some arcane tensor expression is to convert it to linear algebra. (Remember to check the heights of the indices when doing so. If they are on the wrong height, restore the omitted factor $g .$. or $\left(g^{-1}\right) \cdots$.) Some additional results that are useful in this context are

$$
\Lambda^{-\mathrm{T}} G \Lambda^{-1}=G \quad \Lambda G^{-1} \Lambda^{\mathrm{T}}=G^{-1} \quad \Lambda G \Lambda^{\mathrm{T}}=G
$$

The first of these implies that the inverse of a Lorentz transform is a Lorentz transform too. That is readily verified from the defining relation (A.13) by premultiplying by $\Lambda^{-\mathrm{T}}$ and postmultiplying by $\Lambda^{-1}$. The second expression is simply the matrix inverse of the first. Both of these expressions generalize to any symmetric metric $G$. The final expression implies that the transpose of a Lorentz transform is a Lorentz transform too. That is only true for Lorentz transforms and the associated Minkowski metric. Or actually, it is also true for any other metric in which $G^{-1}=G$, including Cartesian tensors. For these metrics, the final expression above is the same as the second expression.

## A. 5 The reduced mass

Two-body systems, like the earth-moon system of celestial mechanics or the proton-electron hydrogen atom of quantum mechanics, can be analyzed more simply using reduced mass. In this note both a classical and a quantum derivation will be given. The quantum derivation will need to anticipate some results on multi-particle systems from chapter 5.1.

In two-body systems the two bodies move around their combined center of gravity. However, in examples such as the ones mentioned, one body is much more massive than the other. In that case the center of gravity almost coincides with the heavy body, (earth or proton). Therefore, in a naive first approximation it may be assumed that the heavy body is at rest and that the
lighter one moves around it. It turns out that this naive approximation can be made exact by replacing the mass of the lighter body by an reduced mass. That simplifies the mathematics greatly by reducing the two-body problem to that of a single one. Also, it now produces the exact answer regardless of the ratio of masses involved.

The classical derivation is first. Let $m_{1}$ and $\vec{r}_{1}$ be the mass and position of the massive body (earth or proton), and $m_{2}$ and $\vec{r}_{2}$ those of the lighter one (moon or electron). Classically the force $\vec{F}$ between the masses will be a function of the difference $\vec{r}_{21}=\vec{r}_{2}-\vec{r}_{1}$ in their positions. In the naive approach the heavy mass is assumed to be at rest at the origin. Then $\vec{r}_{21}=\vec{r}_{2}$, and so the naive equation of motion for the lighter mass is, according to Newton's second law,

$$
m_{2} \ddot{\vec{r}}_{21}=\vec{F}\left(\vec{r}_{21}\right)
$$

Now consider the true motion. The center of gravity is defined as a massweighted average of the positions of the two masses:

$$
\vec{r}_{\mathrm{cg}}=w_{1} \vec{r}_{1}+w_{2} \vec{r}_{2} \quad w_{1}=\frac{m_{1}}{m_{1}+m_{2}} \quad w_{2}=\frac{m_{2}}{m_{1}+m_{2}}
$$

It is shown in basic physics that the net external force on the system equals the total mass times the acceleration of the center of gravity. Since in this case it will be assumed that there are no external forces, the center of gravity moves at a constant velocity. Therefore, the center of gravity can be taken as the origin of an inertial coordinate system. In that coordinate system, the positions of the two masses are given by

$$
\vec{r}_{1}=-w_{2} \vec{r}_{21} \quad \vec{r}_{2}=w_{1} \vec{r}_{21}
$$

because the position $w_{1} \vec{r}_{1}+w_{2} \vec{r}_{2}$ of the center of gravity must be zero in this system, and the difference $\vec{r}_{2}-\vec{r}_{1}$ must be $\vec{r}_{21}$. (Note that the sum of the two weight factors is one.) Solve these two equations for $\vec{r}_{1}$ and $\vec{r}_{2}$ and you get the result above.

The true equation of motion for the lighter body is $m_{2} \ddot{\vec{r}}_{2}=\vec{F}\left(\vec{r}_{21}\right)$, or plugging in the above expression for $\vec{r}_{2}$ in the center of gravity system,

$$
m_{2} w_{1} \ddot{\vec{r}}_{21}=\vec{F}\left(\vec{r}_{21}\right)
$$

That is exactly the naive equation of motion if you replace $m_{2}$ in it by the reduced mass $m_{2} w_{1}$, i.e. by

$$
\begin{equation*}
m_{\mathrm{red}}=\frac{m_{1} m_{2}}{m_{1}+m_{2}} \tag{A.16}
\end{equation*}
$$

The reduced mass is almost the same as the lighter mass if the difference between the masses is large, like it is in the cited examples, because then $m_{2}$ can be ignored compared to $m_{1}$ in the denominator.

The bottom line is that the motion of the two-body system consists of the motion of its center of gravity plus motion around its center of gravity. The motion around the center of gravity can be described in terms of a single reduced mass moving around a fixed center.

The next question is if this reduced mass idea is still valid in quantum mechanics. Quantum mechanics is in terms of a wave function $\psi$ that for a twoparticle system is a function of both $\vec{r}_{1}$ and $\vec{r}_{2}$. Also, quantum mechanics uses the potential $V\left(\vec{r}_{21}\right)$ instead of the force. The Hamiltonian eigenvalue problem for the two particles is:

$$
H \psi=E \psi \quad H=-\frac{\hbar^{2}}{2 m_{1}} \nabla_{1}^{2}-\frac{\hbar^{2}}{2 m_{2}} \nabla_{2}^{2}+V\left(\vec{r}_{21}\right)
$$

where the two kinetic energy Laplacians in the Hamiltonian $H$ are with respect to the position coordinates of the two particles:

$$
\nabla_{1}^{2} \psi \equiv \sum_{j=1}^{3} \frac{\partial^{2} \psi}{\partial r_{1, j}^{2}} \quad \nabla_{2}^{2} \psi \equiv \sum_{j=1}^{3} \frac{\partial^{2} \psi}{\partial r_{2, j}^{2}}
$$

Now make a change of variables from $\vec{r}_{1}$ and $\vec{r}_{2}$ to $\vec{r}_{\mathrm{cg}}$ and $\vec{r}_{21}$ where

$$
\vec{r}_{\mathrm{cg}}=w_{1} \vec{r}_{1}+w_{2} \vec{r}_{2} \quad \vec{r}_{21}=\vec{r}_{2}-\vec{r}_{1}
$$

The derivatives of $\psi$ can be converted using the chain rule of differentiation:

$$
\frac{\partial \psi}{\partial r_{1, j}}=\frac{\partial \psi}{\partial r_{\mathrm{cg}, j}} \frac{\partial r_{\mathrm{cg}, j}}{\partial r_{1, j}}+\frac{\partial \psi}{\partial r_{21, j}} \frac{\partial r_{21, j}}{\partial r_{1, j}}=\frac{\partial \psi}{\partial r_{\mathrm{cg}, j}} w_{1}-\frac{\partial \psi}{\partial r_{21, j}}
$$

or differentiating once more and summing

$$
\nabla_{1}^{2} \psi=\sum_{j=1}^{3} \frac{\partial^{2} \psi}{\partial r_{1, j}^{2}}=w_{1}^{2} \sum_{j=1}^{3} \frac{\partial^{2} \psi}{\partial r_{\mathrm{cg}, j}^{2}}-2 w_{1} \sum_{j=1}^{3} \frac{\partial^{2} \psi}{\partial r_{\mathrm{cg}, j} \partial r_{21, j}}+\sum_{j=1}^{3} \frac{\partial^{2} \psi}{\partial r_{21, j}^{2}}
$$

and a similar expression for $\nabla_{2}^{2} \psi$, but with $w_{2}$ instead of $w_{1}$ and a plus sign instead of the minus sign. Combining them together in the Hamiltonian, and substituting for $w_{1}$ and $w_{2}$, the mixed derivatives drop out against each other and what is left is

$$
H=-\frac{\hbar^{2}}{2\left(m_{1}+m_{2}\right)} \nabla_{\mathrm{cg}}^{2}-\frac{\hbar^{2}}{2 m_{\mathrm{red}}} \nabla_{21}^{2}+V\left(\vec{r}_{21}\right)
$$

The first term is the kinetic energy that the total mass would have if it was at the center of gravity; the next two terms are kinetic and potential energy around the center of gravity, in terms of the distance between the masses and the reduced mass.

The Hamiltonian eigenvalue problem $H \psi=E \psi$ has separation of variables solutions of the form

$$
\psi=\psi_{\mathrm{cg}}\left(\vec{r}_{\mathrm{cg}}\right) \psi_{21}\left(\vec{r}_{21}\right)
$$

Substituting this and the Hamiltonian above into $H \psi=E \psi$ and dividing by $\psi_{\mathrm{cg}} \psi_{21}$ produces

$$
-\frac{\hbar^{2}}{2\left(m_{1}+m_{2}\right)} \frac{1}{\psi_{\mathrm{cg}}} \nabla_{\mathrm{cg}}^{2} \psi_{\mathrm{cg}}+\frac{1}{\psi_{21}}\left[-\frac{\hbar^{2}}{2 m_{\mathrm{red}}} \nabla_{21}^{2}+V\right] \psi_{21}=E
$$

Call the first term in the left hand side $E_{\mathrm{cg}}$ and the second $E_{21}$. By that definition, $E_{\mathrm{cg}}$ would normally be a function of $\vec{r}_{\mathrm{cg}}$, because $\psi_{\mathrm{cg}}$ is, but since it is equal to $E-E_{21}$ and those do not depend on $\vec{r}_{\text {cg }}, E_{\text {cg }}$ cannot either, and must be a constant. By similar reasoning, $E_{21}$ cannot depend on $\vec{r}_{21}$ and must be a constant too. Therefore, rewriting the definitions of $E_{\mathrm{cg}}$ and $E_{21}$, two separate eigenvalue problems are obtained:

$$
-\frac{\hbar^{2}}{2\left(m_{1}+m_{2}\right)} \nabla_{\mathrm{cg}}^{2} \psi_{\mathrm{cg}}=E_{\mathrm{cg}} \psi_{\mathrm{cg}} \quad\left[-\frac{\hbar^{2}}{2 m_{\mathrm{red}}} \nabla_{21}^{2}+V\right] \psi_{21}=E_{21} \psi_{21}
$$

The first describes the quantum mechanics of an imaginary total mass $m_{1}+m_{2}$ located at the center of gravity. The second describes an imaginary reduced mass $m_{\text {red }}$ at a location $\vec{r}_{21}$ away from a fixed center that experiences a potential $V\left(\vec{r}_{21}\right)$.

For the hydrogen atom, it means that if the problem with a stationary proton is solved using an reduced electron mass $m_{\mathrm{p}} m_{\mathrm{e}} /\left(m_{\mathrm{p}}+m_{\mathrm{e}}\right)$, it solves the true problem in which the proton moves a bit too. Like in the classical analysis, the quantum analysis shows that in addition the atom can move as a unit, with a motion described in terms of its center of gravity.

It can also be concluded, from a slight generalization of the quantum analysis, that a constant external gravity field, like that of the sun on the earth-moon system, or of the earth on a hydrogen atom, causes the center of gravity to accelerate correspondingly, but does not affect the motion around the center of gravity at all. That reflects a basic tenet of general relativity.

## A. 6 Constant spherical potentials

This addendum describes the solutions of the Hamiltonian eigenvalue problem in spherical coordinates if the potential is constant.

These solutions are important for many reasons. For example, you might want to create a simplified model for the hydrogen atom that way. To do so, you could, for example, assume that the potential energy has a constant negative value up to say the Bohr radius and is zero beyond it. That is not really a very good model for the hydrogen atom. However, it works much better for nucleons in atomic nuclei, chapter 14.12.

The solutions in this note are also important for describing experiments in which particles are scattered from some target, $\{\mathrm{A} .30\}$. And more fundamentally, they give the energy states of definite angular momentum for particles in empty space.

## A.6.1 The eigenvalue problem

The Hamiltonian eigenvalue problem is

$$
-\frac{\hbar^{2}}{2 m} \nabla^{2} \psi+V \psi=E \psi
$$

In this note it is assumed that the potential $V$ is a constant in the radial region of interest.

To clean the problem up a bit, take the potential energy term to the other side, and also the coefficient of the Laplacian. That produces

$$
-\nabla^{2} \psi=\frac{p_{\mathrm{c}}^{2}}{\hbar^{2}} \psi
$$

where

$$
p_{\mathrm{c}} \equiv \sqrt{2 m(E-V)}
$$

The constant $p_{\mathrm{c}}$ is what classical physics would take to be the linear momentum of a particle with total energy $E$ and potential energy $V$.

## A.6.2 The eigenfunctions

Because the potential is spherically symmetric like for the hydrogen atom, the eigenfunctions are of similar form:

$$
\begin{equation*}
\psi_{E l m}(r, \theta, \phi)=R_{E l}(r) Y_{l}^{m}(\theta, \phi) \tag{A.17}
\end{equation*}
$$

Here the $Y_{l}^{m}$ are again the spherical harmonics. These eigenfunctions have definite square angular momentum $l(l+1) \hbar^{2}$ where $l$ is an nonnegative integer. They also have definite angular momentum in the chosen $z$-direction equal to $m \hbar$, where $m$ is an integer that satisfies $|m| \leqslant l$.

The radial functions $R_{E l}$ in the eigenfunctions $\psi_{E l m}$ are different from those of the hydrogen atom. Depending on whatever is easiest in a given application, they can be written in two ways, $\{\mathrm{D} .16\}$.

The first way is as

$$
\begin{equation*}
R_{E l}=c_{\mathrm{s}} j_{l}\left(p_{\mathrm{c}} r / \hbar\right)+c_{\mathrm{c}} n_{l}\left(p_{\mathrm{c}} r / \hbar\right) \quad p_{\mathrm{c}} \equiv \sqrt{2 m(E-V)} \tag{A.18}
\end{equation*}
$$

Here $c_{\mathrm{s}}$ and $c_{\mathrm{c}}$ are arbitrary constants. The functions $j_{l}$ and $n_{l}$ are called the "spherical Bessel functions" of the first and second kinds. The $n_{l}$ are also called the "Neumann functions" and might instead be indicated by $y_{l}$ or $\eta_{l}$.

Expressions for these Bessel functions can be found in advanced mathematical handbooks, [1]:

$$
\begin{equation*}
j_{l}(x)=(-x)^{l}\left(\frac{1}{x} \frac{\mathrm{~d}}{\mathrm{~d} x}\right)^{l} \frac{\sin x}{x} \tag{A.19}
\end{equation*}
$$

$$
\begin{equation*}
n_{l}(x)=-(-x)^{l}\left(\frac{1}{x} \frac{\mathrm{~d}}{\mathrm{~d} x}\right)^{l} \frac{\cos x}{x} \tag{A.20}
\end{equation*}
$$

The spherical Bessel functions are often convenient in a region of constant potential that includes the origin, because the Bessel functions of the first kind $j_{l}$ give the solutions that are finite at the origin. (To see that, note that the Taylor series of $\sin x$ divided by $x$ is a power series in $x^{2}$, and that $x \mathrm{~d} x=\frac{1}{2} \mathrm{~d} x^{2}$.) In particular for small $x$ :

$$
\begin{equation*}
j_{l}(x)=\frac{2^{l} l!}{(2 l+1)!} x^{l}+O\left(x^{l+2}\right) \equiv \frac{x^{l}}{(2 l+1)!!}+O\left(x^{l+2}\right) \tag{A.21}
\end{equation*}
$$

Here !! is one of these unfortunate notations. The second! means that all even factors are dropped from the factorial.

The Bessel functions of the second kind are singular at the origin and normally do not appear if the origin is part of the considered region.

Also, the spherical Bessel functions are real for real $x$. However, in a region where the potential $V$ is larger than the energy $E$ of the particles, the argument of the Bessel functions in (A.18) will be imaginary.

The other way to write the radial functions is as

$$
R_{E l}=c_{\mathrm{f}} h_{l}^{(1)}\left(p_{\mathrm{c}} r / \hbar\right)+c_{\mathrm{b}} h_{l}^{(2)}\left(p_{\mathrm{c}} r / \hbar\right) \quad p_{\mathrm{c}} \equiv \sqrt{2 m(E-V)}
$$

where $h_{l}^{(1)}$ and $h_{l}^{(2)}$ are called the "spherical Hankel functions."
The spherical Hankel functions can again be found in advanced mathematical handbooks, [1]:

$$
\begin{equation*}
h_{l}^{(1)}(x)=-\mathrm{i}(-x)^{l}\left(\frac{1}{x} \frac{\mathrm{~d}}{\mathrm{~d} x}\right)^{l} \frac{e^{\mathrm{i} x}}{x}=j_{l}(x)+\mathrm{i} n_{l}(x) \tag{A.22}
\end{equation*}
$$

$$
\begin{equation*}
h_{l}^{(2)}(x)=\mathrm{i}(-x)^{l}\left(\frac{1}{x} \frac{\mathrm{~d}}{\mathrm{~d} x}\right)^{l} \frac{e^{-\mathrm{i} x}}{x}=j_{l}(x)-\mathrm{i} n_{l}(x) \tag{A.23}
\end{equation*}
$$

The given expressions in terms of the spherical Bessel functions are readily inverted to give the Bessel functions in terms of the Hankel functions,

$$
\begin{equation*}
j_{l}(x)=\frac{h_{l}^{(1)}(x)+h_{l}^{(2)}(x)}{2} \quad n_{l}(x)=\frac{h_{l}^{(1)}(x)-h_{l}^{(2)}(x)}{2 \mathrm{i}} \tag{A.24}
\end{equation*}
$$

For large $x$ the spherical Hankel functions can be approximated as

$$
\begin{equation*}
h_{l}^{(1)}(x) \sim(-i)^{l+1} \frac{e^{\mathrm{i} x}}{x} \quad h_{l}^{(2)}(x) \sim i^{l+1} \frac{e^{-\mathrm{i} x}}{x} \tag{A.25}
\end{equation*}
$$

This asymptotic behavior tends to make the Hankel functions more convenient far from the origin. Exponentials are mathematically simpler and more fundamental than the sines and cosines in the asymptotic behavior of the Bessel functions.

## A.6.3 About free space solutions

The most important case for which the energy eigenfunctions of the previous subsection apply is for particles in empty space. They describe energy states with definite square and $z$ angular momentum. However, sometimes particles in empty space are better described by states of definite linear momentum. And in some cases, like in scattering problems, you need both types of solution. Then you also need to convert between them.

The energy states in empty space with definite square and $z$ angular momentum are

$$
\begin{equation*}
\psi_{E l m}=j_{l}\left(p_{\mathrm{c}} r / \hbar\right) Y_{l}^{m}(\theta, \phi) \quad p_{\mathrm{c}} \equiv \sqrt{2 m E} \tag{A.26}
\end{equation*}
$$

These states have square angular momentum $l(l+1) \hbar^{2}$ and angular momentum in the chosen $z$-direction $m \hbar$. They are nonsingular at the origin.

A state that has definite linear momentum $p_{\mathrm{c}}$ purely in the $z$-direction has an energy eigenfunction

$$
\begin{equation*}
\psi_{\vec{k}}=e^{\mathrm{i} p_{\mathrm{c}} z / \hbar} \quad p_{\mathrm{c}} \equiv \sqrt{2 m E} \tag{A.27}
\end{equation*}
$$

This eigenfunction is not normalized, and cannot be normalized. However, neither can the eigenfunction $\psi_{\text {Elm }}$ above be. It is the curse of eigenfunctions in infinite empty space. An introduction to the adjustments that must be made to deal with this is given in chapter 7.9.

It is sometimes necessary to write a linear momentum eigenfunction of the form (A.27) in terms of angular momentum ones of the form (A.26). Rayleigh worked out the correct combination a very long time ago, $\{$ D.16\}:

$$
\begin{equation*}
e^{\mathrm{i} p_{\mathrm{c}} z / \hbar}=\sum_{l=0}^{\infty} c_{\mathrm{w}, l} j_{l}\left(p_{\mathrm{c}} r / \hbar\right) Y_{l}^{0}(\theta) \quad c_{\mathrm{w}, l}=\mathrm{i}^{l} \sqrt{4 \pi(2 l+1)} \tag{A.28}
\end{equation*}
$$

Note that only eigenfunctions with $m=0$ are needed.

## A. 7 Accuracy of the variational method

This note has a closer look at the accuracy of the variational method.
Any approximate ground state wave function $\psi$ may always be written as a combination of all the energy eigenfunctions $\psi_{1}, \psi_{2}, \ldots$ :

$$
\psi=c_{1} \psi_{1}+\delta_{2} \psi_{2}+\delta_{3} \psi_{3}+\ldots
$$

where $c_{1}$ and the $\delta_{i}$ for $i=2,3, \ldots$ are numerical coefficients. But if the approximation is any good at all, the coefficient $c_{1}$ of the correct ground state $\psi_{1}$ must be close to one, while the coefficients $\delta_{i}$ of the higher energy states must be small.

The wave function pollution with higher energy states can be related to the error in energy, call it $\varepsilon$, using a few simple manipulations. First the condition that $\psi$ is normalized, $\langle\psi \mid \psi\rangle=1$, works out to be

$$
1=\left\langle c_{1} \psi_{1}+\delta_{2} \psi_{2}+\ldots \mid c_{1} \psi_{1}+\delta_{2} \psi_{2}+\ldots\right\rangle=c_{1}^{2}+\delta_{2}^{2}+\delta_{3}^{2}+\ldots
$$

since the eigenfunctions $\psi_{1}, \psi_{2}, \ldots$ are orthonormal. Similarly, the expectation energy $\langle E\rangle=\langle\psi \mid H \psi\rangle$ of the approximate solution works out to be

$$
\langle E\rangle=\left\langle c_{1} \psi_{1}+\delta_{2} \psi_{2}+\ldots \mid E_{1} c_{1} \psi_{1}+E_{2} \delta_{2} \psi_{2}+\ldots\right\rangle=c_{1}^{2} E_{1}+\delta_{2}^{2} E_{2}+\delta_{3}^{2} E_{3}+\ldots
$$

Multiplying the normalization condition by $E_{1}$ and subtracting it from the expression for the expectation energy above gives the error in energy as:

$$
\varepsilon \equiv\langle E\rangle-E_{1}=\delta_{2}^{2}\left(E_{2}-E_{1}\right)+\delta_{3}^{2}\left(E_{3}-E_{1}\right)+\ldots
$$

Note first that since all the terms in the right hand side are positive, any approximate wave function has more expectation energy than the ground state $E_{1}$. It does not have to be a single energy eigenfunction of higher energy. But that should not be a surprise.

Nor is it surprising that the expression above shows that the error in energy $\varepsilon$ will be small if the coefficients $\delta_{i}$ of the incorrect energy eigenfunctions are small and decrease suitably in magnitude when $i$ increases.

However, note that while the errors in wave function are directly proportional to the coefficients $\delta_{i}$, the error in energy is proportional to the squares of these coefficients. That makes the error in energy unexpectedly small, because the square of any small quantity is much smaller still. (This assumes that the term "small" is defined in a meaningful nondimensional way.)

That small error in energy is great because the computed energy is important for a number of things, like determining whether a stable ground state of the supposed form exists in the first place, and if it does, how fast it interacts with other energy eigenfunctions if there is uncertainty in energy, chapter 7.

While it may seem obvious that if the approximate wave function is close to the correct one, then the approximate energy will be close to the correct one,
the reverse is less trivial. If the approximate energy is close to the exact energy, does that necessarily mean that entire wave function is close to the exact one? Fortunately, the answer to that question is usually yes.

In particular, note from the expression for the error in energy above that for any coefficient $\delta_{i}$

$$
\delta_{i} \leq \sqrt{\frac{\varepsilon}{E_{i}-E_{1}}}
$$

even in the worst-case scenario that all the error is in the $i$-th term. From the above, the amount $\delta_{i}$ of each polluting higher-energy eigenfunction function is small if $\varepsilon$ is small.

But do also note the effect of the denominator. If it too is small, it may increase the possible error. The worst case occurs for the second lowest energy state. If the second-lowest energy $E_{2}$ is very close to the ground-state energy $E_{1}$, unusual good accuracy in energy may be required to ensure that the approximate wave function is accurate. (However, if $E_{2}$ equals the ground state energy, the second state is a ground state too; the ground state is then no longer unique. In that case the error from some valid ground state is described by the third energy state, not the second.)

Consider also the magnitude of the error in the approximate wave function. It is defined as

$$
\left\|\delta_{2} \psi_{2}+\delta_{3} \psi_{3}+\ldots\right\|=\sqrt{\delta_{2}^{2}+\delta_{3}^{2}+\ldots}
$$

This can be related to the error in energy by noting that from its given expression

$$
\varepsilon \leqslant \delta_{2}^{2}\left(E_{2}-E_{1}\right)+\delta_{3}^{2}\left(E_{2}-E_{1}\right)+\ldots
$$

since $E_{i}-E_{1}$ is at least as big as $E_{2}-E_{1}$. Comparing the expressions above shows that

$$
\left\|\delta_{2} \psi_{2}+\delta_{3} \psi_{3}+\ldots\right\| \leqslant \sqrt{\frac{\varepsilon}{E_{2}-E_{1}}}
$$

So if the error in energy $\varepsilon$ is small, the magnitude of the error in the wave function is too.

The bottom line is that the lower you can get your expectation energy, the closer you will get to the true ground state energy. In addition the small error in energy will reflect in a small error in wave function too.

## A. 8 Positive ground state wave function

This addendum discusses why in at least the simplest cases a ground state wave function can be assumed to be real, positive, and unique (i.e. nondegenerate). It is assumed that the potential is a real function of position. That is true for the hydrogen molecular ion. It is also true for a single hydrogen atom and most
other simple systems, at least in the nonrelativistic approximations normally used in this book.

It should first be noted that if potentials are allowed that are positive infinity in a finite region, nonunique ground states that cannot be taken positive may in fact possible. Such a potential can provide an impenetrable boundary, completely separating one region of space from another. In that case the ground state wave functions at the two sides of the boundary become decoupled, allowing for indeterminacy in the combined ground state. Such artificial cases are not covered here. But you can readily find examples in lots of books on quantum mechanics, especially in one dimension. Here it will be assumed that the potentials stay away from positive infinity. For practical purposes, it may also be noted that if the potential becomes positive infinity at just a few points, it is usually not a problem unless the approach to singularity is very steep.

There is however a much more important restriction to the conclusions in this note: ground states may not be positive if you go to many-particle systems. That is discussed further in the final paragraphs of this addendum.

First consider why the ground state, and any other energy eigenstate, can be assumed to be real without loss of generality. Suppose that you had a complex eigenfunction $\psi$ for the eigenvalue problem $H \psi=E \psi$. Write the eigenfunction as

$$
\psi=\psi_{\mathrm{r}}+\mathrm{i} \psi_{\mathrm{i}}
$$

where the real part $\psi_{\mathrm{r}}$ and the imaginary part $\psi_{\mathrm{i}}$ are real functions. Plugging this into the eigenvalue problem, you see that the real and imaginary parts each separately must satisfy the eigenvalue problem. (For the complex number $H \psi-E \psi$ to be zero, both its real and imaginary parts have to be zero.) So each of $\psi_{\mathrm{r}}$ and $\psi_{\mathrm{i}}$ is just as good an eigenfunction as $\psi$ and each is real. Since the original complex $\psi$ is a linear combination of the two, you do not need it separately. (If either $\psi_{\mathrm{r}}$ or $\psi_{\mathrm{i}}$ is zero, it is not an eigenfunction, but then it is not needed to describe $\psi$ either. And if it is nonzero, it can be normalized.)

Next consider why the ground state can be taken to be positive, assuming, for now, that it is unique. What characterizes the ground state $\psi_{\mathrm{gs}}$ is that it has the lowest possible expectation value of the energy. The expectation energy can be written for arbitrary, but normalized, wave functions $\psi$ as

$$
\langle E\rangle=\frac{\hbar^{2}}{2 m} \int_{\text {all }}(\nabla \psi)^{2} \mathrm{~d}^{3} \vec{r}+\int_{\text {all }} V \psi^{2} \mathrm{~d}^{3} \vec{r}
$$

In the first term, the kinetic energy, integrations by part have been used to get rid of the second order derivatives. Note that $(\nabla \psi)^{2}$ stands for the sum of the square partial derivatives of $\psi$. Now by definition $\psi_{\mathrm{gs}}$ has the lowest possible value of the above expectation energy among all possible normalized functions $\psi$. But only terms square in $\psi$ appear in the expectation energy. So $\left|\psi_{\mathrm{gs}}\right|$ has the same expectation energy. That means that $\left|\psi_{\mathrm{gs}}\right|$ is a ground state wave function
too. Under the given assumption that the ground state is unique, $\left|\psi_{\mathrm{gs}}\right|$ can be taken to be the ground state. That makes the ground state positive. (Note that a constant of magnitude one does not make a difference in an eigenfunction. So the original $\psi_{\mathrm{gs}}$ might well have been equal to $-\left|\psi_{\mathrm{gs}}\right|$. But $\left|\psi_{\mathrm{gs}}\right|$ is equivalent to that.)

Finally, it needs to be shown that the ground state is indeed unique as assumed above. That is really messy, so it has been banned to derivation $\{D .22\}$. It is based on the same idea that the absolute value of a ground state is a ground state too.

Regrettably the arguments above stop working for more than two electrons. To really understand the reason, you will first need to read chapter 5.6 on multiple-particle systems. But in a nutshell, the wave function for systems with multiple electrons must satisfy additional requirements, called the "antisymmetrization" requirements. These requirements normally turn $\left|\psi_{\mathrm{gs}}\right|$ into an unacceptable wave function. Then obviously the above arguments fall apart. Fortunately, for just two electrons, there is a loophole in the requirement called "spin." That allows the hydrogen molecule, with two electrons, still to be covered.

The same problem occurs for atomic nuclei that contain multiple protons and/or neutrons. (For atomic nuclei, the potentials also tend to be far more complicated than assumed here. But that is another matter.) In general, particles for which antisymmetrization requirements apply are called fermions.

There is however a different class of particles called "bosons." For those, the wave function has to satisfy "symmetrization" requirements. Symmetrization requirements are still OK if you replace $\psi$ by $|\psi|$. So the ideas above are helpful for understanding the ground state of large numbers of bosons. For example, they are helpful in understanding the superfluidity of liquid helium near its ground state, [18, pp. 321-323]. Complete helium atoms are bosons.

## A. 9 Wave function symmetries

Symmetries are very important in physics. For example, symmetries in wave functions are often quite helpful to understand the physics qualitatively.

As an example, the hydrogen molecular ion is mirror symmetric around its midplane. This midplane is the plane halfway in between the two nuclei, orthogonal to the line connecting them. To roughly understand what the mirror symmetry around this plane means, think of the midplane as an infinitely thin mirror. Take this mirror to be two-sided, so that you can look in it from either side. That allows you to see the mirror image of each side of the molecule. Simply put, the mirror symmetry of the ion means that the mirror image looks exactly the same as the original ion.
(If you would place the entire molecule at one side of the mirror, its entire mirror image would be at the other side of it. But except for this additional shift in location, everything would remain the same as in the case assumed here.)

Under the same terms, human beings are roughly mirror symmetric around the plane separating their left and right halves. But that symmetry is far from perfect. For example, if you part your hair at one side, your mirror image parts it at the other side. And your heart changes sides too.

To describe mirror symmetry more precisely, take the line through the nuclei to be the $z$-axis. And take $z$ to be zero at the mirror. Then all that the mirror does mathematically is replace $z$ by $-z$. For example, the mirror image of the nucleus at positive $z$ is located at the corresponding negative $z$ value. And vice-versa.

The effect of mirroring on any molecular wave function $\Psi$ can be represented by a "mirror operator" $\mathcal{M}$. According to the above, all this operator does is replace $z$ by $-z$ :

$$
\mathcal{M} \Psi(x, y, z)=\Psi(x, y,-z)
$$

By definition a wave function is mirror symmetric if the mirror operator has no effect on it. Mathematically, if the mirror operator does not do anything, then $\mathcal{M} \Psi$ must be the same as $\Psi$. So mirror symmetry requires

$$
\mathcal{M} \Psi(x, y, z) \equiv \Psi(x, y,-z)=\Psi(x, y, z)
$$

The final equality above shows that a mirror-symmetric wave function is the same at positive values of $z$ as at the corresponding negative values. Mathematicians might simply say that the wave function is symmetric around the $x y$ plane, (i.e. the mirror). The ground state $\psi_{\mathrm{gs}}$ of the molecular ion is mirror symmetric in this sense. The big question to be addressed in this addendum is, why?

The fundamental reason why the ion is mirror symmetric is a mathematical one. The mirror operator $\mathcal{M}$ commutes with the Hamiltonian $H$. Recall from chapter 4.5.1 what this means:

$$
\mathcal{M} H=H \mathcal{M}
$$

In words, it does not make a difference in which order you apply the two operators.

That can be seen from the physics. The Hamiltonian consists of potential energy $V$ and kinetic energy $T$. Now it does not make a difference whether you multiply a wave function value by the potential before or after you flip the value over to the opposite $z$-position. The potential is the same at opposite $z$ values, because the nuclei at the two sides of the mirror are the same. As far as the kinetic energy is concerned, if it involved a first-order $z$-derivative, there would be a change of sign when you flip over the sign of $z$. But the kinetic energy has
only a second order $z$-derivative. A second order derivative does not change. So all together it makes no difference whether you first mirror and then apply the Hamiltonian or vice-versa. The two operators commute.

Also according to chapter 4.5.1, that has a consequence. It implies that you can take energy eigenfunctions to be mirror eigenfunctions too. And the ground state is an energy eigenfunction. So it can be taken to be an eigenfunction of $\mathcal{M}$ too:

$$
\mathcal{M} \psi_{\mathrm{gs}}(x, y, z)=\lambda \psi_{\mathrm{gs}}(x, y, z)
$$

Here $\lambda$ is a constant called the eigenvalue. But what would this eigenvalue be?
To answer that, apply $\mathcal{M}$ twice. That multiplies the wave function by the square eigenvalue. But if you apply $\mathcal{M}$ twice, you always get the original wave function back, because $-(-z)=z$. So the square eigenvalue $\lambda^{2}$ must be 1 , in order that the wave function does not change when multiplied by it. That means that the eigenvalue $\lambda$ itself can be either 1 or -1 . So for the ground state wave function $\psi_{\mathrm{gs}}$, either

$$
\mathcal{M} \psi_{\mathrm{gs}}(x, y, z) \equiv \psi_{\mathrm{gs}}(x, y,-z)=1 \times \psi_{\mathrm{gs}}(x, y, z)
$$

or

$$
\mathcal{M} \psi_{\mathrm{gs}}(x, y, z) \equiv \psi_{\mathrm{gs}}(x, y,-z)=-1 \times \psi_{\mathrm{gs}}(x, y, z)
$$

If the first possibility applies, the wave function does not change under the mirroring. So by definition it is mirror symmetric. If the second possibility applies, the wave function changes sign under the mirroring. Such a wave function is called "mirror antisymmetric." But the second possibility has wave function values of opposite sign at opposite values of $z$. That is not possible, because the previous addendum showed that the ground state wave function is everywhere positive. So it must be possibility one. That means that the ground state must indeed be mirror symmetric as claimed.

It may be noted that the state of second lowest energy will be antisymmetric. You can see the same thing happening for the eigenfunctions of the particle in a pipe. The ground state figure 3.8, (or 3.11 in three dimensions), is symmetric around the center cross-section of the pipe. The first excited state, at the top of figures 3.9, (or 3.12), is antisymmetric. (Note that the grey tones show the square wave function. If the wave function is antisymmetric, the square wave function is symmetric. But it will be zero at the symmetry plane.)

Next consider the rotational symmetry of the hydrogen molecular ion around the axis through the nuclei. The ground state of the molecular ion does not change if you rotate the ion around the $z$-axis through the nuclei. That makes it rotationally symmetric. The big question is again, why?

In this case, let $\mathcal{R}_{\varphi}$ be the operator that rotates a wave function $\Psi$ over an angle $\varphi$ around the $z$-axis. This operator too commutes with the Hamiltonian. After all, the only physically meaningful direction is the $z$-axis through the nuclei. The angular orientation of the $x y$ axes system normal to it is a completely
arbitrary choice. So it should not make a difference at what angle around the $z$ axis you apply the Hamiltonian.

Therefore the ground state must be an eigenfunction of the rotation operator just like it is one of the mirror operator:

$$
\mathcal{R}_{\varphi} \psi_{\mathrm{gs}}=\lambda \psi_{\mathrm{gs}}
$$

But now what is that eigenvalue $\lambda$ ? First note that the magnitude of all eigenvalues of $\mathcal{R}_{\varphi}$ must be 1 . Otherwise the magnitude of the wave function would change correspondingly during the rotation. However, the magnitude of a wave function does not change if you simply rotate it. And if the eigenvalue is a complex number of magnitude 1 , then it can always be written as $e^{\mathrm{i} \alpha}$ where $\alpha$ is some real number. So the rotated ground state is some multiple $e^{\mathrm{i} \alpha}$ of the original ground state. But the values of the rotated ground state are real and positive just like that of the original ground state. That can only be true if the multiplying factor $e^{\mathrm{i} \alpha}$ is real and positive too. And if you check the Euler formula (2.5), you see that $e^{\mathrm{i} \alpha}$ is only real and positive if it is 1 . Since multiplying by 1 does not change the wave function, the ground state does not change when rotated. That then makes it rotationally symmetric around the $z$-axis through the nuclei as claimed.

You might of course wonder about the rotational changes of excited energy states. For those a couple of additional observations apply. First, the number $\alpha$ must be proportional to the rotation angle $\varphi$, since rotating $\Psi$ twice is equivalent to rotating it once over twice the angle. That means that, more precisely, the eigenvalues are of the form $e^{\mathrm{i} m \varphi}$, where $m$ is a real constant independent of $\varphi$. Second, rotating the ion over a $2 \pi$ full turn puts each point back to where it came from. That should reproduce the original wave function. So an eigenvalue $e^{\mathrm{i} m 2 \pi}$ for a full turn must be 1. According to the Euler formula, that requires $m$ to be an integer, one of $\ldots,-2,-1,0,1,2, \ldots$. For the ground state, $m$ will have to be zero; that is the only way to get $e^{\mathrm{im} \mathrm{\varphi}}$ equal to 1 for all angles $\varphi$. But for excited states, $m$ can be a nonzero integer. In that case, these states do not have rotational symmetry.

Recalling the discussion of angular momentum in chapter 4.2.2, you can see that $m$ is really the magnetic quantum number of the state. Apparently, there is a connection between rotations around the $z$-axis and the angular momentum in the $z$-direction. That will be explored in more detail in chapter 7.3.

For the neutral hydrogen molecule discussed in chapter 5.2, there is still another symmetry of relevance. The neutral molecule has two electrons, instead of just one. This allows another operation: you can swap the two electrons. That is called "particle exchange." Mathematically, what the particle exchange operator $\mathcal{P}$ does with the wave function is swap the position coordinates of electron 1 with those of electron 2. Obviously, physically this does not do anything at all; the two electrons are exactly the same. It does not make a
difference which of the two is where. So particle exchange commutes again with the Hamiltonian.

The mathematics of the particle exchange is similar to that of the mirroring discussed above. In particular, if you exchange the particles twice, they are back to where they were originally. From that, just like for the mirroring, it can be seen that swapping the particle positions does nothing to the ground state. So the ground state is symmetric under particle exchange.

It should be noted that the ground state of systems involving three or more electrons is not symmetric under exchanging the positions of the electrons. Wave functions for multiple electrons must satisfy special particle-exchange requirements, chapter 5.6. In fact they must be antisymmetric under an expanded definition of the exchange operator. This is also true for systems involving three or more protons or neutrons. However, for some particle types, like three or more helium atoms, the symmetry under particle exchange continues to apply. This is very helpful for understanding the properties of superfluid helium, [18, p. 321].

## A. 10 Spin inner product

In quantum mechanics, the angle between two angular momentum vectors is not really defined. That is because at least two components of a nonzero angular momentum vector are uncertain. However, the inner product of angular momentum vectors can be well defined. In some sense, that gives an angle between the two vectors.

An important case is the inner product between the spins of two particles. It is related to the square net combined spin of the particles as

$$
\widehat{S}_{\mathrm{net}}^{2}=\left(\widehat{\vec{S}}_{1}+\hat{\vec{S}}_{2}\right) \cdot\left(\widehat{\vec{S}}_{1}+\widehat{\vec{S}}_{2}\right)
$$

If you multiply out the right hand side and rearrange, you find the inner product between the spins as

$$
\begin{equation*}
\widehat{\vec{S}}_{1} \cdot \widehat{\vec{S}}_{2}=\frac{1}{2}\left(\widehat{S}_{\mathrm{net}}^{2}-\widehat{S}_{1}^{2}-\widehat{S}_{2}^{2}\right) \tag{A.29}
\end{equation*}
$$

Now an elementary particle has a definite square spin angular momentum

$$
\widehat{S}^{2}=s(s+1) \hbar^{2}
$$

where $s$ is the spin quantum number. If the square combined spin also has a definite value, then so does the dot product between the spins as given above.

As an important example, consider two fermions with spin $s_{1}=s_{2}=\frac{1}{2}$. These fermions may be in a singlet state with combined spin $s_{\text {net }}=0$. Or they
may be in a triplet state with combined $\operatorname{spin} s_{\text {net }}=1$. If that is plugged into the formulae above, the inner product between the spins is found to be

$$
\begin{equation*}
\text { singlet: } \quad \widehat{\vec{S}}_{1} \cdot \widehat{\vec{S}}_{2}=-\frac{3}{4} \hbar^{2} \quad \text { triplet: } \quad \hat{\vec{S}}_{1} \cdot \widehat{\vec{S}}_{2}=\frac{1}{4} \hbar^{2} \tag{A.30}
\end{equation*}
$$

Based on that, you could argue that in the singlet state the angle between the spin vectors is $180^{\circ}$. In the triplet state the angle is not zero, but about $70^{\circ}$.

## A. 11 Thermoelectric effects

This note gives additional information on thermoelectric effects.

## A.11.1 Peltier and Seebeck coefficient ballparks

The approximate expressions for the semiconductor Peltier coefficients come from [29]. Straub et al (App. Phys. Let. 95, 052107, 2009) note that to better approximation, $\frac{3}{2} k_{\mathrm{B}} T$ should be $\left(\frac{5}{2}+r\right) k_{\mathrm{B}} T$ with $r$ typically $-\frac{1}{2}$. Also, a phonon contribution should be added.

The estimate for the Peltier coefficient of a metal assumes that the electrons form a free-electron gas. The conduction will be assumed to be in the $x$ direction. To ballpark the Peltier coefficient requires the average charge flow per electron $\overline{-e v_{x}}$ and the average energy flow per electron $\overline{E^{\mathrm{p}} v_{x}}$. Here $v_{x}$ is the electron velocity in the $x$-direction, $-e$ the electron charge, $E^{\mathrm{p}}$ the electron energy, and an overline is used to indicate an average over all electrons. To find ballparks for the two averages, assume the model of conduction of the freeelectron gas as given in chapter 6.20. The conduction occurred since the Fermi sphere got displaced a bit towards the right in the wave number space figure 6.17. Call the small amount of displacement $k_{\mathrm{d}}$. Assume for simplicity that in a coordinate system $k_{x} k_{y} k_{z}$ with origin at the center of the displaced Fermi sphere, the occupation of the single-particle states by electrons is still exactly given by the equilibrium Fermi-Dirac distribution. However, due to the displacement $k_{\mathrm{d}}$ along the $k_{x}$ axis, the velocities and energies of the single-particle states are now given by
$v_{x}=\frac{\hbar}{m}\left(k_{x}+k_{\mathrm{d}}\right) \quad E^{\mathrm{p}}=\frac{\hbar^{2}}{2 m}\left[\left(k_{x}+k_{\mathrm{d}}\right)^{2}+k_{y}^{2}+k_{z}^{2}\right]=\frac{\hbar^{2}}{2 m}\left(k^{2}+2 k_{x} k_{\mathrm{d}}+k_{\mathrm{d}}^{2}\right)$
To simplify the notations, the above expressions will be abbreviated to

$$
v_{x}=C_{v}\left(k_{x}+k_{\mathrm{d}}\right) \quad E^{\mathrm{p}}=C_{E}\left(k^{2}+2 k_{x} k_{\mathrm{d}}+k_{\mathrm{d}}^{2}\right)
$$

In this notation, the average charge and energy flows per electron become

$$
\overline{-e v_{x}}=\overline{-e C_{v}\left(k_{x}+k_{\mathrm{d}}\right)} \quad \overline{E^{\mathrm{p}} v_{x}}=\overline{C_{E}\left(k^{2}+2 k_{x} k_{\mathrm{d}}+k_{\mathrm{d}}^{2}\right) C_{v}\left(k_{x}+k_{\mathrm{d}}\right)}
$$

Next note that the averages involving odd powers of $k_{x}$ are zero, because for every state of positive $k_{x}$ in the Fermi sphere there is a corresponding state of negative $k_{x}$. Also the constants, including $k_{\mathrm{d}}$, can be taken out of the averages. So the flows simplify to

$$
\overline{-e v_{x}}=-e C_{v} k_{\mathrm{d}} \quad \overline{E^{\mathrm{p}} v_{x}}=C_{E}\left(2 \overline{k_{x}^{2}}+\overline{k^{2}}\right) C_{v} k_{\mathrm{d}}
$$

where the term cubically small in $k_{\mathrm{d}}$ was ignored. Now by symmetry the averages of $k_{x}^{2}, k_{y}^{2}$, and $k_{z}^{2}$ are equal, so each must be one third of the average of $k^{2}$. And $C_{E}$ times the average of $k^{2}$ is the average energy per electron $E_{\mathrm{ave}}^{\mathrm{p}}$ in the absence of conduction. Also, by definition $C_{v} k_{\mathrm{d}}$ is the drift velocity $v_{\mathrm{d}}$ that produces the current. Therefore:

$$
\overline{-e v_{x}}=-e v_{\mathrm{d}} \quad \overline{v_{x} E^{\mathrm{p}}}=\frac{5}{3} E_{\mathrm{ave}}^{\mathrm{p}} v_{\mathrm{d}}
$$

Note that if you would simply have ballparked the average of $v_{x} E^{\mathrm{p}}$ as the average of $v_{x}$ times the average of $E^{\mathrm{p}}$ you would have missed the factor $5 / 3$. That would produce a Peltier coefficient that would be gigantically wrong.

To get the heat flow, the energy must be taken relative to the Fermi level $\mu$. In other words, the energy flow $\overline{v_{x} \mu}$ must be subtracted from $\overline{v_{x} E^{\mathrm{p}}}$. The Peltier coefficient is the ratio of that heat flow to the charge flow:

$$
\mathcal{P}=\frac{\overline{v_{x}\left(E^{\mathrm{p}}-\mu\right)}}{\overline{-e v_{x}}}=\frac{\frac{5}{3} E_{\mathrm{ave}}^{\mathrm{p}}-\mu}{-e}
$$

If you plug in the expressions for the average energy per electron and the chemical potential found in derivation $\{$ D. 62$\}$, you get the Peltier ballpark listed in the text.

To get Seebeck coefficient ballparks, simply divide the Peltier coefficients by the absolute temperature. That works because of Kelvin's second relationship discussed below. To get the Seebeck coefficient ballpark for a metal directly from the Seebeck effect, equate the increase in electrostatic potential energy of an electron migrating from hot to cold to the decrease in average electron kinetic energy. Using the average kinetic energy of derivation \{D.62\}:

$$
-e \mathrm{~d} \varphi=-\mathrm{d} \frac{\pi^{2}}{4} \frac{\left(k_{\mathrm{B}} T\right)^{2}}{E_{\mathrm{F}}^{\mathrm{p}}}
$$

Divide by $e \mathrm{~d} T$ to get the Seebeck coefficient.

## A.11.2 Figure of merit

To compare thermoelectric materials, an important quantity is the figure of merit of the material. The figure of merit is by convention written as $M^{2}$ where

$$
M=\mathcal{P} \sqrt{\frac{\sigma}{\kappa T}}
$$

The temperature $T$ of the material should typically be taken as the average temperature in the device being examined. The reason that $M$ is important has to do with units. Number $M$ is "nondimensional," it has no units. In SI units, the Peltier coefficient $\mathcal{P}$ is in volts, the electrical conductivity $\sigma$ in ampere/ volt-meter, the temperature in Kelvin, and the thermal conductivity $\kappa$ in watt/ Kelvin-meter with watt equal to volt ampere. That makes the combination above nondimensional.

To see why that is relevant, suppose you have a material with a low Peltier coefficient. You might consider compensating for that by, say, scaling up the size of the material or the current through it. And maybe that does give you a better device than you would get with a material with a higher Peltier coefficient. Maybe not. How do you know?
dimensional analysis can help answer that question. It says that nondimensional quantities depend only on nondimensional quantities. For example, for a Peltier cooler you might define an efficiency as the heat removed from your ice cubes per unit electrical energy used. That is a nondimensional number. It will not depend on, say, the actual size of the semiconductor blocks, but it will depend on such nondimensional parameters as their shape, and their size relative to the overall device. Those are within your complete control during the design of the cooler. But the efficiency will also depend on the nondimensional figure of merit $M$ above, and there you are limited to the available materials. Having a material with a higher figure of merit would give you a higher thermoelectric effect for the same losses due to electrical resistance and heat leaks.

To be sure, it is somewhat more complicated than that because two different materials are involved. That makes the efficiency depend on at least two nondimensional figures of merit, one for each material. And it might also depend on other nondimensional numbers that can be formed from the properties of the materials. For example, the efficiency of a simple thermoelectric generator turns out to depend on a net figure of merit given by, [9],

$$
M_{\text {net }}=M_{\mathrm{A}} \frac{\sqrt{\kappa_{\mathrm{A}} / \sigma_{\mathrm{A}}}}{\sqrt{\kappa_{\mathrm{A}} / \sigma_{\mathrm{A}}}+\sqrt{\kappa_{\mathrm{B}} / \sigma_{\mathrm{B}}}}-M_{\mathrm{B}} \frac{\sqrt{\kappa_{\mathrm{B}} / \sigma_{\mathrm{B}}}}{\sqrt{\kappa_{\mathrm{A}} / \sigma_{\mathrm{A}}}+\sqrt{\kappa_{\mathrm{B}} / \sigma_{\mathrm{B}}}}
$$

It shows that the figures of merit $M_{\mathrm{A}}$ and $M_{\mathrm{B}}$ of the two materials get multiplied by nondimensional fractions. These fractions are in the range from 0 to 1 , and they sum to one. To get the best efficiency, you would like $M_{\mathrm{A}}$ to be as large positive as possible, and $M_{\mathrm{B}}$ as large negative as possible. That is as noted in the text. But all else being the same, the efficiency also depends to some extent on the nondimensional fractions multiplying $M_{\mathrm{A}}$ and $M_{\mathrm{B}}$. It helps if the material with the larger figure of merit $|M|$ also has the larger ratio of $\kappa / \sigma$. If say $M_{\mathrm{A}}$ exceeds $-M_{\mathrm{B}}$ for the best materials A and B , then you could potentially replace $B$ by a cheaper material with a much lower figure of merit, as long as that replacement material has a very low value of $\kappa / \sigma$ relative to A. In general,
the more nondimensional numbers there are that are important, the harder it is to analyze the efficiency theoretically.

## A.11.3 Physical Seebeck mechanism

The given qualitative description of the Seebeck mechanism is very crude. For example, for semiconductors it ignores variations in the number of charge carriers. Even for a free-electron gas model for metals, there may be variations in charge carrier density that offset velocity effects. Worse, for metals it ignores the exclusion principle that restricts the motion of the electrons. And it ignores that the hotter side does not just have electrons with higher energy relative to the Fermi level than the colder side, it also has electrons with lower energy that can be excited to move. If the lower energy electrons have a larger mean free path, they can come from larger distances than the higher energy ones. And for metal electrons in a lattice, the velocity might easily go down with energy instead of up. That is readily appreciated from the spectra in chapter 6.22.2.

For a much more detailed description, see "Thermoelectric Effects in Metals: Thermocouples" by S. O. Kasap, 2001. This paper is available on the web for personal study. It includes actual data for metals compared to the simple theory.

## A.11.4 Full thermoelectric equations

To understand the Peltier, Seebeck, and Thomson effects more precisely, the full equations of heat and charge flow are needed. That is classical thermodynamics, not quantum mechanics. However, standard undergraduate thermodynamics classes do not cover it, and even the thick standard undergraduate text books do not provide much more than a superficial mention that thermoelectric effects exist. Therefore this subsection will describe the equations of thermoelectrics in a nutshell.

The discussion will be one-dimensional. Think of a bar of material aligned in the $x$-direction. If the full three-dimensional equations of charge and heat flow are needed, for isotropic materials you can simply replace the $x$ derivatives by gradients.

Heat flow is primarily driven by variations in temperature, and electric current by variations in the chemical potential of the electrons. The question is first of all what is the precise relation between those variations and the heat flow and current that they cause.

Now the microscopic scales that govern the motion of atoms and electrons are normally extremely small. Therefore an atom or electron "sees" only a very small portion of the macroscopic temperature and chemical potential distributions. The atoms and electrons do notice that the distributions are not constant, otherwise they would not conduct heat or current at all. But they see
so little of the distributions that to them they appear to vary linearly with position. As a result it is simple gradients, i.e. first derivatives, of the temperature and potential distributions that drive heat flow and current in common solids. Symbolically:

$$
q=f_{1}\left(\frac{\mathrm{~d} T}{\mathrm{~d} x}, \frac{\mathrm{~d} \varphi_{\mu}}{\mathrm{d} x}\right) \quad j=f_{2}\left(\frac{\mathrm{~d} T}{\mathrm{~d} x}, \frac{\mathrm{~d} \varphi_{\mu}}{\mathrm{d} x}\right)
$$

Here $q$ is the "heat flux density;" "flux" is a fancy word for "flow" and the qualifier "density" indicates that it is per unit cross-sectional area of the bar. Similarly $j$ is the current density, the current per unit cross-sectional area. If you want, it is the charge flux density. Further $T$ is the temperature, and $\varphi_{\mu}$ is the chemical potential $\mu$ per unit electron charge $-e$. That includes the electrostatic potential (simply put, the voltage) as well as an intrinsic chemical potential of the electrons. The unknown functions $f_{1}$ and $f_{2}$ will be different for different materials and different conditions.

The above equations are not valid if the temperature and potential distributions change nontrivially on microscopic scales. For example, shock waves in supersonic flows of gases are extremely thin; therefore you cannot use equations of the type above for them. Another example is highly rarefied flows, in which the molecules move long distances without collisions. Such extreme cases can really only be analyzed numerically and they will be ignored here. It is also assumed that the materials maintain their internal integrity under the conduction processes.

Under normal conditions, a further approximation can be made. The functions $f_{1}$ and $f_{2}$ in the expressions for the heat flux and current densities would surely depend nonlinearly on their two arguments if these would appear finite on a microscopic scale. But on a microscopic scale, temperature and potential hardly change. (Supersonic shock waves and similar are again excluded.) Therefore, the gradients appear small in microscopic terms. And if that is true, functions $f_{1}$ and $f_{2}$ can be linearized using Taylor series expansion. That gives:

$$
q=A_{11} \frac{\mathrm{~d} T}{\mathrm{~d} x}+A_{12} \frac{\mathrm{~d} \varphi_{\mu}}{\mathrm{d} x} \quad j=A_{21} \frac{\mathrm{~d} T}{\mathrm{~d} x}+A_{22} \frac{\mathrm{~d} \varphi_{\mu}}{\mathrm{d} x}
$$

The four coefficients $A_{\text {.. }}$ will normally need to be determined experimentally for a given material at a given temperature. The properties of solids vary normally little with pressure.

By convention, the four coefficients are rewritten in terms of four other, more intuitive, ones:

$$
\begin{equation*}
q=-(\kappa+\mathcal{P} \mathcal{S} \sigma) \frac{\mathrm{d} T}{\mathrm{~d} x}-\mathcal{P} \sigma \frac{\mathrm{d} \varphi_{\mu}}{\mathrm{d} x} \quad j=-\mathcal{S} \sigma \frac{\mathrm{d} T}{\mathrm{~d} x}-\sigma \frac{\mathrm{d} \varphi_{\mu}}{\mathrm{d} x} \tag{A.31}
\end{equation*}
$$

This defines the heat conductivity $\kappa$, the electrical conductivity $\sigma$, the Seebeck coefficient $\mathcal{S}$ and the Peltier coefficient $\mathcal{P}$ of the material. (The signs of the Peltier and Seebeck coefficients vary considerably between references.)

If conditions are isothermal, the second equation is Ohm's law for a unit cube of material, with $\sigma$ the usual conductivity, the inverse of the resistance of the unit cube. The Seebeck effect corresponds to the case that there is no current. In that case, the second equation produces

$$
\begin{equation*}
\frac{\mathrm{d} \varphi_{\mu}}{\mathrm{d} x}=-\mathcal{S} \frac{\mathrm{d} T}{\mathrm{~d} x} \tag{A.32}
\end{equation*}
$$

To see what this means, integrate this along a closed circuit all the way from lead 1 of a voltmeter through a sample to the other lead 2. That gives

$$
\begin{equation*}
\varphi_{\mu, 2}-\varphi_{\mu, 1}=-\int_{1}^{2} \mathcal{S} \mathrm{~d} T \tag{A.33}
\end{equation*}
$$

Assuming that the two leads of the voltmeter are at the same temperature, their intrinsic chemical potentials are the same. In that case, the difference in potentials is equal to the difference in electrostatic potentials. In other words, the integral gives the difference between the voltages inside the two leads. And that is the voltage that will be displayed by the voltmeter.

It is often convenient to express the heat flux density $q$ in terms of the current density instead of the gradient of the potential $\varphi_{\mu}$. Eliminating this gradient from the equations (A.31) produces

$$
\begin{equation*}
q=-\kappa \frac{\mathrm{d} T}{\mathrm{~d} x}+\mathcal{P} j \tag{A.34}
\end{equation*}
$$

In case there is no current, this is the well-known Fourier's law of heat conduction, with $\kappa$ the usual thermal conductivity. Note that the heat flux density is often simply called the heat flux, even though it is per unit area. In the presence of current, the heat flux density is augmented by the Peltier effect, the second term.

The total energy flowing through the bar is the sum of the thermal heat flux and the energy carried along by the electrons:

$$
j_{E}=q+j \varphi_{\mu}
$$

If the energy flow is constant, the same energy flows out of a piece $\mathrm{d} x$ of the bar as flows into it. Otherwise the negative $x$-derivative of the energy flux density gives the net energy accumulation $\dot{e}$ per unit volume:

$$
\dot{e}=-\frac{\mathrm{d} j_{E}}{\mathrm{~d} x}=-\frac{\mathrm{d} q}{\mathrm{~d} x}-j \frac{\mathrm{~d} \varphi_{\mu}}{\mathrm{d} x}
$$

where it was assumed that the electric current is constant as it must be for a steady state. Of course, in a steady state any nonzero $\dot{e}$ must be removed through heat conduction through the sides of the bar of material being tested,
or through some alternative means. Substituting in from (A.34) for $q$ and from the second of (A.31) for the gradient of the potential gives:

$$
\dot{e}=\frac{\mathrm{d}}{\mathrm{~d} x}\left(\kappa \frac{\mathrm{~d} T}{\mathrm{~d} x}\right)+\frac{j^{2}}{\sigma}-\mathcal{K} \frac{\mathrm{d} T}{\mathrm{~d} x} j \quad \mathcal{K} \equiv \frac{\mathrm{~d} \mathcal{P}}{\mathrm{~d} T}-\mathcal{S}
$$

The final term in the energy accumulation is the Thomson effect or Kelvin heat. The Kelvin (Thomson) coefficient $\mathcal{K}$ can be cleaned up using the second Kelvin relationship given in a later subsection.

The equations (A.31) are often said to be representative of nonequilibrium thermodynamics. However, they correspond to a vanishingly small perturbation from thermodynamical equilibrium. The equations would more correctly be called quasi-equilibrium thermodynamics. Nonequilibrium thermodynamics is what you have inside a shock wave.

## A.11.5 Charge locations in thermoelectrics

The statement that the charge density is neutral inside the material comes from【8】.

A simplified macroscopic derivation can be given based on the thermoelectric equations (A.31). The derivation assumes that the temperature and chemical potential are almost constant. That means that derivatives of thermodynamic quantities and electric potential are small. That makes the heat flux and current also small.

Next, in three dimensions replace the $x$ derivatives in the thermoelectric equations (A.31) by the gradient operator $\nabla$. Now under steady-state conditions, the divergence of the current density must be zero, or there would be an unsteady local accumulation or depletion of net charge, chapter 13.2. Similarly, the divergence of the heat flux density must be zero, or there would be an accumulation or depletion of thermal energy. (This ignores local heat generation as an effect that is quadratically small for small currents and heat fluxes.)

Therefore, taking the divergence of the equations (A.31) and ignoring the variations of the coefficients, which give again quadratically small contributions, it follows that the Laplacians of both the temperature and the chemical potential are zero.

Now the chemical potential includes both the intrinsic chemical potential and the additional electrostatic potential. The intrinsic chemical potential depends on temperature. Using again the assumption that quadratically small terms can be ignored, the Laplacian of the intrinsic potential is proportional to the Laplacian of the temperature and therefore zero.

Then the Laplacian of the electrostatic potential must be zero too, to make the Laplacian of the total potential zero. And that then implies the absence of net charge inside the material according to Maxwell's first equation, chapter 13.2. Any net charge must accumulate at the surfaces.

## A.11.6 Kelvin relationships

This subsection gives an explanation of the definition of the thermal heat flux in thermoelectrics. It also explains that the Kelvin (or Thomson) relationships are a special case of the more general "Onsager reciprocal relations." If you do not know what thermodynamical entropy is, you should not be reading this subsection. Not before reading chapter 11, at least.

For simplicity, the discussion will again assume one-dimensional conduction of heat and current. The physical picture is therefore conduction along a bar aligned in the $x$-direction. It will be assumed that the bar is in a steady state, in other words, that the temperature and chemical potential distributions, heat flux and current through the bar all do not change with time.

Figure A.1: Analysis of conduction.
The primary question is what is going on in a single short segment $\mathrm{d} x$ of such a bar. Here $\mathrm{d} x$ is assumed to be small on a macroscopic scale, but large on a microscopic scale. To analyze the segment, imagine it taken out of the bar and sandwiched between two big idealized "reservoirs" 1 and 2 of the same material, as shown in figure A.1. The idealized reservoirs are assumed to remain at uniform, thermodynamically reversible, conditions. Reservoir 1 is at the considered time at the same temperature and chemical potential as the start of the segment, and reservoir 2 at the same temperature and chemical potential as the end of the segment. The reservoirs are assumed to be big enough that their properties change slowly in time. Therefore it is assumed that their time variations do not have an effect on what happens inside the bar segment at the considered time. For simplicity, it will also be assumed that the material consists of a single particle type. Some of these particles are allowed to move through the bar segment from reservoir 1 to reservoir 2.

In other words, there is a flow, or flux, of particles through the bar segment. The corresponding particle flux density $j_{I}$ is the particle flow per unit area. For simplicity, it will be assumed that the bar has unit area. Then there is no difference between the particle flow and the particle flux density. Note that the
same flow of particles $j_{I}$ must enter the bar segment from reservoir 1 as must exit from the segment into reservoir 2. If that was not the case, there would be a net accumulation or depletion of particles inside the bar segment. That is not possible, because the bar segment is assumed to be in a steady state. Therefore the flow of particles through the bar segment decreases the number of particles $I_{1}$ in reservoir 1, but increases the number $I_{2}$ in reservoir 2 correspondingly:

$$
j_{I}=-\frac{\mathrm{d} I_{1}}{\mathrm{~d} t}=\frac{\mathrm{d} I_{2}}{\mathrm{~d} t}
$$

Further, due to the energy carried along by the moving particles, as well as due to thermal heat flow, there will be a net energy flow $j_{E}$ through the bar segment. Like the particle flow, the energy flow comes out of reservoir 1 and goes into reservoir 2:

$$
j_{E}=-\frac{\mathrm{d} E_{1}}{\mathrm{~d} t}=\frac{\mathrm{d} E_{2}}{\mathrm{~d} t}
$$

Here $E_{1}$ is the total energy inside reservoir 1 , and $E_{2}$ that inside reservoir 2. It is assumed that the reservoirs are kept at constant volume and are thermally insulated except at the junction with the bar, so that no energy is added due to pressure work or heat conduction elsewhere. Similarly, the sides of the bar segment are assumed thermally insulated.

One question is how to define the heat flux through the bar segment. In the absence of particle motion, the second law of thermodynamics allows an unambiguous answer. The heat flux $q$ through the bar enters reservoir 2 , and the second law of thermodynamics then says:

$$
q_{2}=T_{2} \frac{\mathrm{~d} S_{2}}{\mathrm{~d} t}
$$

Here $S_{2}$ is the entropy of the reservoir 2. In the presence of particles moving through the bar, the definition of thermal energy, and so the corresponding heat flux, becomes more ambiguous. The particles also carry along nonthermal energy. The question then becomes what should be counted as thermal energy, and what as nonthermal. To resolve that, the heat flux into reservoir 2 will be defined by the expression above. Note that the heat flux out of reservoir 1 might be slightly different because of variations in energy carried by the particles. It is the total energy flow $j_{E}$, not the heat flow $q$, that must be exactly constant.

To understand the relationship between heat flux and energy flux more clearly, some basic thermodynamics can be used. See chapter 11.12 for more details, including generalization to more than one particle type. A combination of the first and second laws of thermodynamics produces

$$
T \mathrm{~d} \bar{s}=\mathrm{d} \bar{e}+P \mathrm{~d} \bar{v} \quad S=\bar{s} I \quad E=\bar{e} I \quad V=\bar{v} I
$$

in which $\bar{s}, \bar{e}$, and $\bar{v}$ are the entropy, internal energy, and volume per particle, and $P$ is the pressure. That can be used to rewrite the derivative of entropy in
the definition of the heat flux above:

$$
T \mathrm{~d} S=T \mathrm{~d}(\bar{s} I)=T(\mathrm{~d} \bar{s}) I+T \bar{s}(\mathrm{~d} I)=(\mathrm{d} \bar{e}+P \mathrm{~d} \bar{v}) I+T \bar{s}(\mathrm{~d} I)
$$

That can be rewritten as

$$
T \mathrm{~d} S=\mathrm{d} E+P \mathrm{~d} V-(\bar{e}+P \bar{v}-T \bar{s}) \mathrm{d} I
$$

as can be verified by writing $E$ and $V$ as $\bar{e} I$ and $\bar{v} I$ and differentiating out. The parenthetical expression in the above equation is in thermodynamics known as the Gibbs free energy. Chapter 11.13 explains that it is the same as the chemical potential $\mu$ in the distribution laws. Therefore:

$$
T \mathrm{~d} S=\mathrm{d} E+P \mathrm{~d} V-\mu \mathrm{d} I
$$

(Chapter 11.13 does not include an additional electrostatic energy due to an ambient electric field. But an intrinsic chemical potential can be defined by subtracting the electrostatic potential energy. The corresponding intrinsic energy also excludes the electrostatic potential energy. That makes the expression for the chemical potential the same in terms of intrinsic quantities as in terms of nonintrinsic ones. See also the discussion in chapter 6.14.)

Using the above expression for the change in entropy in the definition of the heat flux gives, noting that the volume is constant,

$$
q_{2}=\frac{\mathrm{d} E_{2}}{\mathrm{~d} t}-\mu_{2} \frac{\mathrm{~d} I_{2}}{\mathrm{~d} t}=j_{E}-\mu_{2} j_{I}
$$

It can be concluded from this that the nonthermal energy carried along per particle is $\mu$. The rest of the net energy flow is thermal energy.

The Kelvin relationships are related to the net entropy generated by the segment of the bar. The second law implies that irreversible processes always increase the net entropy in the universe. And by definition, the complete system figure A. 1 examined here is isolated. It does not exchange work nor heat with its surroundings. Therefore, the entropy of this system must increase in time due to irreversible processes. More specifically, the net system entropy must go up due to the irreversible heat conduction and particle transport in the segment of the bar. The reservoirs are taken to be thermodynamically reversible; they do not create entropy out of nothing. But the heat conduction in the bar is irreversible; it goes from hot to cold, not the other way around, in the absence of other effects. Similarly, the particle transport goes from higher chemical potential to lower.

While the conduction processes in the bar create net entropy, the entropy of the bar still does not change. The bar is assumed to be in a steady state. Instead the entropy created in the bar causes a net increase in the combined entropy of the reservoirs. Specifically,

$$
\frac{\mathrm{d} S_{\mathrm{net}}}{\mathrm{~d} t}=\frac{\mathrm{d} S_{2}}{\mathrm{~d} t}+\frac{\mathrm{d} S_{1}}{\mathrm{~d} t}
$$

By definition of the heat flux,

$$
\frac{\mathrm{d} S_{\text {net }}}{\mathrm{d} t}=\frac{q_{2}}{T_{2}}-\frac{q_{1}}{T_{1}}
$$

Substituting in the expression for the heat flux in terms of the energy and particle fluxes gives

$$
\frac{\mathrm{d} S_{\mathrm{net}}}{\mathrm{~d} t}=\left(\frac{1}{T_{2}} j_{E}-\frac{\mu_{2}}{T_{2}} j_{I}\right)-\left(\frac{1}{T_{1}} j_{E}-\frac{\mu_{1}}{T_{1}} j_{I}\right)
$$

Since the area of the bar is one, its volume is $\mathrm{d} x$. Therefore, the entropy generation per unit volume is:

$$
\begin{equation*}
\frac{1}{\mathrm{~d} x} \frac{\mathrm{~d} S_{\mathrm{net}}}{\mathrm{~d} t}=\frac{\mathrm{d} 1 / T}{\mathrm{~d} x} j_{E}+\frac{\mathrm{d}-\mu / T}{\mathrm{~d} x} j_{I} \tag{A.35}
\end{equation*}
$$

That used that any expression of the form $\left(f_{2}-f_{1}\right) / \mathrm{d} x$ is by definition the derivative of $f$.

The above expression for the entropy generation implies that a nonzero derivative of $1 / T$ must cause an energy flow of the same sign. Otherwise the entropy of the system would decrease if the derivative in the second term is zero. Similarly, a nonzero derivative of $-\mu / T$ must cause a particle flow of the same sign. Of course, that does not exclude that the derivative of $1 / T$ may also cause a particle flow as a secondary effect, or a derivative of $-\mu / T$ an energy flow. Using the same reasoning as in an earlier subsection gives:

$$
\begin{equation*}
j_{E}=L_{11} \frac{\mathrm{~d} 1 / T}{\mathrm{~d} x}+L_{12} \frac{\mathrm{~d}-\mu / T}{\mathrm{~d} x} \quad j_{I}=L_{21} \frac{\mathrm{~d} 1 / T}{\mathrm{~d} x}+L_{22} \frac{\mathrm{~d}-\mu / T}{\mathrm{~d} x} \tag{A.36}
\end{equation*}
$$

where the $L_{\text {.. }}$ are again coefficients to be determined experimentally. But in this case, the coefficients $L_{11}$ and $L_{22}$ must necessarily be positive. That can provide a sanity check on the experimental results. It is an advantage gained from taking the flows and derivatives directly from the equation of entropy generation. In fact, somewhat stronger constraints apply. If the expressions for $j_{E}$ and $j_{I}$ are plugged into the expression for the entropy generation, the result must be positive regardless of what the values of the derivatives are. That requires not just that $L_{11}$ and $L_{22}$ are positive, but also that the average of $L_{12}$ and $L_{21}$ is smaller in magnitude than the geometric average of $L_{11}$ and $L_{22}$.

The so-called Onsager reciprocal relations provide a further, and much more specific constraint. They say that the coefficients of the secondary effects, $L_{12}$ and $L_{21}$, must be equal. In the terms of linear algebra, matrix $L_{\text {.. }}$ must be symmetric and positive definite. In real life, it means that only three, not four coefficients have to be determined experimentally. That is very useful because the experimental determination of secondary effects is often difficult.

The Onsager relations remain valid for much more general systems, involving flows of other quantities. Their validity can be argued based on experimental evidence, or also theoretically based on the symmetry of the microscopic dynamics with respect to time reversal. If there is a magnetic field involved, a coefficient $L_{i j}$ will only equal $L_{j i}$ after the magnetic field has been reversed: time reversal causes the electrons in your electromagnet to go around the opposite way. A similar observation holds if Coriolis forces are a factor in a rotating system.

The equations (A.36) for $j_{E}$ and $j_{I}$ above can readily be converted into expressions for the heat flux density $q=j_{E}-\mu j_{I}$ and the current density $j=$ $-e j_{I}$. If you do so, then differentiate out the derivatives, and compare with the thermoelectric equations (A.31) given earlier, you find that the Onsager relation $L_{12}=L_{21}$ translates into the second Kelvin relation

$$
\mathcal{P}=S T
$$

That allows you to clean up the Kelvin coefficient to the first Kelvin relationship:

$$
\mathcal{K} \equiv \frac{\mathrm{d} \mathcal{P}}{\mathrm{~d} T}-\mathcal{S}=T \frac{\mathrm{~d} \mathcal{S}}{\mathrm{~d} T}=\frac{\mathrm{d} \mathcal{S}}{\mathrm{~d} \ln T}
$$

It should be noted that while the second Kelvin relationship is named after Kelvin, he never gave a valid proof of the relationship. Neither did many other authors that tried. It was Onsager who first succeeded in giving a more or less convincing theoretical justification. Still, the most convincing support for the reciprocal relations remains the overwhelming experimental data. See Miller (Chem. Rev. 60, 15, 1960) for examples. Therefore, the reciprocal relationships are commonly seen as an additional axiom to be added to thermodynamics to allow quasi-equilibrium systems to be treated.

## A. 12 Heisenberg picture

This book follows the formulation of quantum mechanics as developed by Schrödinger. However, there is another, earlier, formulation due to Heisenberg. This subsection gives a brief description so that you are aware of it when you run into it in literature.

In the Schrödinger picture, physical observables like position and momentum are represented by time-independent operators. The time dependence is in the wave function. This is somewhat counterintuitive because classically position and momentum are time dependent quantities. The Heisenberg picture removes the time dependence from the wave function and absorbs it into the operator.

To see how that works out, consider first the general form of the wave function. It can be written as

$$
\begin{equation*}
\Psi(\ldots ; t)=e^{-\mathrm{i} H t / \hbar} \Psi(\ldots ; 0) \tag{A.37}
\end{equation*}
$$

where the exponential of an operator is defined through its Taylor series:

$$
\begin{equation*}
e^{-\mathrm{i} H t / \hbar}=1-\mathrm{i} \frac{t}{\hbar} H-\frac{t^{2}}{2!\hbar^{2}} H^{2}+\ldots \tag{A.38}
\end{equation*}
$$

(To check the above expression for the wave function, take the initial wave function to be any energy eigenfunction of energy $E$. You get the correct $e^{-\mathrm{i} E t / \hbar}$ time dependence, chapter 7.1.2. Every $H$ becomes an $E$. And if the expression works for any eigenfunction, it works for all their combinations too. That means that it works for any wave function, because the eigenfunctions are complete. To be sure, the above form of the wave function applies only if the Hamiltonian is independent of time. Even if it is not, the transformation from the initial wave function $\Psi(\ldots ; 0)$ to a later one $\Psi(\ldots ; t)$ still remains a "unitary" one; one that keeps the wave function normalized. But then you will need to use the Schrödinger equation directly to figure out the time dependence.)

Now consider an arbitrary Schrödinger operator $\widehat{A}$. The physical effects of the operator can be characterized by inner products, as in

$$
\begin{equation*}
\left\langle\Psi_{1}(\ldots ; t) \mid \widehat{A} \Psi_{2}(\ldots ; t)\right\rangle \tag{A.39}
\end{equation*}
$$

Such a dot product tells you what amount of a wave function $\Psi_{1}$ is produced by applying the operator on a wave function $\Psi_{2}$. Knowing these inner products for all wave functions is equivalent to knowing the operator.

If the time-dependent exponentials are now peeled off $\Psi_{1}$ and $\Psi_{2}$ and absorbed into the operator, you get the time-dependent Heisenberg operator

$$
\begin{equation*}
\widetilde{A} \equiv e^{\mathrm{i} H t / \hbar} \widehat{A} e^{-\mathrm{i} H t / \hbar} \tag{A.40}
\end{equation*}
$$

Heisenberg operators will be indicated with a tilde instead of a hat. Note that the argument of the first exponential changed sign because it was taken to the other side of the inner product.

The operator $\widetilde{A}$ depends on time. To see how it evolves, differentiate the product with respect to time:

$$
\frac{\mathrm{d} \widetilde{A}}{\mathrm{~d} t}=\frac{\mathrm{i}}{\hbar} H e^{\mathrm{i} H t / \hbar} \widehat{A} e^{-\mathrm{i} H t / \hbar}+e^{\mathrm{i} H t / \hbar} \frac{\partial \widehat{A}}{\partial t} e^{-\mathrm{i} H t / \hbar}-e^{\mathrm{i} H t / \hbar} \widehat{A} e^{-\mathrm{i} H t / \hbar} \frac{\mathrm{i}}{\hbar} H
$$

The first and third terms can be recognized as a multiple of the commutator of $H$ and $\widetilde{A}$, while the middle term is the Heisenberg version of the time derivative of $\widehat{A}$, in case $\widehat{A}$ does happen to depend on time. So the evolution equation for the Heisenberg operator becomes

$$
\begin{equation*}
\frac{\mathrm{d} \widetilde{A}}{\mathrm{~d} t}=\frac{\mathrm{i}}{\hbar}[H, \widetilde{A}]+\frac{\widetilde{\partial \widehat{A}}}{\partial t} \quad[H, \widetilde{A}]=e^{\mathrm{i} H t / \hbar}[H, \widehat{A}] e^{-\mathrm{i} H t / \hbar} \tag{A.41}
\end{equation*}
$$

(Note that there is no difference between the Hamiltonians $\widehat{H}$ and $\widetilde{H}$ because $H$ commutes with itself, hence with its exponentials.)

For example, consider the Schrödinger $\widehat{x}$ position and $\widehat{p}_{x}$ linear momentum operators of a particle. These do not depend on time. Using the commutators as figured out in chapter 7.2.1, the corresponding Heisenberg operators evolve as:

$$
\frac{\mathrm{d} \widetilde{x}}{\mathrm{~d} t}=\frac{1}{m} \widetilde{p}_{x} \quad \frac{\mathrm{~d} \widetilde{p}_{x}}{\mathrm{~d} t}=-\frac{\widetilde{\partial V}}{\partial x}
$$

Those have the exact same form as the equations for the classical position and momentum of the particle.

In fact, the equivalent of the general equation (A.41) is also found in classical physics: it is derived in advanced mechanics, with the so-called "Poisson bracket" taking the place of the commutator. As a simple example, consider one-dimensional motion of a particle. Any variable $a$ that depends on the position and linear momentum of the particle, and maybe also explicitly on time, has a time derivative given by

$$
\frac{\mathrm{d} a}{\mathrm{~d} t}=\frac{\partial a}{\partial x} \frac{\mathrm{~d} x}{\mathrm{~d} t}+\frac{\partial a}{\partial p_{x}} \frac{\mathrm{~d} p_{x}}{\mathrm{~d} t}+\frac{\partial a}{\partial t}
$$

according to the total differential of calculus. And from the classical Hamiltonian

$$
H=\frac{p_{x}^{2}}{2 m}+V
$$

it is seen that the time derivatives of position and momentum obey the classical "Hamiltonian dynamics"

$$
\frac{\mathrm{d} x}{\mathrm{~d} t}=\frac{\partial H}{\partial p_{x}} \quad \frac{\mathrm{~d} p_{x}}{\mathrm{~d} t}=-\frac{\partial H}{\partial x}
$$

Substituting this into the time derivative of $a$ gives

$$
\frac{\mathrm{d} a}{\mathrm{~d} t}=\frac{\partial a}{\partial x} \frac{\partial H}{\partial p_{x}}-\frac{\partial a}{\partial p_{x}} \frac{\partial H}{\partial x}+\frac{\partial a}{\partial t}
$$

The first two terms in the right hand side are by definition minus the Poisson bracket $\{H, a\}_{\mathrm{P}}$, so

$$
\frac{\mathrm{d} a}{\mathrm{~d} t}=-\{H, a\}_{\mathrm{P}}+\frac{\partial a}{\partial t} \quad\{H, a\}_{\mathrm{P}} \equiv \frac{\partial H}{\partial x} \frac{\partial a}{\partial p_{x}}-\frac{\partial a}{\partial x} \frac{\partial H}{\partial p_{x}}
$$

Note that the Poisson bracket, like the commutator, is antisymmetric under exchange of $H$ and $a$. Apparently, formally identifying the Poisson bracket with the commutator divided by i $\hbar$ brings you from classical mechanics to Heisenberg's quantum mechanics.

More generally, the classical Hamiltonian can depend on multiple and nonCartesian coordinates, generically called "generalized coordinates." In that case, in the Poisson bracket you must sum over all generalized coordinates and their
associated so-called "canonical" momenta. For a Cartesian position coordinate, the canonical momentum is the corresponding linear momentum. For an angular coordinate, it is the corresponding angular momentum. In general, using the socalled Lagrangian formulation usually covered in an engineering education, and otherwise found in addendum $\{\mathrm{A} .1\}$, the canonical momentum is the derivative of the Lagrangian with respect to the time derivative of the coordinate.

The bottom line is that the Heisenberg equations are usually not easy to solve unless you return to the Schrödinger picture by peeling off the time dependence. In relativistic applications however, time joins space as an additional coordinate, and the Heisenberg picture becomes more helpful. It can also make it easier to identify the correspondence between classical equations and the corresponding quantum operators.

## Key Points

$0-$ In the Heisenberg picture, operators evolve in time just like their physical variables do in classical physics.

## A. 13 Integral Schrödinger equation

The Hamiltonian eigenvalue problem, or time-independent Schrödinger equation, is the central equation of quantum mechanics. It reads

$$
\frac{\hbar^{2}}{2 m} \nabla^{2} \psi(\vec{r})+V(\vec{r}) \psi(\vec{r})=E \psi(\vec{r})
$$

Here $\psi$ is the wave function, $E$ is the energy of the state described by the wave function, $V$ is the potential energy, $m$ is the mass of the particle, and $\hbar$ is the scaled Planck constant.

The equation also involves the Laplacian operator, defined as

$$
\nabla^{2} \equiv \frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}
$$

Therefore the Hamiltonian eigenvalue problem involves partial derivatives, and it is called a partial differential equation.

However, it is possible to manipulate the equation so that the wave function $\psi$ appears inside an integral rather than inside partial derivatives. The equation that you get this way is called the "integral Schrödinger equation." It takes the form, $\{$ D. 31$\}$ :

$$
\begin{equation*}
\psi(\vec{r})=\psi_{0}(\vec{r})-\frac{m}{2 \pi \hbar^{2}} \int_{\text {all } \vec{r}^{\prime}} \frac{e^{\mathrm{i} k\left|\vec{r}-\vec{r}^{\prime}\right|}}{\left|\vec{r}-\vec{r}^{\prime}\right|} V\left(\vec{r}^{\prime}\right) \psi\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime} \quad k=\frac{\sqrt{2 m E}}{\hbar} \tag{A.42}
\end{equation*}
$$

Here $\psi_{0}$ is any wave function of energy $E$ in free space. In other words $\psi_{0}$ is any wave function for the particle in the absence of the potential $V$. The constant $k$ is a measure of the energy of the particle. It also corresponds to a wave number far from the potential. While not strictly required, the integral Schrödinger equation above tends to be most suited for particles in infinite space.

## A. 14 The Klein-Gordon equation

The Schrödinger equation for the quantum wave function is based on the nonrelativistic expression for the energy of a particle. This addendum looks at the simplest relativistic equation for wave functions, called the Klein-Gordon equation. The discussion will largely be restricted to a spinless particle in empty space, where there is no potential energy. However, the Klein-Gordon equation is the first step to more complex relativistic equations.

Recall first how the Schrödinger equation arose. If there is no potential energy, classical physics says that the energy $E$ is just the kinetic energy $p^{2} / 2 m$ of the particle. Here $p$ is the linear momentum of the particle and $m$ its mass. Quantum mechanics replaces the energy $E$ by the operator $\mathrm{i} \hbar \partial / \partial t$ and the momentum $\vec{p}$ by $\hbar \nabla / \mathrm{i}$, where

$$
\nabla=\hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

Then it applies the resulting operators on the wave function $\Psi$. That then produces the Schrödinger equation

$$
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=-\frac{\hbar^{2}}{2 m} \nabla^{2} \Psi
$$

Solutions with a definite value $E$ for the energy take the form $\Psi=c e^{-\mathrm{i} E t / \hbar} \psi$. Substituting that into the Schrödinger equation and rearranging produces the so-called Hamiltonian eigenvalue problem

$$
-\frac{\hbar^{2}}{2 m} \nabla^{2} \psi=E \psi
$$

Here $\psi$ is called the energy eigenfunction.
According to classical relativity however, the energy $E$ of a particle in empty space is not just kinetic energy, but also rest mass energy $m c^{2}$, where $c$ is the speed of light. In particular, chapter 1.1.2 (1.2),

$$
E=\sqrt{\left(m c^{2}\right)^{2}+p^{2} c^{2}}
$$

The momentum can be identified with the same operator as before. But square roots of operators are very ugly. So the smart thing to do is to square both
sides above. Making the same substitutions as for the Schrödinger equation and cleaning up then gives the "Klein-Gordon equation"

$$
\begin{equation*}
-\frac{1}{c^{2}} \frac{\partial^{2} \Psi}{\partial t^{2}}+\nabla^{2} \Psi=\left(\frac{m c^{2}}{\hbar c}\right)^{2} \Psi \tag{A.43}
\end{equation*}
$$

Solutions $c e^{-\mathrm{i} E t / \hbar} \psi$ with definite energy $E$ satisfy the "time-independent Klein-Gordon equation" or square Hamiltonian eigenvalue problem

$$
-\hbar^{2} c^{2} \nabla^{2} \psi+\left(m c^{2}\right)^{2} \psi=E^{2} \psi
$$

This may be rewritten in a form so that both the Schrödinger equation and the Klein-Gordon equation are covered:

$$
\text { empty space: }-\nabla^{2} \psi=k^{2} \psi \begin{cases}\text { Schrödinger: } & k=\frac{\sqrt{2 m E}}{\hbar}  \tag{A.44}\\ \text { Klein-Gordon: } & k=\frac{\sqrt{E^{2}-\left(m c^{2}\right)^{2}}}{\hbar c}\end{cases}
$$

Here the constant $k$ is called the "wave number." Note that the nonrelativistic energy does not include the rest mass energy. When that is taken into account, the Schrödinger expression for $k$ above is the nonrelativistic approximation for the Klein-Gordon $k$ as it should be.

Further note that relativistic or not, the magnitude of linear momentum $p$ is given by the "de Broglie relation" $p=\hbar k$. That is because relativistic or not the momentum operator is $\hbar \nabla / \mathrm{i}$, so $\widehat{p}^{2}=-\hbar^{2} \nabla^{2}$. Similarly, relativistic or not, the energy is associated the operator $i \hbar \partial / \partial t$. That means that the timedependent factor in states of definite energy is $e^{-\mathrm{i} E t / \hbar}$. That allows the energy to be associated with an "angular frequency" $\omega$ by writing the exponential as $e^{-\mathrm{i} \omega t}$. The relationship between energy and frequency is then $E=\hbar \omega$. That is known as the "Planck-Einstein relation" when applied to photons. In short, relativistic or not,

$$
\begin{equation*}
p=\hbar k \quad E=\hbar \omega \tag{A.45}
\end{equation*}
$$

The wave number $k$ is the quantum number of linear momentum, and the angular frequency $\omega$ is the one of energy. See addendum \{A.19\} for more on how these numbers arise physically from symmetries of nature.

It may be noted that Schrödinger wrote down the Klein-Gordon equation first. But when he added the Coulomb potential, he was not able to get the energy levels of the hydrogen atom. To fix that problem, he wrote down the simpler nonrelativistic equation that bears his name. The problem in the relativistic case is that after you add the Coulomb potential to the energy, you can no longer square away the square root. Eventually, Dirac figured out how to get around that problem, chapter 12.12 and \{D.81\}. In brief, he assumed
that the wave function for the electron is not a scalar, but a four-dimensional vector, (two spin states for the electron, plus two spin states for the associated antielectron, or positron.) Then he assumed that the square root takes a simple form for that vector.

Since this addendum assumes a particle in empty space, the problem with the Coulomb potential does not arise. But there are other issues. The good news is that according to the Klein-Gordon equation, effects do not propagate at speeds faster than the speed of light. That is known from the theory of partial differential equations. In classical physics, effects cannot propagate faster than the speed of light, so it is somewhat reassuring that the Klein-Gordon equation respects that.

Also, all inertial observers agree about the Klein-Gordon equation, regardless of the motion of the observer. That is because all inertial observers agree about the rest mass $m$ of a particle and the value of the speed of light $c$. So they all agree about the right hand side in the Klein-Gordon equation (A.43). And the left hand side in the Klein-Gordon equation is also the same for all inertial observers. You can crunch that out using the Lorentz transform as given in chapter 1.2.1 (1.6). (Those familiar with index notation as briefly described in chapter 1.2 .5 recognize the entire left hand side as being simply $\partial^{\mu} \partial_{\mu} \Psi$. That is unchanged going from one observer to the next, because the upper index transforms under the Lorentz transform and the lower index under the inverse Lorentz transform. The operator $\partial^{\mu} \partial_{\mu}$ is called the "D'Alembertian," much like $\nabla^{2}$ is called the Laplacian.)

But the bad news is that the Klein-Gordon equation does not necessarily preserve the integral of the square magnitude of the wave function. The Schrödinger equation implies that, $\{\mathrm{D} .32\}$,

$$
\int_{\text {all }}|\Psi|^{2} \mathrm{~d}^{3} \vec{r}=\text { constant, the same for all time }
$$

The wave function is then normalized so that the constant is 1 . According to the Born statistical interpretation, chapter 3.1, the integral above represents the probability of finding the particle if you look at all possible positions. That must be 1 at whatever time you look; the particle must be somewhere. Because the Schrödinger equation ensures that the integral above stays 1 , it ensures that the particle cannot just disappear, and that no second particle can show up out of nowhere.

But the Klein-Gordon equation does not preserve the integral above. Therefore the number of particles is not necessarily preserved. That is not as bad as it looks, anyway, because in relativity the mass-energy equivalence allows particles to be created or destroyed, chapter 1.1.2. But certainly, the interpretation of the wave function is not a priori obvious. The integral that the Klein-Gordon
equation does preserve is, $\{\mathrm{D} .32\}$,

$$
\int_{\text {all }}\left|\frac{1}{c} \frac{\partial \Psi}{\partial t}\right|^{2}+|\nabla \Psi|^{2}+\left|\frac{m c^{2}}{\hbar c} \Psi\right|^{2} \mathrm{~d}^{3} \vec{r}=\text { constant }
$$

It is maybe somewhat comforting that according to this expression, the integral of $|\Psi|^{2}$ must at least remain bounded. That does assume that the rest mass $m$ of the particle is not zero. Photons need not apply.

Another problem arises because even though the square energy $E^{2}$ is normally positive, the energy $E$ itself can still be both positive or negative. That is a problem, because then there is no lower limit to the energy, there is no ground state. The particle can then transition to states of lower and lower energy tending to minus infinity. That would release unbounded amounts of energy. (Since the kinetic energy can be arbitrarily large, the positive value of the energy can be arbitrarily large. That makes the negative value of the energy also arbitrarily large in magnitude.)

You might say, just ignore the negative energy possibility. But Dirac found that that does not work; you need both positive and negative energy states to explain such things as the hydrogen energy levels. The way Dirac solved the problem for electrons is to assume that all negative states are already filled with electrons. Unfortunately, that does not work for bosons, since any number of bosons can go into a state.

The modern view is to consider the negative energy solutions to represent antiparticles. In that view, antiparticles have positive energy, but move backwards in time. For example, Dirac's negative energy states are not electrons with negative energy, but positrons with positive energy. Positrons are then electrons that move backward in time. To illustrate the idea, consider two hypothetical wave functions of the form

$$
e^{-\mathrm{i} E t / \hbar} \psi_{1} \quad \text { and } \quad e^{\mathrm{i} E t / \hbar} \psi_{2}
$$

where $E$ is the positive root for the energy. The first wave function is no problem; it is of the form of a wave function that you would get for a nonrelativistic particle of energy $E$. The second wave function is the problem. It is not considered to be a particle of negative energy $-E$. Instead it is considered an antiparticle of positive energy $E$ that moves backward in time. It is the reversal of the relevant direction of time that causes the sign change in the argument of the exponential.

You see why so much quantum physics is done using nonrelativistic equations.

## A. 15 Quantum Field Theory in a Nanoshell

The "classical" quantum theory discussed in this book runs into major difficulties with truly relativistic effects. In particular, relativity allows particles to
be created or destroyed. For example, a very energetic photon near a heavy nucleus might create an electron and a positron. Einstein's $E=m c^{2}$ implies that that is possible because mass is equivalent to energy. The photon energy is converted into the electron and positron masses. Similarly, an electron and positron can annihilate each other, releasing their energy as photons. The quantum formalism in this book cannot deal with particles that appear out of nothing or disappear. A modified formulation called "quantum field theory" is needed.

And quantum field theory is not just for esoteric conditions like electronpositron pair creation. The photons of light are routinely created and destroyed under normal conditions. Still more basic to an engineer, so are their equivalents in solids, the phonons of crystal vibrations. Then there is the band theory of semiconductors: electrons are "created" within the conduction band, if they pick up enough energy, or "annihilated" when they lose it. And the same happens for the real-life equivalent of positrons, holes in the valence band.

Such phenomena are routinely described within the framework of quantum field theory. Almost unavoidably you will run into it in literature, [18, 29]. Electron-phonon interactions are particularly important for engineering applications, leading to electrical resistance (along with crystal defects and impurities), and to the combination of electrons into Cooper pairs that act as bosons and so give rise to superconductivity.

This addendum explains some of the basic ideas of quantum field theory. It should allow you to recognize it when you see it. Addendum \{A. 23$\}$ uses the ideas to explain the quantization of the electromagnetic field. That then allows the quantum description of spontaneous emission of radiation by excited atoms or nuclei in $\{\mathrm{A} .24\}$. Here a photon is created.

Unfortunately a full discussion of quantum field theory is far outside the scope of this book. Especially the fully relativistic theory is very involved. To explain quantum field theory in a nutshell takes Zee 500 pages, [53]. Tong 【17】 writes: "This is charming book, where emphasis is placed on physical understanding and the author isn't afraid to hide the ugly truth when necessary. It contains many gems." But you first need to learn linear algebra, at the minimum read all of chapter 1 on relativity, chapter 1.2.5 and \{A.4\} on index notation, chapter 12.12 and $\{A .36\}$ on the Dirac equation, addendum \{A.14\} on the Klein-Gordon equation, $\{\mathrm{A} .1\}$ on Lagrangian mechanics, $\{\mathrm{A} .12\}$ on the Heisenberg interpretation, and pick up enough group theory. Learning something about the path integral approach to quantum mechanics, like from [22], cannot hurt either. In the absence of 1000 pages and a willing author, the following discussion will truly be quantum field theory in a nanoshell.

If you want to get a start on a more advanced treatment of quantum field theory of elementary particles at a relatively low level of mathematics, Griffiths [24] is recommended.

And if you are just interested in relativistic quantum mechanics from an
intellectual point of view, there is good news. Feynman gave a set of lectures on "quantum electrodynamics" for a general audience around 1983, and the text is readily available at low cost. Without doubt, this is the best exposition of the fundamentals of quantum mechanics that has ever been written, or ever will. The subject is reduced to its bare abstract axioms, and no more can be said. If the human race is still around a millennium or so from now, artificial intelligence may take care of the needed details of quantum mechanics. But those who need or want to understand what it means will still reach for Feynman. The 2006 edition, [19], has a foreword by Zee that gives a few hints how to relate the basic concepts in the discussion to more conventional mathematics like the complex numbers found in this book. It will not be much help applying quantum field theory to engineering problems, however.

## A.15.1 Occupation numbers

The first concept that must be understood in quantum field theory is occupation numbers. They will be the new way to represent quantum wave functions.

Recall first the form of wave functions in "classical" quantum mechanics, as normally covered in this book. Assume a system of independent, or maybe weakly interacting particles. The energy eigenfunctions of such a system can be written in terms of whatever are the single-particle energy eigenfunctions

$$
\psi_{1}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \psi_{2}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \psi_{3}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \ldots
$$

For each single-particle eigenfunction, $\vec{r}$ indicates the position of the particle and $S_{z}$ its spin angular momentum in the chosen $z$-direction.

Now consider a system of, say, 36 particles. A completely arbitrary example of an energy eigenfunction for such a system would be:

$$
\begin{align*}
& \psi^{\mathrm{S}}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \vec{r}_{3}, S_{z 3}, \vec{r}_{4}, S_{z 4}, \vec{r}_{5}, S_{z 5}, \ldots, \vec{r}_{36}, S_{z 36}\right)= \\
& \quad \psi_{24}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{7}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right) \psi_{6}^{\mathrm{p}}\left(\vec{r}_{5}, S_{z 5}\right) \ldots \psi_{54}^{\mathrm{p}}\left(\vec{r}_{36}, S_{z 36}\right) \tag{A.46}
\end{align*}
$$

This system eigenfunction has particle 1 in the single-particle state $\psi_{24}^{\mathrm{p}}$, particle 2 in $\psi_{4}^{\mathrm{p}}$, etcetera. The system energy is the sum of the separate energies of the 36 single-particle states involved:

$$
E^{\mathrm{S}}=E_{\psi_{24}}^{\mathrm{p}}+E_{\psi_{4}}^{\mathrm{p}}+E_{\psi_{7}}^{\mathrm{p}}+E_{\psi_{1}}^{\mathrm{p}}+E_{\psi_{6}}^{\mathrm{p}}+\ldots+E_{\psi_{54}}^{\mathrm{p}}
$$

Instead of writing out the example eigenfunction mathematically as done in (A.46) above, it can be graphically depicted as in figure A.2. In the figure the single-particle states are shown as boxes, and the particles that are in those particular single-particle states are shown inside the boxes. In the example, particle 1 is inside the $\psi_{24}^{\mathrm{p}}$ box, particle 2 is inside the $\psi_{4}^{\mathrm{p}}$ one, etcetera. It is just the reverse from the mathematical expression (A.46): the mathematical

Figure A.2: Graphical depiction of an arbitrary system energy eigenfunction for 36 distinguishable particles.
expression shows for each particle in turn what the single-particle eigenstate of that particle is. The figure shows for each single-particle eigenstate in turn what particles are in that eigenstate.

However, if the 36 particles are identical bosons, (like photons or phonons), the example mathematical eigenfunction (A.46) and corresponding depiction figure A. 2 is unacceptable. As chapter 5.7 explained, wave functions for bosons must be unchanged if two particles are swapped. But if, for example, particles 2 and 5 in eigenfunction (A.46) above are exchanged, it puts 2 in state 6 and 5 in state 4:

$$
\begin{aligned}
& \psi_{2 \leftrightarrow 5}^{\mathrm{S}}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \vec{r}_{3}, S_{z 3}, \vec{r}_{4}, S_{z 4}, \vec{r}_{5}, S_{z 5}, \ldots, \vec{r}_{36}, S_{z 36}\right)= \\
& \quad \psi_{24}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{6}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{7}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{5}, S_{z 5}\right) \ldots \psi_{54}^{\mathrm{p}}\left(\vec{r}_{36}, S_{z 36}\right)
\end{aligned}
$$

That is simply a different energy eigenfunction. So neither (A.46) nor this swapped form are acceptable by themselves. To fix up the problem, eigenfunctions must be combined. To get a valid energy eigenfunction for bosons out of (A.46), all the different eigenfunctions that can be formed by swapping the 36 particles must be summed together. The normalized sum gives the correct eigenfunction for bosons. But note that there is a humongous number of different eigenfunctions that can be obtained by swapping the particles. Over $10^{37}$ if you care to count them. As a result, there is no way that the gigantic expression for the resulting 36-boson energy eigenfunction could ever be written out here.

It is much easier in terms of the graphical depiction figure A.2: graphically all these countless system eigenfunctions differ only with respect to the numbers in the particles. And since in the final eigenfunction, all particles are present in exactly the same way, then so are their numbers within the particles. Every

Figure A.3: Graphical depiction of an arbitrary system energy eigenfunction for 36 identical bosons.
number appears equally in every particle. So the numbers do no longer add distinguishing information and can be left out. That makes the graphical depiction of the example eigenfunction for a system of identical bosons as in figure A.3. It illustrates why identical particles are commonly called "indistinguishable."

For a system of identical fermions, (like electrons or quarks), the eigenfunctions must change sign if two particles are swapped. As chapter 5.7 showed, that is very restrictive. It means that you cannot create an eigenfunction for a system of 36 fermions from the example eigenfunction (A.46) and the swapped versions of it. Various single-particle eigenfunctions appear multiple times in (A.46), like $\psi_{4}^{\mathrm{p}}$, which is occupied by particles 2,31 , and 33. That cannot happen for fermions. A system eigenfunction for 36 identical fermions requires 36 different single-particle eigenfunctions.

It is the same graphically. The example figure A. 3 for bosons is impossible for a system of identical fermions; there cannot be more than one fermion in a single-particle state. A depiction of an arbitrary energy eigenfunction that is acceptable for a system of 33 identical fermions is in figure A.4.

As explained in chapter 5.7, a neat way of writing down the system energy eigenfunction of the pictured example is to form a Slater determinant from the "occupied states"

$$
\psi_{1}^{\mathrm{p}}, \psi_{2}^{\mathrm{p}}, \psi_{3}^{\mathrm{p}}, \ldots, \psi_{43}^{\mathrm{p}}, \psi_{45}^{\mathrm{p}}, \psi_{56}^{\mathrm{p}}
$$

It is good to meet old friends again, isn't it?
Now consider what happens in relativistic quantum mechanics. For example, suppose that an electron and positron annihilate each other. What are you going to do, leave holes in the parameter list of your wave function, where the electron

Figure A.4: Graphical depiction of an arbitrary system energy eigenfunction for 33 identical fermions.
and positron used to be? Like

$$
\Psi\left(\vec{r}_{1}, S_{z 1},[\text { gone }], \vec{r}_{3}, S_{z 3},[\text { gone }], \vec{r}_{5}, S_{z 5}, \ldots, \vec{r}_{36}, S_{z 36} ; t\right)
$$

say? Or worse, what if a photon with very high energy hits an heavy nucleus and creates an electron-positron pair in the collision from scratch? Are you going to scribble in a set of additional parameters for the new particles into your parameter list? Scribble in another row and column in the Slater determinant for your electrons? That is voodoo mathematics. The classical way of writing wave functions fails.

And if positrons are too weird for you, consider photons, the particles of electromagnetic radiation, like ordinary light. As chapters 6.8 and 7.8 showed, the electrons in hot surfaces create and destroy photons readily when the thermal equilibrium shifts. Moving at the speed of light, with zero rest mass, photons are as relativistic as they come. Good luck scribbling in trillions of new states for the photons into your wave function when your black box heats up. Then there are solids; as chapter 11.14 .6 shows, the phonons of crystal vibrational waves are the equivalent of the photons of electromagnetic waves.

One of the key insights of quantum field theory is to do away with classical mathematical forms of the wave function such as (A.46) and the Slater determinants. Instead, the graphical depictions, such as the examples in figures A. 3 and A.4, are captured in terms of mathematics. How do you do that? By listing how many particles are in each type of single-particle state. In other words, you do it by listing the single-state "occupation numbers."

Consider the example bosonic eigenfunction of figure A.3. The occupation
numbers for that state would be

$$
|3,4,1,3,2,2,2,1,1,0,0,2,1,2,0,1,1,1,1,1,0,0,0,1,0,0,0,0,0,0,1, \ldots\rangle
$$

indicating that there are 3 bosons in single-particle state $\psi_{1}^{\mathrm{p}}, 4$ in $\psi_{2}^{\mathrm{p}}, 1$ in $\psi_{3}^{\mathrm{p}}$, etcetera. Knowing those numbers is completely equivalent to knowing the classical system energy eigenfunction; it could be reconstructed from them. Similarly, the occupation numbers for the example fermionic eigenfunction of figure A. 4 would be
$|1,1,1,1,1,1,1,1,1,1,1,1,1,1,0,1,0,1,1,1,1,1,1,1,0,1,0,0,1,1,1, \ldots\rangle$
Such sets of occupation numbers are called "Fock basis states." Each describes one system energy eigenfunction.

General wave functions can be described by taking linear combinations of these basis states. The most general Fock wave function for a classical set of exactly $I$ particles is a linear combination of all the basis states whose occupation numbers add up to $I$. But Fock states make it also possible to describe systems like photons in a box with varying numbers of particles. Then the most general wave function is a linear combination of all the Fock basis states, regardless of the total number of particles. The set of all possible wave functions that can be formed from linear combinations of the Fock basis states is called the "Fock space."

How about the case of distinguishable particles as in figure A.2? In that case, the numbers inside the particles also make a difference, so where do they go?? The answer of quantum field theory is to deny the existence of generic particles that take numbers. There are no generic particles in quantum field theory. There is a field of electrons, there is a field of protons, (or quarks, actually), there is a field of photons, etcetera, and each of these fields is granted its own set of occupation numbers. There is no way to describe a generic particle using a number. For example, if there is an electron in a single-particle state, in quantum field theory it means that the electron field has a particle in that energy state. The particle has no number.

Some physicist feel that this is a strong point in favor of believing that quantum field theory is the way nature really works. In the classical formulation of quantum mechanics, the (anti) symmetrization requirements under particle exchange are an additional ingredient, added to explain the data. In quantum field theory, it comes naturally: particles that are distinguishable simply cannot be described by the formalism. Still, our convenience in describing it is an uncertain motivator for nature.

The successful analysis of the blackbody spectrum in chapter 6.8 already testified to the usefulness of the Fock space. If you check the derivations in chapter 11 leading to it, they were all conducted based on occupation numbers. A classical wave function for the system of photons was never written down; that simply cannot be done.

Figure A.5: Example wave functions for a system with just one type of single particle state. Left: identical bosons; right: identical fermions.

There is a lot more involved in quantum field theory than just the blackbody spectrum, of course. To explain some of the basic ideas, simple examples can be helpful. The simplest example that can be studied involves just one singleparticle state, say just a single-particle ground state. The graphical depiction of an arbitrary example wave function is then as in figure A.5. There is just one single-particle box. In nonrelativistic quantum mechanics, this would be a completely trivial quantum system. In the case of $I$ identical bosons, shown to the left in the figure, all of them would have to go into the only state there is. In the case of identical fermions, shown to the right, there can only be one fermion, and it has to go into the only state there is.

But when particles can be created or destroyed, things get more interesting. When there is no given number of particles, there can be any number of identical bosons within that single particle state. That allows $|0\rangle$ (no particles,) $|1\rangle$ (1 particle), $|2\rangle$ ( 2 particles), etcetera. And the general wave function can be a linear combination of those possibilities. It is the same for identical fermions, except that there are now only the states $|0\rangle$ (no particles) and $|1\rangle$ (1 particle). The wave function can still be a combination of these two possibilities.

A relativistic system with just one type of single-particle state does seem very artificial. It raises the question how esoteric such an example is. But there are in fact two very well established classical systems that behave just like this:

1. The one-dimensional harmonic oscillator of chapter 4.1 has energy levels that happen to be exactly equally spaced. It can pick up an energy above the ground state that is any whole multiple of $\hbar \omega$, where $\omega$ is its natural frequency. If you are willing to accept the "particles" to be quanta of energy of size $\hbar \omega$, then it provides a model of a bosonic system with just one single-particle state. The ground state, $h_{0}$ in the notations of chapter 4.1, is the state $|0\rangle$. The first excited state $h_{1}$ is $|1\rangle$; it has one additional energy quantum $\hbar \omega$. The second excited state $h_{2}$ is $|2\rangle$, with two quanta more than the ground state, etcetera.

Recall from chapter 4.1 that there is an additional ground state energy of half a $\hbar \omega$ quantum. In a quantum field theory, this additional energy that exists even when there are no particles is called the "vacuum energy."

The general wave function of a harmonic oscillator is a linear combination of the energy states. In terms of chapter 4.1, that expresses an uncertainty in energy. In the present context, it expresses an
uncertainty in the number of these energy particles!
2. A single electron has exactly two spin states. It can pick up exactly one unit $\hbar$ of $z$-momentum above the spin-down state. If you accept the "particles" to be single quanta of $z$-momentum of size $\hbar$, then it provides an example of a fermionic system with just one singleparticle state. There can be either 0 or 1 quantum $\hbar$ of angular momentum in that single-particle state. The general wave function is a linear combination of the state with one angular momentum "particle" and the state with no angular momentum "particle".
This example is less intuitive, since normally when you talk about a particle, you talk about an amount of energy, like in Einstein's mass-energy relation. If it bothers you, think of the electron as being confined inside a magnetic field; then the spin-up state is associated with a corresponding increase in energy.
While the above two examples of "relativistic" systems with only one singleparticle state are obviously made up, they do provide a very valuable sanity check on any relativistic analysis.

Not only that, the two examples are also very useful to understand the difference between a zero wave function and the so-called "vacuum state"

$$
\begin{equation*}
|\overrightarrow{0}\rangle \equiv|0,0,0, \ldots\rangle \tag{A.47}
\end{equation*}
$$

in which all occupation numbers are zero. The vacuum state is a normalized, nonzero, wave function just like the other possible sets of occupation numbers. It describes that there are no particles with certainty. You can see it from the two examples above. For the harmonic oscillator, the state $|0\rangle$ is the ground state $h_{0}$ of the oscillator. For the electron-spin example, it is the spin-down state of the electron. These are completely normal eigenstates that the system can be in. They are not zero wave functions, which would be unable to describe a system.

Fock basis kets are taken to be orthonormal; an inner product between kets is zero unless all occupation numbers are equal. If they are all equal, the inner product is 1 . In short:

$$
\left\langle\ldots, \underline{i}_{3}, \underline{i}_{2}, \underline{i}_{1} \mid i_{1}, i_{2}, i_{3}, \ldots\right\rangle=\left\{\begin{array}{l}
1 \text { if } \underline{i}_{1}=i_{1} \text { and } \underline{i}_{2}=i_{2} \text { and } \underline{i}_{3}=i_{3} \ldots  \tag{А.48}\\
0 \text { otherwise }
\end{array}\right.
$$

If the two kets have the same total number of particles, this orthonormality is required because the corresponding classical wave functions are orthonormal. Inner products between classical eigenfunctions that have even a single particle in a different state are zero. That is easily verified if the wave functions are simple products of single-particle ones. But then it also holds for sums of such eigenfunctions, as you have for bosons and fermions.

If the two kets have different total numbers of particles, the inner product between the classical wave functions does not exist. But basis kets are still orthonormal. To see that, take the two simple examples given above. For the harmonic oscillator example, different occupation numbers for the "particles" correspond to different energy eigenfunctions of the actual harmonic oscillator. These are orthonormal. It is similar for the spin example. The state of 0 "particles" is the spin-down state of the electron. The state of 1 "particle" is the spin-up state. These spin states are orthonormal states of the actual electron.

## A.15.2 Creation and annihilation operators

The key to relativistic quantum mechanics is that particles can be created and annihilated. So it may not be surprising that it is very helpful to define operators that "create" and "annihilate" particles.

To keep the notations relatively simple, it will initially be assumed that there is just one type of single-particle state. Graphically that means that there is just one single-particle state box, like in figure A.5. However, there can be an arbitrary number of particles in that box.

The desired actions of the creation and annihilation operators are sketched in figure A.6. An annihilation operator $\widehat{a}$ turns a state $|i\rangle$ with $i$ particles into a state $|i-1\rangle$ with $i-1$ particles. A creation operator $\widehat{a}^{\dagger}$ turns a state $|i\rangle$ with $i$ particles into a state $|i+1\rangle$ with $i+1$ particles.

Figure A.6: Creation and annihilation operators for a system with just one type of single particle state. Left: identical bosons; right: identical fermions.

The operators are therefore defined by the relations
$\widehat{a}|i\rangle=\alpha_{i}|i-1\rangle$ but $\widehat{a}|0\rangle=0 \quad \widehat{a}^{\dagger}|i\rangle=\alpha_{i}^{\dagger}|i+1\rangle$ but $\widehat{a}^{\dagger}|1\rangle=0$ for fermions
Here the $\alpha_{i}$ and $\alpha_{i}^{\dagger}$ are numerical constants still to be chosen.
Note that the above relations only specify what the operators $\widehat{a}$ and $\widehat{a}^{\dagger}$ do to basis kets. But that is enough information to define them. To figure out what these operators do to linear combinations of basis kets, just apply them to each term in the combination separately.

Mathematically you can always define whatever operators you want. But you must hope that they will turn out to be operators that are physically helpful. To help achieve that, you want to chose the numerical constants $\alpha_{i}$ and $\alpha_{i}^{\dagger}$ appropriately. Consider what happens if the operators are applied in sequence:

$$
\widehat{a}^{\dagger} \widehat{a}|i\rangle=\widehat{a}^{\dagger} \alpha_{i}|i-1\rangle=\alpha_{i-1}^{\dagger} \alpha_{i}|i\rangle
$$

Reading from right to left, the order in which the operators act on the state, first $\widehat{a}$ destroys a particle, then $\widehat{a}^{\dagger}$ restores it again. It gives the same state back, except for the numerical factor $\alpha_{i-1}^{\dagger} \alpha_{i}$. That makes every state $|i\rangle$ an eigenvector of the operator $\widehat{a}^{\dagger} \widehat{a}$ with eigenvalue $\alpha_{i-1}^{\dagger} \alpha_{i}$.

If the constants $\alpha_{i-1}^{\dagger}$ and $\alpha_{i}$ are chosen to make the eigenvalue a real number, then the operator $\widehat{a}^{\dagger} \stackrel{\uparrow}{a}$ will be Hermitian. More specifically, if they are chosen to make the eigenvalue equal to $i$, then $\widehat{a}^{\dagger} \widehat{a}$ will be the "particle number operator" whose eigenvalues are the number of particles in the single-particle state. The most logical choice for the constants to achieve that is clearly

$$
\alpha_{i}=\sqrt{i} \quad \alpha_{i-1}^{\dagger}=\sqrt{i} \quad \Longrightarrow \quad \alpha_{i}^{\dagger}=\sqrt{i+1}
$$

The full definition of the annihilation and creation operators can now be written in a nice symmetric way as

$$
\begin{equation*}
\widehat{a}|i\rangle=\sqrt{i}|i-1\rangle \quad \widehat{a}^{\dagger}|i-1\rangle=\sqrt{i}|i\rangle \quad \text { except } \widehat{a}^{\dagger}|1\rangle=0 \text { for fermions } \tag{A.50}
\end{equation*}
$$

In words, the annihilation operator $\widehat{a}$ kills off one particle and adds a factor $\sqrt{i}$. The operator $\widehat{a}^{\dagger}$ puts the particle back in and adds another factor $\sqrt{i}$.

These operators are particularly convenient since they are Hermitian conjugates. That means that if you take them to the other side in an inner product, they turn into each other. In particular, for inner products between basis kets,

$$
\left.\left.\left.\left.\left.\left.\langle\mid \underline{i}\rangle|\widehat{a}| i\rangle\rangle=\left\langle\widehat{a}^{\dagger} \mid \underline{i}\right\rangle| | i\right\rangle\right\rangle \quad\langle\mid i\rangle\left|\widehat{a}^{\dagger}\right| \underline{i}\right\rangle\right\rangle=\langle\widehat{a} \mid i\rangle| | \underline{i}\right\rangle\right\rangle
$$

Note that if such relations apply for basis kets, they also apply for all linear combinations of basis kets.

To verify that the above relations apply, recall from the previous subsection that kets are orthonormal. In the equalities above, the inner products are only nonzero if $\underline{i}=i-1$ : after lowering the particle number with $\widehat{a}$, or raising it with $\widehat{a}^{\dagger}$, the particle numbers must be the same at both sides of the inner product. And when $\underline{i}=i-1$, according to the definitions (A.50) of $\widehat{a}$ and $\widehat{a}^{\dagger}$ all inner products above equal $\sqrt{i}$, so the equalities still apply.

It remains true for fermions that $\widehat{a}$ and $\widehat{a}^{\dagger}$ are Hermitian conjugates, even though $\widehat{a}^{\dagger}|1\rangle=0$ instead of $\sqrt{2}|2\rangle$. The reason is that the latter would only make a difference if there was a $|2\rangle$ state in the other side of the inner product, and such a state does not exist.

The inner products are usually written in the more esthetic form

$$
\langle\underline{i}| \widehat{a}|i\rangle=\langle\underline{i}|(\widehat{a}|i\rangle)=(\langle\underline{i}| \widehat{a})|i\rangle \quad\langle i| \widehat{a}^{\dagger}|\underline{i}\rangle=\langle i|\left(\widehat{a}^{\dagger}|\underline{i}\rangle\right)=\left(\langle i| \widehat{a}^{\dagger}\right)|\underline{i}\rangle
$$

Here it is to be understood that, say, $\langle\underline{i}| \mid \widehat{a}$ stands for $\widehat{a}^{\dagger}|\underline{i}\rangle$ pushed into the left hand side of an inner product, chapter 2.7.1.

You may well wonder why $\widehat{a}^{\dagger} \widehat{a}$ is the particle count operator; why not $\widehat{a} \widehat{a}^{\dagger}$ ? The reason is that $\widehat{a} \widehat{a}^{\dagger}$ would not work for the state $|0\rangle$ unless you took $\widehat{a}^{\dagger}|0\rangle$ to be zero or $\widehat{a}|1\rangle$ to be zero, and then they could no longer create or annihilate $|1\rangle$.

Still, it is interesting to see what the effect of $\widehat{a} \widehat{a}^{\dagger}$ is. It turns out that this depends on the type of particle. For bosons, using (A.50),

$$
\widehat{a}_{\mathrm{b}} \widehat{a}_{\mathrm{b}}^{\dagger}|i\rangle=\widehat{a}_{\mathrm{b}} \sqrt{i+1}|i+1\rangle=\sqrt{i+1} \sqrt{i+1}|i\rangle=(i+1)|i\rangle
$$

So the operator $\widehat{a}_{\mathrm{b}} \widehat{a}_{\mathrm{b}}^{\dagger}$ has eigenvalues one greater than the number of particles. That means that if you subtract $\widehat{a}_{\mathrm{b}} \widehat{a}_{\mathrm{b}}^{\dagger}$ and $\widehat{a}_{\mathrm{b}}^{\dagger} \widehat{a}_{\mathrm{b}}$, you get the unit operator that leaves all states unchanged. And the difference between $\widehat{a}_{\mathrm{b}} \widehat{a}_{\mathrm{b}}^{\dagger}$ and $\widehat{a}_{\mathrm{b}}^{\dagger} \widehat{a}_{\mathrm{b}}$ is by definition the commutator of $\widehat{a}_{\mathrm{b}}$ and $\widehat{a}_{\mathrm{b}}^{\dagger}$, indicated by square brackets:

$$
\begin{equation*}
\left[\widehat{a}_{\mathrm{b}}, \widehat{a}_{\mathrm{b}}^{\dagger}\right] \equiv \widehat{a}_{\mathrm{b}} \widehat{a}_{\mathrm{b}}^{\dagger}-\widehat{a}_{\mathrm{b}}^{\dagger} \widehat{a}_{\mathrm{b}}=1 \tag{A.51}
\end{equation*}
$$

Isn't that cute! Of course, $\left[\widehat{a}_{\mathrm{b}}, \widehat{a}_{\mathrm{b}}\right]$ and $\left[\widehat{a}_{\mathrm{b}}^{\dagger}, \widehat{a}_{\mathrm{b}}^{\dagger}\right]$ are zero since everything commutes with itself. It turns out that you can learn a lot from these commutators, as seen in later subsections.

The same commutator does not apply to fermions, because if you apply $\widehat{a}_{\mathrm{f}} \widehat{a}_{\mathrm{f}}^{\dagger}$ to $|1\rangle$, you get zero instead of $2|1\rangle$. But for fermions, the only state for which $\widehat{a}_{\mathrm{f}} \widehat{a}_{\mathrm{f}}^{\dagger}$ produces something nonzero is $|0\rangle$ and then it leaves the state unchanged. Similarly, the only state for which $\widehat{a}_{\mathrm{f}}^{\dagger} \widehat{a}_{\mathrm{f}}$ produces something nonzero is $|1\rangle$ and then it leaves that state unchanged. That means that if you add $\widehat{a}_{\mathrm{f}} \widehat{a}_{\mathrm{f}}^{\dagger}$ and $\widehat{a}_{\mathrm{f}}^{\dagger} \widehat{a}_{\mathrm{f}}$ together, instead of subtract them, it reproduces the same state state whether it is $|0\rangle$ or $|1\rangle$ (or any combination of them). The sum of $\widehat{a}_{\mathrm{f}} \widehat{a}_{\mathrm{f}}^{\dagger}$ and $\widehat{a}_{\mathrm{f}}^{\dagger} \widehat{a}_{\mathrm{f}}$ is called the "anticommutator" of $\widehat{a}_{\mathrm{f}}$ and $\widehat{a}_{\mathrm{f}}^{\dagger}$; it is indicated by curly brackets:

$$
\begin{equation*}
\left\{\widehat{a}_{\mathrm{f}}, \widehat{a}_{\mathrm{f}}^{\dagger}\right\} \equiv \widehat{a}_{\mathrm{f}} \widehat{a}_{\mathrm{f}}^{\dagger}+\widehat{a}_{\mathrm{f}}^{\dagger} \widehat{a}_{\mathrm{f}}=1 \tag{A.52}
\end{equation*}
$$

Isn't that neat? Note also that $\left\{\widehat{a}_{\mathrm{f}}, \widehat{a}_{\mathrm{f}}\right\}$ and $\left\{\widehat{a}_{\mathrm{f}}, \widehat{,}_{\mathrm{f}}\right\}$ are zero since applying either operator twice ends up in a nonexisting state.

How about the Hamiltonian for the energy of the system of particles? Well, for noninteracting particles the energy of $i$ particles is $i$ times the single particle energy $E^{\mathrm{p}}$. And since the operator that gives the number of particles is $\widehat{a}^{\dagger} \widehat{a}$, that is $E^{\mathrm{p}} \widehat{a}^{\dagger} \widehat{a}$. The total Hamiltonian for noninteracting particles becomes therefore:

$$
\begin{equation*}
H=E^{\mathrm{p}} a^{\dagger} \widehat{a}+E_{\mathrm{ve}} \tag{A.53}
\end{equation*}
$$

Here $E_{\text {ve }}$ stands for any additional "vacuum energy" that exists even if there are no particles. That is the ground state energy of the system. The above Hamiltonian allows the Schrödinger equation to be written in terms of occupation numbers and creation and annihilation operators.

## A.15.3 The caHermitians

It is important to note that the creation and annihilation operators $\widehat{a}^{\dagger}$ and $\widehat{a}$ are not Hermitian. They cannot be taken unchanged to the other side of an inner product. And their eigenvalues are not real. Therefore they cannot correspond to physically observable quantities. But since they are Hermitian conjugates, it is easy to form operators from them that are Hermitian. For example, their products $\widehat{a}^{\dagger} \widehat{a}$ and $\widehat{a} \widehat{a}^{\dagger}$ are Hermitian. The Hamiltonian for noninteracting particles (A.53) given in the previous subsection illustrates that.

Hermitian operators can also be formed from linear combinations of the creation and annihilation operators. Two combinations that are often physically relevant are

$$
\widehat{P} \equiv \frac{1}{2}\left(\widehat{a}+\widehat{a}^{\dagger}\right) \quad \widehat{Q} \equiv \frac{1}{2} \mathrm{i}\left(\widehat{a}-\widehat{a}^{\dagger}\right)
$$

In lack of a better name that the author knows of, this book will call $\widehat{P}$ and $\widehat{Q}$ the caHermitians.

Conversely, the annihilation and creation operators can be written in terms of the caHermitians as

$$
\begin{equation*}
\widehat{a}=\widehat{P}-\mathrm{i} \widehat{Q} \quad \widehat{a}^{\dagger}=\widehat{P}+\mathrm{i} \widehat{Q} \tag{A.54}
\end{equation*}
$$

This can be verified by substituting in the definitions of $\widehat{P}$ and $\widehat{Q}$.
The Hamiltonian (A.53) for noninteracting particles can be written in terms of $\widehat{P}$ and $\widehat{Q}$ as

$$
H=E^{\mathrm{p}}\left(\widehat{P}^{2}+\widehat{Q}^{2}-\mathrm{i}[\widehat{P}, \widehat{Q}]\right)+E_{\mathrm{ve}}
$$

Here $E^{\mathrm{p}}$ is again the single-particle energy and $E_{\text {ve }}$ the vacuum energy. The square brackets indicate again the commutator of the enclosed operators.

What this Hamiltonian means depends on whether the particles being described are bosons or fermions. They have different commutators $[\widehat{P}, \widehat{Q}]$.

Consider first the case that the particles are bosons. The previous subsection showed that the commutator $\left[\widehat{a}_{\mathrm{b}}, \widehat{a}_{\mathrm{b}}^{\dagger}\right]$ is 1 . From that the commutator of $P_{\mathrm{b}}$ and $Q_{\mathrm{b}}$ is readily found using the rules of chapter 4.5.4. It is;

$$
\begin{equation*}
\left[\widehat{P}_{\mathrm{b}}, \widehat{Q}_{\mathrm{b}}\right]=-\frac{1}{2} \mathrm{i} \tag{A.55}
\end{equation*}
$$

So the commutator is an imaginary constant. That is very much like Heisenberg's canonical commutator between position and linear momentum in classical quantum mechanics. It implies a similar uncertainty principle, chapter 4.5.2 (4.46). In particular, $P_{\mathrm{b}}$ and $Q_{\mathrm{b}}$ cannot have definite values at the same time. Their values have uncertainties $\sigma_{P_{\mathrm{b}}}$ and $\sigma_{Q_{\mathrm{b}}}$ that are at least so big that

$$
\sigma_{P_{\mathrm{b}}} \sigma_{Q_{\mathrm{b}}} \geqslant \frac{1}{4}
$$

The Hamiltonian for bosons becomes, using the commutator above,

$$
\begin{equation*}
H_{\mathrm{b}}=E^{\mathrm{p}}\left(\widehat{P}_{\mathrm{b}}^{2}+\widehat{Q}_{\mathrm{b}}^{2}\right)+E_{\mathrm{ve}}-\frac{1}{2} E^{\mathrm{p}} \tag{A.56}
\end{equation*}
$$

Often, the Hamiltonian is simply the first term in the right hand side. In that case, the vacuum energy is half a particle.

For fermions, the following useful relations follow from the anticommutators for the creation and annihilation operators given in the previous subsection:

$$
\begin{equation*}
\widehat{P}_{\mathrm{f}}^{2}=\frac{1}{4} \quad \widehat{Q}_{\mathrm{f}}^{2}=\frac{1}{4} \tag{A.57}
\end{equation*}
$$

The Hamiltonian then becomes

$$
\begin{equation*}
H=E^{\mathrm{p}}\left(\frac{1}{2}-\mathrm{i}\left[\widehat{P}_{\mathrm{f}}, \widehat{Q}_{\mathrm{f}}\right]\right)+E_{\mathrm{ve}} \tag{A.58}
\end{equation*}
$$

## A.15.4 Recasting a Hamiltonian as a quantum field one

The arguments of the previous subsection can be reversed. Given a suitable Hamiltonian, it can be recast in terms of annihilation and creation operators. This is often useful. It provides a way to quantize systems such as a harmonic oscillator or electromagnetic radiation.

Assume that some system has a Hamiltonian with the following properties:

$$
\begin{equation*}
H=E^{\mathrm{p}}\left(\widehat{P}^{2}+\widehat{Q}^{2}\right)+E_{\text {ref }} \quad[\widehat{P}, \widehat{Q}]=-\frac{1}{2} \mathrm{i} \tag{A.59}
\end{equation*}
$$

Here $\widehat{P}$ and $\widehat{Q}$ must be Hermitian operators and $E^{\mathrm{p}}$ and $E_{\text {ref }}$ must be constants with units of energy.

It may be noted that typically $E_{\text {ref }}$ is zero. It may also be noted that it suffices that the commutator is an imaginary constant. A different magnitude of the constant can be accommodated by rescaling $\widehat{P}$ and $\widehat{Q}$, and absorbing the
scaling factor in $E^{\mathrm{p}}$. A sign change can be accommodated by swapping $\widehat{P}$ and $\widehat{Q}$.

From the given apparently limited amount of information, all of the following conclusions follow:

1. The observable quantities $P$ and $Q$ corresponding to the Hermitian operators are always uncertain. As explained in chapter 4.4, if you measure an uncertain quantity, say $P$, for a lot of identical systems, you do get some average value. That average value is called the expectation value $\langle P\rangle$. However, the individual measured values will deviate from that expectation value. The average deviation is called the standard deviation or uncertainty $\sigma_{P}$. For the system above, the uncertainties in $P$ and $Q$ must satisfy the relation

$$
\sigma_{P} \sigma_{Q} \geqslant \frac{1}{4}
$$

Neither uncertainty can be zero, because that would make the other uncertainty infinite.
2. The expectation values of the observables $P$ and $Q$ satisfy the equations

$$
\frac{\mathrm{d}\langle P\rangle}{\mathrm{d} t}=-\omega\langle Q\rangle \quad \frac{\mathrm{d}\langle Q\rangle}{\mathrm{d} t}=\omega\langle P\rangle \quad \text { where } \omega \equiv \frac{E^{\mathrm{p}}}{\hbar}
$$

That means that the expectation values vary harmonically with time,

$$
\langle P\rangle=A \cos (\omega t+\alpha) \quad\langle Q\rangle=A \sin (\omega t+\alpha)
$$

Here the "amplitude" $A$ and the "phase angle" $\alpha$ are arbitrary constants.
3. In energy eigenstates, the expectation values $\langle P\rangle$ and $\langle Q\rangle$ are always zero.
4. The ground state energy of the system is

$$
E_{0}=\frac{1}{2} E^{\mathrm{p}}+E_{\mathrm{ref}}
$$

For now it will be assumed that the ground state is unique. It will be indicated as $|0\rangle$. It is often called the vacuum state.
5 . The higher energy states will be indicated by $|1\rangle,|2\rangle, \ldots$ in order of increasing energy $E_{1}, E_{2}, \ldots$. The states are unique and their energy is

$$
\text { wave function: }|i\rangle \quad \text { energy: } E_{i}=\left(i+\frac{1}{2}\right) E_{p}+E_{\text {ref }}
$$

So a state $|i\rangle$ has $i$ additional "quanta" of energy $E^{\mathrm{p}}$ more than the vacuum state. In particular that means that the energy levels are equally spaced. There is no maximum energy.
6. In energy eigenstates,

$$
\left\langle E^{\mathrm{p}} P^{2}\right\rangle=\left\langle E^{\mathrm{p}} Q^{2}\right\rangle=\frac{1}{2}\left(i+\frac{1}{2}\right) E_{p}
$$

So the expectation values of these two terms in the Hamiltonian are equal. Each contributes half to the energy of the quanta.
7. In the ground state, the two expectation energies above are the absolute minimum allowed by the uncertainty relation. Each expectation energy is then $\frac{1}{4} E^{\mathrm{p}}$.
8. Annihilation and creation operators can be defined as

$$
\widehat{a} \equiv \widehat{P}-\mathrm{i} \widehat{Q} \quad \widehat{a}^{\dagger} \equiv \widehat{P}+\mathrm{i} \widehat{Q}
$$

These have the following effects on the energy states:

$$
\widehat{a}|i\rangle=\sqrt{i}|i-1\rangle \quad \widehat{a}^{\dagger}|i-1\rangle=\sqrt{i}|i\rangle
$$

(This does assume that the normalization factors in the energy eigenstates are chosen consistently. Otherwise there might be additional factors of magnitude 1.) The commutator $\left[\widehat{a}, \widehat{a}^{\dagger}\right]$ is 1 .
9. The Hamiltonian can be rewritten as

$$
H=E^{\mathrm{p}} \widehat{a}^{\dagger} \widehat{a}+\frac{1}{2} E_{p}+E_{\mathrm{ref}}
$$

Here the operator $\widehat{a}^{\dagger} \widehat{a}$ gives the number of energy quanta of the state it acts on.
10. If the ground state is not unique, each independent ground state gives rise to its own set of energy eigenfunctions, with the above properties. Consider the example that the system describes an electron, and that the energy does not depend on the spin. In that case, there will be a spin-up and a spin-down version of the ground state, $|0\rangle \uparrow$ and $|0\rangle \downarrow$. These will give rise to two families of energy states $|i\rangle \uparrow$ respectively $|i\rangle \downarrow$. Each family will have the properties described above.
The derivation of the above properties is really quite simple and elegant. It can be found in $\{D .33\}$.

Note that various properties above are exactly the same as found in the analysis of bosons starting with the annihilation and creation operators. The difference in this subsection is that the starting point was a Hamiltonian in terms of two square Hermitian operators; and those merely needed to have a purely imaginary commutator.

## A.15.5 The harmonic oscillator as a boson system

This subsection will illustrate the power of the introduced quantum field ideas by example. The objective is to use these ideas to rederive the one-dimensional
harmonic oscillator from scratch. The derivation will be much cleaner than the elaborate algebraic derivation of chapter 4.1, and in particular $\{$ D. 12 $\}$.

The Hamiltonian of a harmonic oscillator in classical quantum mechanics is, chapter 4.1,

$$
H=\frac{1}{2 m} \widehat{p}_{x}^{2}+\frac{m}{2} \omega^{2} x^{2}
$$

Here the first term is the kinetic energy and the second the potential energy.
According to the previous subsection, a system like this can be solved immediately if the commutator of $\widehat{p}_{x}$ and $x$ is an imaginary constant. It is, that is the famous "canonical commutator" of Heisenberg:

$$
\left[x, \widehat{p}_{x}\right]=\mathrm{i} \hbar
$$

To use the results of the previous subsection, first the Hamiltonian must be rewritten in the form

$$
H=E^{\mathrm{p}}\left(\widehat{P}^{2}+\widehat{Q}^{2}\right)
$$

where $\widehat{P}$ and $\widehat{Q}$ satisfy the commutation relationship for bosonic caHermitians:

$$
[\widehat{P}, \widehat{Q}]=-\frac{1}{2} \mathrm{i}
$$

That requires that you define

$$
E^{\mathrm{p}}=\hbar \omega \quad \widehat{P}=\sqrt{\frac{1}{2 \hbar m \omega}} \widehat{p}_{x} \quad \widehat{Q}=\sqrt{\frac{m \omega}{2 \hbar}} x
$$

According to the previous subsection, the energy eigenvalues are

$$
E_{i}=\left(i+\frac{1}{2}\right) \hbar \omega
$$

So the spectrum has already been found.
And various other interesting properties of the solution may also be found in the previous subsection. Like the fact that there is half a quantum of energy left in the ground state. True, the zero level of energy is not important for the dynamics. But this half quantum does have a physical meaning. Assume that you have a lot of identical harmonic oscillators in the ground state, and that you do a measurement of the kinetic energy for each. You will not get zero kinetic energy. In fact, the average kinetic energy measured will be a quarter quantum, half of the total energy. The other quarter quantum is what you get on average if you do potential energy measurements.

Another observation of the previous subsection is that the expectation position of the particle will vary harmonically with time. It is a harmonic oscillator, after all.

The energy eigenfunctions will be indicated by $h_{i}$, rather than $|i\rangle$. What has not yet been found are specific expressions for these eigenfunctions. However,
as figure A. 6 shows, if you apply the annihilation operator $\widehat{a}$ on the ground state $h_{0}$, you get zero:

$$
\widehat{a} h_{0}=0
$$

And also according to the previous subsection

$$
\widehat{a}=\widehat{P}-\mathrm{i} \widehat{Q}
$$

Putting in the expressions for $\widehat{P}$ and $\widehat{Q}$ above, with $\widehat{p}_{x}=\hbar \partial / \mathrm{i} \partial x$, and rearranging gives

$$
\frac{1}{h_{0}} \frac{\partial h_{0}}{\partial x}=-\frac{m \omega}{\hbar} x
$$

This can be simplified by defining a scaled $x$ coordinate:

$$
\frac{1}{h_{0}} \frac{\partial h_{0}}{\partial \xi}=-\xi \quad \xi \equiv \frac{x}{\ell} \quad \ell \equiv \sqrt{\frac{\hbar}{m \omega}}
$$

Integrating both sides with respect to $\xi$ and cleaning up by taking an exponential gives the ground state as

$$
h_{0}=C e^{-\xi^{2} / 2}
$$

The integration constant $C$ can be found from normalizing the wave function. The needed integral can be found under "!" in the notations section. That gives the final ground state as

$$
h_{0}=\frac{1}{\left(\pi \ell^{2}\right)^{1 / 4}} e^{-\xi^{2} / 2}
$$

To get the other eigenfunctions $h_{i}$ for $i=1,2, \ldots$, apply the creation operator $\widehat{a}^{\dagger}$ repeatedly:

$$
h_{i}=\frac{1}{\sqrt{i}} \widehat{a}^{\dagger} h_{i-1}
$$

According to the previous subsection, the creation operator is

$$
\widehat{a}^{\dagger}=\widehat{P}+\mathrm{i} \widehat{Q}=\sqrt{\frac{1}{2 \hbar m \omega}} \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial x}+\mathrm{i} \sqrt{\frac{m \omega}{2 \hbar}} x=\frac{\mathrm{i}}{\sqrt{2}}\left(\xi-\frac{\partial}{\partial \xi}\right)
$$

So the entire process involves little more than a single differentiation for each energy eigenfunction found. In particular, unlike in $\{\mathrm{D} .12\}$, no table books are needed. Note that factors i do not make a difference in eigenfunctions. So the i in the final expression for $\widehat{a}^{\dagger}$ may be left out to get real eigenfunctions. That gives table 4.1.

That was easy, wasn't it?

## A.15.6 Canonical (second) quantization

"Canonical quantization" is a procedure to turn a classical system into the proper quantum one. If it is applied to a field, like the electromagnetic field, it is often called "second quantization."

Recall the quantum analysis of the harmonic oscillator in the previous subsection. The key to the correct solution was the canonical commutator between position and momentum. Apparently, if you get the commutators right in quantum mechanics, you get the quantum mechanics right. That is the idea behind canonical quantization.

The basic idea can easily be illustrated for the harmonic oscillator. The standard harmonic oscillator in classical physics is a simple spring-mass system. The classical governing equations are:

$$
\frac{\mathrm{d} x}{\mathrm{~d} t}=v_{x} \quad m \frac{\mathrm{~d} v_{x}}{\mathrm{~d} t}=-k x
$$

Here $x$ is the position of the oscillating mass $m$ and $k$ is the spring constant. The first of these equations is merely the definition of velocity. The second is Newton's second law.

As you can readily check by substitution, the most general solution is

$$
x=A \sin (\omega t+\alpha) \quad v_{x}=A \omega \cos (\omega t+\alpha) \quad \omega \equiv \sqrt{\frac{k}{m}}
$$

Here the "amplitude" $A$ and the "phase angle" $\alpha$ are arbitrary constants. The "frequency" $\omega$ is given in terms of the known spring constant and mass.

This system is now to be quantized using canonical quantization. The process is somewhat round-about. First a "canonical momentum," or "conjugate momentum," or "generalized momentum," $p_{x}$ is defined by taking the derivative of the kinetic energy, $\frac{1}{2} m v_{x}^{2}$, (or more generally, of the Lagrangian $\{\mathrm{A} .1\}$ ), with respect to the time derivative of $x$. Since the time derivative of $x$ is $v_{x}$, the momentum is $m v_{x}$. That is the usual linear momentum.

Next a classical Hamiltonian is defined. It is the total energy of the system expressed in terms of position and momentum:

$$
H_{\mathrm{cl}}=\frac{p_{x}^{2}}{2 m}+\frac{m}{2} \omega^{2} x^{2}
$$

Here the first term is the kinetic energy, with $v_{x}$ rewritten in terms of the momentum. The second term is the potential energy in the spring. The spring constant in it was rewritten as $m \omega^{2}$ because $m$ and $\omega$ are physically more important variables, and the symbol $k$ is already greatly overworked in quantum mechanics as it is. See $\{$ A. 1$\}$ for more on classical Hamiltonians.

To quantize the system, the momentum and position in the Hamiltonian must be turned into operators. Actual values of momentum and position are
then the eigenvalues of these operators. Basically, you just put a hat on the momentum and position in the Hamiltonian:

$$
H=\frac{\widehat{p}_{x}^{2}}{2 m}+\frac{m}{2} \omega^{2} \widehat{x}^{2}
$$

Note that the hat on $x$ is usually omitted. However, it is still an operator in the sense that it is supposed to multiply wave functions now. Now all you need is the right commutator between $\widehat{p}_{x}$ and $\widehat{x}$.

In general, you identify commutators in quantum mechanics with so-called "Poisson brackets" in classical mechanics. Assume that $A$ and $B$ are any two quantities that depend on $x$ and $p_{x}$. Then their Poisson bracket is defined as, \{A.12\},

$$
\{A, B\}_{\mathrm{P}} \equiv \frac{\partial A}{\partial x} \frac{\partial B}{\partial p_{x}}-\frac{\partial B}{\partial x} \frac{\partial A}{\partial p_{x}}
$$

From that it is immediately seen that

$$
\left\{x, p_{x}\right\}_{\mathrm{P}}=1 \quad\{x, x\}_{\mathrm{P}}=0 \quad\left\{p_{x}, p_{x}\right\}_{\mathrm{P}}=0
$$

Correspondingly, in quantum mechanics you take

$$
\left[x, \widehat{p}_{x}\right]=\mathrm{i} \hbar \quad[x, x]=0 \quad\left[\widehat{p}_{x}, \widehat{p}_{x}\right]=0
$$

In this way the nonzero Poisson brackets bring in Planck's constant that defines quantum mechanics. (In case of fermions, anticommutators take the place of commutators.)

Because of reasons discussed for the Heisenberg picture of quantum mechanics, $\{\mathrm{A} .12\}$, the procedure ensures that the quantum mechanics is consistent with the classical mechanics. And indeed, the results of the previous subsection confirmed that. You can check that the expectation position and momentum had the correct classical harmonic dependence on time.

Fundamentally, quantization of a classical system is just an educated guess. Classical mechanics is a special case of quantum mechanics, but quantum mechanics is not a special case of classical mechanics. For the material covered in this book, there are simpler ways to make an educated guess than canonical quantization. Being less mathematical, they are more understandable and intuitive. That might make them maybe more convincing too.

## A.15.7 Spin as a fermion system

There is, of course, not much analysis that can be done with a fermion system with only one single-particle state. There are only two independent system states; no fermion or one fermion.

However, there is at least one physical example of such a simple system. As noted in subsection A.15.1, a particle with spin $1 / 2$ like an electron can be
considered to be a model for it. The vacuum state $|0\rangle$ is the spin-down state of the electron. The state $|1\rangle$ is the spin-up state. This state has one unit $\hbar$ more angular momentum in the $z$-direction. If the electron is in a magnetic field, that additional momentum corresponds to a quantum of energy.

One reasonable question that can now be asked is whether the annihilation and creation operators, and the caHermitians, have some physical meaning for this system. They do.

Recall that for fermions, the Hamiltonian was given in terms of the caHermitians $\widehat{P}_{\mathrm{f}}$ and $\widehat{Q}_{\mathrm{f}}$ as

$$
H=E^{\mathrm{p}}\left(\frac{1}{2}-\mathrm{i}\left[\widehat{P}_{\mathrm{f}}, \widehat{Q}_{\mathrm{f}}\right]\right)+E_{\mathrm{ve}}
$$

The expression between parentheses is the particle count operator, equal to zero for the spin-down state and 1 for the spin up state. So the second term within parentheses in the Hamiltonian must be the spin in the $z$-direction, nondimensionalized by $\hbar$. (Recall that the spin in the $z$-direction has the values $\pm \frac{1}{2} \hbar$.) So apparently

$$
\left[\widehat{P}_{\mathrm{f}}, \widehat{Q}_{\mathrm{f}}\right]=\mathrm{i} \frac{\widehat{S}_{z}}{\hbar}
$$

Reasonably speaking then, the caHermitians themselves should be the nondimensional components of spin in the $x$ and $y$ directions,

$$
\widehat{P}_{\mathrm{f}}=\frac{\widehat{S}_{x}}{\hbar} \quad \widehat{Q}_{\mathrm{f}}=\frac{\widehat{S}_{y}}{\hbar}
$$

What other variables are there in this problem? And so it is. The commutator above, with the caHermitians equal to the nondimensional spin components, is known as the "fundamental commutation relation." Quantum field analysis is one way to understand that this relation applies.

Recall another property of the caHermitians for fermions:

$$
\widehat{P}_{\mathrm{f}}^{2}=\frac{1}{4} \quad \widehat{Q}_{\mathrm{f}}^{2}=\frac{1}{4}
$$

Apparently then, the square spin components are just constants with no uncertainty. Of course, that is no surprise since the only spin values in any direction are $\pm \frac{1}{2} \hbar$.

Finally consider the annihilation and creation operators, multiplied by $\hbar$ :

$$
\hbar \widehat{a}=\widehat{S}_{x}-\mathrm{i} \widehat{S}_{y} \quad \hbar \widehat{a}^{\dagger}=\widehat{S}_{x}+\mathrm{i} \widehat{S}_{y}
$$

Apparently these operators can remove, respectively add a unit $\hbar$ of angular momentum in the $z$-direction. That is often important in relativistic applications where a fermion emits or absorbs angular momentum in the $z$-direction. This changes the spin of the fermion and that can be expressed by the operators
above. So you will usually find $x$ and $y$ spin operators in the analysis of such processes.

Obviously, you can learn a lot by taking a quantum field type approach. To be sure, the current analysis applies only to particles with spin $1 / 2$. But advanced analysis of angular momentum in general is very similar to quantum field analysis, chapter 12. It resembles some mixture of the boson and fermion cases.

## A.15.8 More single particle states

The previous subsections discussed quantum field theory when there is just one type of single-particle state for the particles. This subsection considers the case that there is more than one. An index $n$ will be used to number the states.

Graphically, the case of multiple single-particle states was illustrated in figures A. 3 and A.4. There is now more than one box that particles can be in. Each box corresponds to one type of single-particle state $\psi_{n}^{\mathrm{p}}$.

Each such single-particle state has an occupation number $i_{n}$ that gives the number of particles in that state. A complete set of such occupation numbers form a Fock space basis ket

$$
\left|i_{1}, i_{2}, i_{3}, i_{4}, \ldots\right\rangle
$$

An annihilation operator $\widehat{a}_{n}$ and a creation operator $\widehat{a}_{n}^{\dagger}$ must be defined for every occupation number. The mathematical definition of these operators for bosons is

$$
\begin{align*}
& \widehat{a}_{\mathrm{b}, n}\left|i_{1}, i_{2}, \ldots, i_{n-1}, i_{n}, i_{n+1}, \ldots\right\rangle=\sqrt{i_{n}}\left|i_{1}, i_{2}, \ldots, i_{n-1}, i_{n}-1, i_{n+1}, \ldots\right\rangle \\
& \widehat{a}_{\mathrm{b}, n}^{\dagger}\left|i_{1}, i_{2}, \ldots, i_{n-1}, i_{n}-1, i_{n+1}, \ldots\right\rangle=\sqrt{i_{n}}\left|i_{1}, i_{2}, \ldots, i_{n-1}, i_{n}, i_{n+1}, \ldots\right\rangle \tag{A.60}
\end{align*}
$$

The commutator relations are

$$
\left[\begin{array}{lll}
{\left[\widehat{a}_{\mathrm{b}, n}, \widehat{a}_{\mathrm{b}, \underline{n}}\right]=0} & {\left[\widehat{a}_{\mathrm{b}, n}^{\dagger}, \widehat{a}_{\mathrm{b}, \underline{n}}^{\dagger}\right]=0} & {\left[\widehat{a}_{\mathrm{b}, n}, \widehat{a}_{\mathrm{b}, \underline{n}}^{\dagger}\right]=\delta_{n \underline{n}}}  \tag{A.61}\\
\hline
\end{array}\right.
$$

Here $\delta_{n \underline{n}}$ is the Kronecker delta, equal to one if $n=\underline{n}$, and zero in all other cases. These commutator relations apply for $n \neq \underline{n}$ because then the operators do unrelated things to different single-particle states; in that case it does not make a difference in what order you apply them. That makes the commutator zero. For $n=\underline{n}$, the commutator relations are unchanged from the case of just one single-particle state.

For fermions it is a bit more complex. The graphical representation of the example fermionic energy eigenfunction figure A. 4 cheats a bit, because it suggests that there is only one classical wave function for a given set of occupation
numbers. Actually, there are two variations, based on how the particles are ordered. The two are the same except that they have the opposite sign. Suppose that you create a particle in a state $n$; classically you would want to call that particle 1 , and then create a particle in a state $\underline{n}$, classically you would want to call it particle 2. Do the particle creation in the opposite order, and it is particle 1 that ends up in state $\underline{n}$ and particle 2 that ends up in state $n$. That means that the classical wave function will have changed sign. However, the Fock space ket will not unless you do something.

What you can do is define the annihilation and creation operators for fermions as follows:

```
\(\widehat{a}_{f, n}\left|i_{1}, i_{2}, \ldots, i_{n-1}, 0, i_{n+1}, \ldots\right\rangle=0\)
\(\widehat{a}_{f, n}\left|i_{1}, i_{2}, \ldots, i_{n-1}, 1, i_{n+1}, \ldots\right\rangle=(-1)^{i_{1}+i_{2}+\ldots+i_{n-1}}\left|i_{1}, i_{2}, \ldots, i_{n-1}, 0, i_{n+1}, \ldots\right\rangle\)
\(\widehat{a}_{f, n}^{\dagger}\left|i_{1}, i_{2}, \ldots, i_{n-1}, 0, i_{n+1}, \ldots\right\rangle=(-1)^{i_{1}+i_{2}+\ldots+i_{n-1}}\left|i_{1}, i_{2}, \ldots, i_{n-1}, 1, i_{n+1}, \ldots\right\rangle\)
\(\widehat{a}_{\mathrm{f}, n}^{\dagger}\left|i_{1}, i_{2}, \ldots, i_{n-1}, 1, i_{n+1}, \ldots\right\rangle=0\)
```

(A.62)

The only difference from the annihilation and creation operators for just one type of single-particle state is the potential sign changes due to the $(-1) \cdots$. It adds a minus sign whenever you swap the order of annihilating/creating two particles in different states. For the annihilation and creation operators of the same state, it may change both their signs, but that does nothing much: it leaves the important products such as $\widehat{a}_{n}^{\dagger} \widehat{a}_{n}$ and the anticommutators unchanged.

Of course, you can define the annihilation and creation operators with whatever sign you want, but putting in the sign pattern above may produce easier mathematics. In fact, there is an immediate benefit already for the anticommutator relations; they take the same form as for bosons, except with anticommutators instead of commutators:

$$
\begin{equation*}
\left\{\widehat{a}_{\mathrm{f}, n}, \widehat{a}_{\mathrm{f}, \underline{n}}\right\}=0 \quad\left\{\widehat{a}_{\mathrm{f}, n}^{\dagger}, \widehat{a}_{\mathrm{f}, \underline{n}}^{\dagger}\right\}=0 \quad\left\{\widehat{a}_{\mathrm{f}, n}, \widehat{a}_{\mathrm{f}, \underline{n}}^{\dagger}\right\}=\delta_{n \underline{n}} \tag{A.63}
\end{equation*}
$$

These relationships apply for $n \neq \underline{n}$ exactly because of the sign change caused by swapping the order of the operators. For $n=\underline{n}$, they are unchanged from the case of just one single-particle state.

The Hamiltonian for a system of noninteracting particles is like the one for just one single-particle state, except that you must now sum over all singleparticle states:

$$
\begin{equation*}
H=\sum_{n} E_{n}^{\mathrm{p}} \widehat{a}_{n}^{\dagger} \widehat{a}_{n}+E_{\mathrm{ve}, n} \tag{A.64}
\end{equation*}
$$

## A.15.9 Field operators

As noted at the start of this section, quantum field theory is particularly suited for relativistic applications because the number of particles can vary. However, in relativistic applications, it is often necessary to work in terms of position coordinates instead of single-particle energy eigenfunctions. To be sure, practical quantum field computations are usually worked out in terms of relativistic energy-momentum states. But to understand them requires consideration of position and time. Relativistic applications must make sure that coordinate systems moving at different speeds are physically equivalent and related through the Lorentz transformation. There is also the "causality problem," that an event at one location and time may not affect an event at another location and time that is not reachable with the speed of light. These conditions are posed in terms of position and time.

To handle such problems, the annihilation and creation operators can be converted into so-called "field operators" $\widehat{a}(\underline{\vec{r}})$ and $\widehat{a}^{\dagger}(\underline{\vec{r}})$ that annihilate respectively create particles at a given position $\overrightarrow{\underline{r}}$ in space. At least, roughly speaking that is what they do.

Now in classical quantum mechanics, a particle at a given position $\overrightarrow{\underline{r}}$ corresponds to a wave function that is nonzero at only that single point. And if the wave function is concentrated at the single point $\underline{\vec{r}}$, it must then be infinitely large at that point. Relaxing the normalization condition a bit, the appropriate infinitely concentrated mathematical function is called the "delta function," $\Psi$ $=\delta^{3}(\vec{r}-\vec{r})$, chapter 7.9. Here $\underline{\vec{r}}$ is the position of the particle and $\vec{r}$ the position at which the delta function is evaluated. If $\vec{r}$ is not equal to $\underline{\vec{r}}$, the delta function is zero; but at $\vec{r}=\overrightarrow{\vec{r}}$ it is infinite. A delta function by itself integrates to 1 ; its square magnitude would integrate to infinity. So it is definitely not normalized.

Like any function, a delta function can be written in terms of the singleparticle energy eigenfunctions $\psi_{n}$ as

$$
\delta^{3}(\vec{r}-\underline{\vec{r}})=\sum_{\text {all } n} c_{n} \psi_{n}(\vec{r})
$$

Here the coefficients $c_{n}$ can be found by taking inner products of both sides with an arbitrary eigenfunction $\psi_{\underline{n}}$. That gives, noting that orthonormality of the eigenfunctions only leaves $c_{\underline{n}}$ in the right-hand side,

$$
c_{\underline{n}}=\int \psi_{\underline{n}}^{*}(\vec{r}) \delta^{3}(\vec{r}-\underline{\vec{r}}) \mathrm{d}^{3} \vec{r}
$$

The integral is over all space. The index $\underline{n}$ can be renotated as $n$ since the above expression applies for all possible values of $\underline{n}$. Also, an inner product with a delta function can easily be evaluated. The inner product above simply picks out the value of $\psi_{n}^{*}$ at $\underline{\vec{r}}$. So

$$
c_{n}=\psi_{n}^{*}(\underline{\vec{r}})
$$

After all, $\vec{r}$ is the only position where the delta function is nonzero. So finally

$$
\delta^{3}(\vec{r}-\underline{\underline{r}})=\sum_{\text {all } n} \psi_{n}^{*}(\underline{\underline{r}}) \psi_{n}(\vec{r})
$$

Since $\psi_{n}^{*}(\overrightarrow{\underline{r}})$ is the amount of eigenfunction $\psi_{n}$ that must be created to create the delta function at $\underline{\underline{r}}$, the annihilation and creation field operators should presumably be

$$
\begin{equation*}
\widehat{a}(\underline{\vec{r}})=\sum_{n} \psi_{n}(\underline{\vec{r}}) \widehat{a}_{n} \quad \widehat{a}^{\dagger}(\underline{\vec{r}})=\sum_{n} \psi_{n}^{*}(\underline{\vec{r}}) \widehat{a}_{n}^{\dagger} \tag{A.65}
\end{equation*}
$$

The annihilation operator is again the Hermitian conjugate of the creation operator.

In the case of noninteracting particles in free space, the energy eigenfunctions are the momentum eigenfunctions $e^{\mathrm{i} \cdot \vec{r} / \hbar}$. The combination $\vec{k}=\vec{p} / \hbar$ is commonly referred to as the "wave number vector." Note that in infinite free space, the sums become integrals called Fourier transforms; see chapter 7.9 and 7.10 .1 for more details.

To check the appropriateness of the creation field operator as defined above, consider its consistency with classical quantum mechanics. A classical wave function $\Psi$ can always be written as a combination of the energy eigenfunctions:

$$
\Psi(\vec{r})=\sum_{n} c_{n} \psi_{n}(\vec{r}) \quad \text { where } \quad c_{n}=\int \psi_{n}^{*}(\vec{r}) \Psi(\vec{r}) \mathrm{d}^{3} \vec{r}
$$

That is the same as for the delta function case above. However, any normal function also always satisfies

$$
\Psi(\vec{r})=\int \Psi(\underline{\vec{r}}) \delta(\vec{r}-\overrightarrow{\vec{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}}
$$

That is because the delta function picks out the value of $\Psi(\underline{\vec{r}})$ at $\overrightarrow{\underline{r}}=\vec{r}$ as also already noted above. You can look at the expression above as follows: $\Psi(\vec{r})$ is a combination of position states $\delta(\vec{r}-\vec{r}) \mathrm{d}^{3} \underline{\vec{r}}$ with coefficients $\Psi(\underline{\vec{r}})$. So here the classical wave function is written as a combination of position states instead of energy states.

Now this needs to be converted to quantum field form. The classical wave function then becomes a combination $|\Psi\rangle$ of Fock space kets. But by definition, the creation field operator $\widehat{a}^{\dagger}(\underline{\underline{r}})$ applied on the vacuum state $|0\rangle$ should produce the Fock space equivalent of a delta function at $\underline{\vec{r}}$. So the above classical wave function should convert to a Fock space wave function as

$$
|\Psi\rangle=\int \Psi(\underline{\vec{r}}) \widehat{a}^{\dagger}(\underline{\vec{r}})|0\rangle \mathrm{d}^{3} \underline{\vec{r}}
$$

To check that, substitute in the definition of the creation field operator:

$$
|\Psi\rangle=\sum_{n} \int \psi_{n}^{*}(\underline{\vec{r}}) \Psi(\overrightarrow{\underline{r}}) \mathrm{d}^{3} \underline{\underline{r}} \widehat{a}_{n}^{\dagger}|0\rangle
$$

But $\widehat{a}_{n}^{\dagger}|0\rangle$ is the Fock space equivalent of the classical energy eigenfunction $\psi_{n}$. The reason is that $\widehat{a}_{n}^{\dagger}$ puts exactly one particle in the state $\psi_{n}$. And the integral is the same coefficient $c_{n}$ of this energy eigenstate as in the classical case. So the creation field operator as defined does produce the correct combination of energy states.

As a check on the appropriateness of the annihilation field operator, consider the Hamiltonian. The Hamiltonian of noninteracting particles satisfies

$$
H|\Psi\rangle=\sum_{n} \widehat{a}_{n}^{\dagger} E_{n}^{\mathrm{p}} \widehat{a}_{n}|\Psi\rangle
$$

Here $E_{n}^{\mathrm{p}}$ is the single-particle energy and $|\Psi\rangle$ stands for a state described by Fock space kets. The ground state energy was taken zero for simplicity. Note the critical role of the trailing $\widehat{a}_{n}$. States with no particles should not produce energy. The trailing $\widehat{a}_{n}$ ensures that they do not; it produces 0 when state $n$ has no particles.

In terms of annihilation and creation field operators, you would like the Hamiltonian to be defined similarly:

$$
H|\Psi\rangle=\int \widehat{a}^{\dagger}(\vec{r}) H^{\mathrm{p}} \widehat{a}(\vec{r})|\Psi\rangle \mathrm{d}^{3} \vec{r}
$$

Note that the sum has become an integral, as $\vec{r}$ is a continuous variable. Also, the single-particle energy $E^{\mathrm{p}}$ has become the single-particle Hamiltonian; that is necessary because position states are not energy eigenstates with definite energy. The trailing $\widehat{a}(\vec{r})$ ensures that positions with no particles do not contribute to the Hamiltonian.

Now, if the definitions of the field operators are right, this Hamiltonian should still produce the same answer as before. Substituting in the definitions of the field operators gives

$$
H|\Psi\rangle=\int \sum_{\underline{n}} \psi_{\underline{\underline{r}}}^{*}(\vec{r}) \widehat{a}_{\underline{\underline{n}}}^{\dagger} H^{\mathrm{p}} \sum_{n} \psi_{n}(\vec{r}) \widehat{a}_{n}|\Psi\rangle \mathrm{d}^{3} \vec{r}
$$

The single-particle Hamiltonian $H^{\mathrm{p}}$ applied on $\psi_{n}$ gives a factor $E_{n}^{\mathrm{p}}$. And orthonormality of the eigenfunctions implies that the integral is zero unless $\underline{n}=$ $n$. And in that case, the square energy eigenfunction magnitude integrates to 1. That then implies that the Hamiltonian is indeed the same as before.

The above argument roughly follows [43, pp. 22-29], but note that this source puts a tilde on $\widehat{a}_{n}^{\dagger}$ and $\widehat{a}_{n}$ as defined here. See also [35, pp. 19-24] for a somewhat
different approach, with a somewhat different definition of the annihilation and creation field operators.

One final question that is much more messy is in what sense these operators really create or annihilate a particle localized at $\underline{\underline{r}}$. An answer can be given using arguments like those used for the electromagnetic magnetic field in $\{\mathrm{A} .23 .4\}$. In particular, you want to leave some uncertainty in the number of particles created at position $\underline{\vec{r}}$. Then the expectation values for the observable field do become strongly localized near position $\underline{\vec{r}}$. The details will be skipped. But qualitatively, the fact that in quantum field theory there is uncertainty in the number of particles does of course add to the uncertainty in the measured quantities.

A big advantage of the way the annihilation and creation operators were defined now shows up: the annihilation and creation field operators satisfy essentially the same (anti)commutation relations. In particular

$$
\begin{align*}
& \begin{array}{|lll}
\left.\hline \widehat{a}_{\mathrm{b}}(\vec{r}) \widehat{a}_{\mathrm{b}}(\underline{\vec{r}})\right]=0 & {\left[\widehat{a}_{\mathrm{b}}^{\dagger}(\vec{r}) \widehat{a}_{\mathrm{b}}^{\dagger}(\vec{r})\right]=0} & {\left[\widehat{a}_{\mathrm{b}}(\vec{r}) \widehat{a}_{\mathrm{b}}^{\dagger}(\underline{\vec{r}})\right]=\delta^{3}(\vec{r}-\underline{\vec{r}})} \\
\hline
\end{array}  \tag{A.66}\\
& \left\{\widehat{a}_{\mathrm{f}}(\vec{r}) \widehat{a}_{\mathrm{f}}(\underline{\vec{r}})\right\}=0 \quad\left\{\widehat{a}_{\mathrm{f}}^{\dagger}(\vec{r}) \widehat{a}_{\mathrm{f}}^{\dagger}(\underline{\vec{r}})\right\}=0 \quad\left\{\widehat{a}_{\mathrm{f}}(\vec{r}) \widehat{a}_{\mathrm{f}}^{\dagger}(\underline{\vec{r}})\right\}=\delta^{3}(\vec{r}-\underline{\vec{r}})
\end{align*}
$$

In other references you might see an additional constant multiplying the threedimensional delta function, depending on how the position and momentum eigenfunctions were normalized.

To check these commutators, plug in the definitions of the field operators. Then the zero commutators above follow immediately from the ones for $a_{n}$ and $\widehat{a}_{n}^{\dagger},(\mathrm{A} .61)$ and (A.63). For the nonzero commutator, multiply by a completely arbitrary function $f(\vec{r})$ and integrate over $\vec{r}$. That gives $f(\underline{\vec{r}})$, which is the same result as obtained from integrating against $\delta^{3}(\vec{r}-\vec{r})$. That can only be true for every function $f$ if the commutator is the delta function. (In fact, producing $f(\underline{\vec{r}})$ for any $f(\vec{r})$ is exactly the way how a delta function would be defined by a conscientious mathematician.)

Field operators help solve a vexing problem for relativistic quantum mechanics: how to put space and time on equal footing, [43, p. 7ff]. Relativity unavoidably mixes up position and time. But classical quantum mechanics, as covered in this book, needs to keep them rigidly apart.

Right at the beginning, this book told you that observable quantities are the eigenvalues of Hermitian operators. That was not completely true, there is an exception. Spatial coordinates are indeed the eigenvalues of Hermitian position operators, chapter 7.9. But time is not an eigenvalue of an operator. When this book wrote a wave function as, say, $\Psi\left(\vec{r}, S_{z} ; t\right)$ the time $t$ was just a label. It indicated that at any given time, you have some wave function. Then you can apply purely spatial operators like $x, \widehat{p}_{x}, H$, etcetera to find out things about the measurable position, momentum, energy, etcetera at that time. At a different time you have a different wave function, for which you can do the same things. Time itself is left out in the cold.

Correspondingly, the classical Schrödinger equation $\mathrm{i} \hbar \partial \Psi / \partial t=H \Psi$ treats space and time quite different. The spatial derivatives, in $H$, are second order, but the time derivative is first order. The first-order time derivative describes the change from one spatial wave function to the next one, a time $\partial t$ later. Of course, you cannot think of the spatial derivatives in the same way. Even if there was only one spatial coordinate instead of three, the second order spatial derivatives would not represent a change of wave function from one position to the next.

The different treatment of time and space causes problems in generalizing the Schrödinger equation to the relativistic case.

For spinless particles, the simplest generalization of the Schrödinger equation is the Klein-Gordon equation, $\{\mathrm{A} .14\}$. However, this equation brings in states with negative energies, including negative rest mass energies. That is a problem. For example, what prevents a particle from transitioning to states of more and more negative energy, releasing infinite amounts of energy in the process? There is no clean way to deal with such problems within the bare context of the KleinGordon equation.

There is also the matter of what to make of the Klein-Gordon wave function. It appears as if a wave function for a single particle is being written down, like it would be for the Schrödinger equation. But for the Schrödinger equation the integrated square magnitude of the wave function is 1 and stays 1 . That is taken to mean that the probability of finding the particle is 1 if you look everywhere. But the Klein-Gordon equation does not preserve the integrated square magnitude of the wave function in time. That is not surprising, since in relativity particles can be created out of energy or annihilated. But if that is so, in what sense could the Klein-Gordon equation possibly describe a wave function for a single, (i.e. exactly 1 ), particle?
(Of course, this is not a problem for single-particle energy eigenstates. Energy eigenstates are stationary, chapter 7.1.4. It is also not a problem if there are only particle states, or only antiparticle states, $\{\mathrm{D} .32\}$. The real problems start when you try to add perturbations to the equation.)

For fermions with spin $1 / 2$, the appropriate generalization of the Schrödinger equation is the Dirac equation, chapter 12.12. However, there are still those negative-energy solutions. Dirac postulated that all, infinitely many, negative energy states in the universe are already filled with electrons. That is obviously a rather ugly assumption. Worse, it would not work for bosons. Any number of bosons can go into a single state, they cannot fill them.

Quantum field theory can put space and time on a more equal footing, especially in the Heisenberg formulation, \{A.12\}. This formulation pushes time from the wave function onto the operator. To see how this works, consider some arbitrary inner product involving a Schrödinger operator $\widehat{A}$ :
(Why look at inner products? Simply put, if you get all inner products right, you get the quantum mechanics right. Anything in quantum mechanics can be found by taking the right inner product.) Now recall that if a wave function $\Psi$ has definite energy $E$, it varies in time as $e^{-\mathrm{i} E t / \hbar} \Psi_{0}$ where $\Psi_{0}$ is independent of time, chapter 7.1.2. If $\Psi$ does not have definite energy, you can replace $E$ in the exponential by the Hamiltonian $H$. (Exponentials of operators are defined by their Taylor series.) So the inner product becomes

$$
\left\langle\Phi_{0} \mid e^{\mathrm{i} H t / \hbar} \widehat{A} e^{-\mathrm{i} H t / \hbar} \Psi_{0}\right\rangle
$$

(Recall that i changes sign when taken to the other side of an inner product.) The Heisenberg $\widetilde{A}$ operator absorbs the exponentials:

$$
\widetilde{A} \equiv e^{\mathrm{i} H t / \hbar} \widehat{A} e^{-\mathrm{i} H t / \hbar}
$$

Now note that if $\widehat{A}$ is a field operator, the position coordinates in it are not Hamiltonian operators. They are labels just like time. They label what position the particle is annihilated or created at. So space and time are now treated much more equally

Here is where the term "field" in "quantum field theory" comes from. In classical physics, a field is a numerical function of position. For example, a pressure field in a moving fluid has a value, the pressure, at each position. An electric field has three values, the components of the electric field, at each position. However, in quantum field theory, a "field" does not consist of values, but of operators. Each position has one or more operator associated with it. Each particle type is associated with a "field." This field will involve both creation and annihilation operators of that particle, or the associated antiparticle, at each position.

Within the quantum field framework, equations like the Klein-Gordon and Dirac ones can be given a clear meaning. The eigenfunctions of these equations give states that particles can be in. Since energy eigenfunctions are stationary, conservation of probability is not an issue.

It may be mentioned that there is an alternate way to put space and time on an equal footing, [43, p. 10]. Instead of turning spatial coordinates into labels, time can be turned into an operator. However, clearly wave functions do evolve with time, even if different observers may disagree about the details. So what to make of the time parameter in the Schrödinger equation? Relativity offers an answer. The time in the Schrödinger equation can be associated with the "proper" time of the considered particle. That is the time measured by an observer moving along with the particle, chapter 1.2.2. The time measured by an observer in an inertial coordinate system is then promoted to an operator. All this can be done. In fact, it is the starting point of the so-called "string theory." In string theory, a second parameter is added to proper time. You might think of the second parameter as the arc length along a string that wiggles around in
time. However, approaches along these lines are extremely complicated. Quantum field theory remains the workhorse of relativistic quantum mechanics.

## A.15.10 Nonrelativistic quantum field theory

This example exercise from Srednicki [43, p. 11] uses quantum field theory to describe nonrelativistic quantum mechanics. It illustrates some of the mathematics that you will encounter in quantum field theories.

The objective is to convert the classical nonrelativistic Schrödinger equation for $I$ particles,

$$
\begin{equation*}
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=H_{\mathrm{cl}} \Psi \tag{A.68}
\end{equation*}
$$

into quantum field form. The classical wave function has the positions of the numbered particles and time as arguments:

$$
\begin{equation*}
\text { classical quantum mechanics: } \Psi=\Psi\left(\vec{r}_{1}, \vec{r}_{2}, \vec{r}_{3}, \ldots, \vec{r}_{I} ; t\right) \tag{A.69}
\end{equation*}
$$

where $\vec{r}_{1}$ is the position of particle $1, \vec{r}_{2}$ is the position of particle 2 , etcetera. (You could include particle spin within the vectors $\vec{r}$ if you want. But particle spin is in fact relativistic, chapter 12.12.) The classical Hamiltonian is

$$
\begin{equation*}
H_{\mathrm{cl}}=\sum_{i=1}^{I}\left(\frac{\hbar^{2}}{2 m} \nabla_{i}^{2}+V_{\mathrm{ext}}\left(\vec{r}_{i}\right)\right)+\frac{1}{2} \sum_{i=1}^{I} \sum_{\substack{i=1 \\ i \neq i}}^{I} V\left(\vec{r}_{i}-\vec{r}_{\underline{i}}\right) \tag{A.70}
\end{equation*}
$$

The $\nabla_{i}^{2}$ term represents the kinetic energy of particle number $i$. The potential $V_{\text {ext }}$ represents forces on the particles by external sources, while the potential $V$ represents forces between particles.

In quantum field theory, the wave function for exactly $I$ particles takes the form

$$
\begin{equation*}
|\Psi\rangle=\int_{\text {all } \vec{r}_{1}} \ldots \int_{\text {all } \vec{r}_{I}} \Psi\left(\vec{r}_{1}, \vec{r}_{2}, \ldots, \vec{r}_{I} ; t\right) \widehat{a}^{\dagger}\left(\vec{r}_{1}\right) \widehat{a}^{\dagger}\left(\vec{r}_{2}\right) \ldots \widehat{a}^{\dagger}\left(\vec{r}_{I}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1} \ldots \mathrm{~d}^{3} \vec{r}_{I} \tag{A.71}
\end{equation*}
$$

Here the ket $|\Psi\rangle$ in the left hand side is the wave function expressed as a Fock space ket. The ket $|\overrightarrow{0}\rangle$ to the far right is the vacuum state where there are no particles. However, the preceding creation operators then put in the particles at positions $\vec{r}_{1}, \vec{r}_{2}, \ldots$. That produces a ket state with the particles at these positions.

The quantum amplitude of that ket state is the preceding $\Psi$, a function, not a ket. This is the classical nonrelativistic wave function, the one found in the nonrelativistic Schrödinger equation. After all, the classical wave function is supposed to give the quantum amplitude for the particles to be at given
positions. In particular, its square magnitude gives the probability for them to be at given positions.

So far, all this gives just the ket for one particular set of particle positions. But then it is integrated over all possible particle positions.

The Fock space Schrödinger equation for $|\Psi\rangle$ takes the form

$$
\begin{equation*}
\mathrm{i} \hbar \frac{\mathrm{~d}|\Psi\rangle}{\mathrm{d} t}=H|\Psi\rangle \tag{A.72}
\end{equation*}
$$

That looks just like the classical case. However, the Fock space Hamiltonian $H$ is defined by

$$
\begin{align*}
H|\Psi\rangle= & \int_{\text {all } \vec{r}} \widehat{a}^{\dagger}(\vec{r})\left[-\frac{\hbar^{2}}{2 m} \nabla_{\vec{r}}^{2}+V_{\text {ext }}(\vec{r})\right] \widehat{a}(\vec{r})|\Psi\rangle \mathrm{d}^{3} \vec{r} \\
& +\frac{1}{2} \int_{\text {all } \vec{r}} \int_{\text {all }} \widehat{a}^{\dagger}(\vec{r}) \widehat{a}^{\dagger}(\underline{\vec{r}}) V(\vec{r}-\vec{r}) \widehat{a}(\underline{\vec{r}}) \widehat{a}(\vec{r})|\Psi\rangle \mathrm{d}^{3} \vec{r} \mathrm{~d}^{3} \underline{\vec{r}} \tag{A.73}
\end{align*}
$$

In order for this to make some sense, note that the Fock space ket $|\Psi\rangle$ is an object that allows you to annihilate or create a particle at any arbitrary location $\vec{r}$. That is because it is a linear combination of basis kets that allow the same thing.

The goal is now to show that the Schrödinger equation (A.72) for the Fock space ket $|\Psi\rangle$ produces the classical Schrödinger equation (A.68) for classical wave function $\Psi(\ldots)$. This needs to be shown whether it is a system of identical bosons or a system of identical fermions.

Before trying to tackle this problem, it is probably a good idea to review representations of functions using delta functions. As the simplest example, a wave function $\Psi(x)$ of just one spatial coordinate can be written as

$$
\Psi(x)=\int_{\text {all } \underline{x}} \underbrace{\Psi(\underline{x})}_{\text {coefficients }} \underbrace{\delta(x-\underline{x}) \mathrm{d} \underline{x}}_{\text {basis states }}
$$

The way to think about the above integral expression for $\Psi(x)$ is just like you would think about a vector in three dimensions being written as $\vec{v}=v_{1} \hat{\imath}+v_{2} \hat{\jmath}+$ $v_{3} \hat{k}$ or a vector in 30 dimensions as $\vec{v}=\sum_{i=1}^{30} v_{i} \hat{\imath}_{i}$. The $\Psi(\underline{x})$ are the coefficients, corresponding to the $v_{i}$-components of the vectors. The $\delta(x-\underline{x}) \mathrm{d} \underline{x}$ are the basis states, just like the unit vectors $\hat{\imath}_{i}$. If you want a graphical illustration, each $\delta(x-\underline{x}) \mathrm{d} \underline{x}$ would correspond to one spike of unit height at a position $\underline{x}$ in figure 2.3, and you need to sum (integrate) over them all, with their coefficients, to get the total vector.

Now assume that $H_{1}$ is the one-dimensional classical Hamiltonian. Then $H_{1} \Psi(x)$ is just another function of $x$, so it can be written similarly:

$$
H_{1} \Psi(x)=\int_{\text {all } \underline{x}} H_{1} \Psi(\underline{x}) \delta(x-\underline{x}) \mathrm{d} \underline{x}
$$

$$
=\int_{\text {all } \underline{x}}\left[-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \Psi(\underline{x})}{\partial \underline{x}^{2}}+V_{\text {ext }}(\underline{x}) \Psi(\underline{x})\right] \delta(x-\underline{x}) \mathrm{d} \underline{x}
$$

Note that the Hamiltonian acts on the coefficients, not on the basis states.
You may be surprised by this, because if you straightforwardly apply the Hamiltonian $H_{1}$, in terms of $x$, on the integral expression for $\Psi(x)$, you get:

$$
H_{1} \Psi(x)=\int_{\text {all } \underline{x}} \Psi(\underline{x})\left[-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \delta(x-\underline{x})}{\partial x^{2}}+V_{\mathrm{ext}}(x) \delta(x-\underline{x})\right] \mathrm{d} \underline{x}
$$

Here the Hamiltonian acts on the basis states, not the coefficients.
However, the two expressions are indeed the same. Whether there is an $x$ or $\underline{x}$ in the potential does not make a difference, because the multiplying delta function is only nonzero when $x=\underline{x}$. And you can use a couple of integrations by parts to get the derivatives off the delta function and on $\Psi(\underline{x})$. Note here that differentiation of the delta function with respect to $x$ or $\underline{x}$ is the same save for a sign change.

The bottom line is that you do not want to use the expression in which the Hamiltonian is applied to the basis states, because derivatives of delta functions are highly singular objects that you should not touch with a ten foot pole. (And if you have mathematical integrity, you would not really want to use delta functions either. At least not the way that they do it in physics. But in that case, you better forget about quantum field theory.)

It may here be noted that if you do have to differentiate an integral for a function $\Psi(x)$ in terms of delta functions, there is a much better way to do it. If you first make a change of integration variable to $u=\underline{x}-x$, the differentiation is no longer on the nasty delta functions.

Still, there is an important observation here: you might either know what an operator does to the coefficients, leaving the basis states untouched, or what it does to the basis states, leaving the coefficients untouched. Either one will tell you the final effect of the operator, but the mathematics is different.

Now that the general terms of engagement have been discussed, it is time to start solving Srednicki's problem. The Fock space wave function ket can be thought of the same way as the example:

$$
|\Psi\rangle=\int_{\text {all } \vec{r}_{1}} \ldots \int_{\text {all }} \vec{r}_{I} \underbrace{\Psi\left(\vec{r}_{1}, \vec{r}_{2}, \ldots, \vec{r}_{I} ; t\right)}_{\text {coefficients }} \underbrace{\widehat{a}^{\dagger}\left(\vec{r}_{1}\right) \widehat{a}^{\dagger}\left(\vec{r}_{2}\right) \ldots \widehat{a}^{\dagger}\left(\vec{r}_{I}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1} \ldots \mathrm{~d}^{3} \vec{r}_{I}}_{\text {Fock space basis state kets }}
$$

The basis states are Fock space kets in which a particle called 1 is in a delta function at a position $\vec{r}_{1}$, a particle called 2 in a delta function at position $\vec{r}_{2}$, etcetera. The classical wave function $\Psi(\ldots)$ gives the quantum amplitude of each such ket. The integration gives $|\Psi\rangle$ as a combined ket.

Note that Fock states do not know about particle numbers. A Fock basis state is the same regardless what the classical wave function calls the particles.

It means that the same Fock basis state ket reappears in the integration above at all swapped positions of the particles. (For fermions read: the same except possibly a sign change, since swapping the order of application of any two $\widehat{a}^{\dagger}$ creation operators flips the sign, compare subsection A.15.2.) This will become important at the end of the derivation.

The left hand side of the Fock space Schrödinger equation (A.72) is evaluated by pushing the time derivative inside the above integral for $|\Psi\rangle$ :
$\mathrm{i} \hbar \frac{\mathrm{d}|\Psi\rangle}{\mathrm{d} t}=\int_{\text {all } \vec{r}_{1}} \ldots \int_{\text {all } \vec{r}_{I}} \mathrm{i} \hbar \frac{\partial \Psi\left(\vec{r}_{1}, \vec{r}_{2}, \ldots, \vec{r}_{I} ; t\right)}{\partial t} \widehat{a}^{\dagger}\left(\vec{r}_{1}\right) \ldots \widehat{a}^{\dagger}\left(\vec{r}_{I}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1} \ldots \mathrm{~d}^{3} \vec{r}_{I}$
so the time derivative drops down on the classical wave function in the normal way.

Applying the Fock-space Hamiltonian (A.73) on the wave function is quite a different story, however. It is best to start with just a single particle:

$$
H|\Psi\rangle=\int_{\text {all } \vec{r}} \int_{\text {all } \vec{r}_{1}} \widehat{a}^{\dagger}(\vec{r})\left[-\frac{\hbar^{2}}{2 m} \nabla_{\vec{r}}^{2}+V_{\text {ext }}(\vec{r})\right] \widehat{a}(\vec{r}) \Psi\left(\vec{r}_{1} ; t\right) \widehat{a}^{\dagger}\left(\vec{r}_{1}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}
$$

The field operator $\widehat{a}(\vec{r})$ may be pushed past the classical wave function $\Psi(\ldots)$; $\widehat{a}(\vec{r})$ is defined by what it does to the Fock basis states while leaving their coefficients, here $\Psi(\ldots)$, unchanged. That gives:

$$
H|\Psi\rangle=\int_{\text {all } \vec{r}} \int_{\text {all } \vec{r}_{1}} \widehat{a}^{\dagger}(\vec{r})\left[-\frac{\hbar^{2}}{2 m} \nabla_{\vec{r}}^{2}+V_{\text {ext }}(\vec{r})\right] \Psi\left(\vec{r}_{1} ; t\right) \widehat{a}(\vec{r}) \widehat{a}^{\dagger}\left(\vec{r}_{1}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}
$$

It is now that the (anti)commutator relations become useful. The fact that for bosons $\left[\widehat{a}(\vec{r}) \widehat{a}^{\dagger}\left(\vec{r}_{1}\right)\right]$ or for fermions $\left\{\widehat{a}(\vec{r}) \widehat{a}^{\dagger}\left(\vec{r}_{1}\right)\right\}$ equals $\delta^{3}\left(\vec{r}-\vec{r}_{1}\right)$ means that you can swap the order of these operators as long as you add a delta function term:

$$
\begin{aligned}
& \widehat{a}_{\mathrm{b}}(\vec{r}) \widehat{a}_{\mathrm{b}}^{\dagger}\left(\vec{r}_{1}\right)=\widehat{a}_{\mathrm{b}}^{\dagger}\left(\vec{r}_{1}\right) \widehat{a}_{\mathrm{b}}(\vec{r})+\delta^{3}\left(\vec{r}-\vec{r}_{1}\right) \\
& \widehat{a}_{\mathrm{f}}(\vec{r}) \widehat{a}_{\mathrm{f}}^{\dagger}\left(\vec{r}_{1}\right)=-\widehat{a}_{\mathrm{f}}^{\dagger}\left(\vec{r}_{1}\right) \widehat{a}_{\mathrm{f}}(\vec{r})+\delta^{3}\left(\vec{r}-\vec{r}_{1}\right)
\end{aligned}
$$

But when you swap the order of these operators, you get a factor $\widehat{a}(\vec{r})|\overrightarrow{0}\rangle$. That is zero, because applying an annihilation operator on the vacuum state produces zero, figure A.6. So the delta function term is all that remains:

$$
H|\Psi\rangle=\int_{\text {all } \vec{r}} \int_{\text {all } \vec{r}_{1}} \widehat{a}^{\dagger}(\vec{r})\left[-\frac{\hbar^{2}}{2 m} \nabla_{\vec{r}}^{2}+V_{\text {ext }}(\vec{r})\right] \Psi\left(\vec{r}_{1} ; t\right) \delta^{3}\left(\vec{r}-\vec{r}_{1}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}
$$

Integration over $\vec{r}_{1}$ now picks out the value $\Psi(\vec{r}, t)$ from function $\Psi\left(\vec{r}_{1}, t\right)$, as delta functions do, so

$$
H|\Psi\rangle=\int_{\text {all } \vec{r}} \widehat{a}^{\dagger}(\vec{r})\left[-\frac{\hbar^{2}}{2 m} \nabla_{\vec{r}}^{2}+V_{\text {ext }}(\vec{r})\right] \Psi(\vec{r} ; t)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}
$$

Note that the term in square brackets is the classical Hamiltonian $H_{\mathrm{cl}}$ for a single particle. The creation operator $\widehat{a}^{\dagger}(\vec{r})$ can be pushed over the coefficient $H_{\mathrm{cl}} \Psi(\vec{r} ; t)$ of the vacuum state ket for the same reason that $\widehat{a}(\vec{r})$ could be pushed over $\Psi\left(\vec{r}_{1} ; t\right)$; these operators do not affect the coefficients of the Fock states, just the states themselves.

Then, renotating $\vec{r}$ to $\vec{r}_{1}$, the grand total Fock state Schrödinger equation for a system of one particle becomes

$$
\begin{aligned}
& \int_{\text {all } \vec{r}_{1}} \mathrm{i} \hbar \frac{\partial \Psi\left(\vec{r}_{1} ; t\right)}{\partial t} \widehat{a}^{\dagger}\left(\vec{r}_{1}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1}= \\
& \int_{\text {all } \vec{r}_{1}}\left[-\frac{\hbar^{2}}{2 m} \nabla_{\vec{r}_{1}}^{2}+V_{\text {ext }}\left(\vec{r}_{1}\right)\right] \Psi\left(\vec{r}_{1} ; t\right) \widehat{a}^{\dagger}\left(\vec{r}_{1}\right)|\overrightarrow{0}\rangle \mathrm{d}^{3} \vec{r}_{1}
\end{aligned}
$$

It is now seen that if the classical wave function $\Psi\left(\vec{r}_{1} ; t\right)$ satisfies the classical Schrödinger equation, the Fock-space Schrödinger equation above is also satisfied. And so is the converse: if the Fock-space equation above is satisfied, the classical wave function must satisfy the classical Schrödinger equation. The reason is that Fock states can only be equal if the coefficients of all the basis states are equal, just like vectors can only be equal if all their components are equal. Here that means that the coefficient of $\widehat{a}^{\dagger}\left(\vec{r}_{1}\right)|\overrightarrow{0}\rangle$ must be the same at both sides, for every single value of $\vec{r}_{1}$.

If there is more than one particle, however, the equivalent latter conclusion is not justified. Remember that the same Fock space kets reappear in the integration at swapped positions of the particles. It now makes a difference. The following example from basic vectors illustrates the problem: yes, $a \hat{\imath}=a^{\prime} \hat{\imath}$ implies that $a=a^{\prime}$, but no, $(a+b) \hat{\imath}=\left(a^{\prime}+b^{\prime}\right) \hat{\imath}$ does not imply that $a=a^{\prime}$ and $b=b^{\prime}$; it merely implies that $a+b=a^{\prime}+b^{\prime}$. However, if additionally it is postulated that the classical wave function has the symmetry properties appropriate for bosons or fermions, then the Fock-space Schrödinger equation does imply the classical one. In terms of the example from vectors, $(a+a) \hat{\imath}=$ $\left(a^{\prime}+a^{\prime}\right) \hat{\imath}$ does imply that $a=a^{\prime}$.

In any case, the problem has been solved for a system with one particle. Doing it for $I$ particles will be left as an exercise for your mathematical skills.

## A. 16 The adiabatic theorem

An adiabatic system is a system whose Hamiltonian changes slowly in time. Despite the time dependence of the Hamiltonian, the wave function can still be written in terms of the energy eigenfunctions $\psi_{\vec{n}}$ of the Hamiltonian, because the eigenfunctions are complete. But since the Hamiltonian changes with time, so do the energy eigenfunctions. And that affects how the coefficients of the eigenfunctions evolve in time.

In particular, in the adiabatic approximation, the wave function of a system can be written as, $\{\mathrm{D} .34\}$ :

$$
\begin{equation*}
\Psi=\sum_{\vec{n}} c_{\vec{n}}(0) e^{\mathrm{i} \theta_{\vec{n}}} e^{\mathrm{i} \gamma_{\vec{n}}} \psi_{\vec{n}} \quad \theta_{\vec{n}}=-\frac{1}{\hbar} \int E_{\vec{n}} \mathrm{~d} t \quad \gamma_{\vec{n}}=\mathrm{i} \int\left\langle\psi_{\vec{n}} \mid \psi_{\vec{n}}^{\prime}\right\rangle \mathrm{d} t \tag{A.74}
\end{equation*}
$$

where the $c_{\vec{n}}(0)$ are constants. The angle $\theta_{\vec{n}}$ is called the "dynamic phase" while the angle $\gamma_{n}$ is called the "geometric phase." Both phases are real. The prime on $\psi_{\vec{n}}$ indicates the time derivative of the eigenfunction.

Note that if the Hamiltonian does not depend on time, the above expression simplifies to the usual solution of the Schrödinger equation as given in chapter 7.1.2. In particular, in that case the geometric phase is zero and the dynamic phase is the usual $-E_{\vec{n}} t / \hbar$.

Even if the Hamiltonian depends on time, the geometric phase is still zero as long as the Hamiltonian is real. The reason is that real Hamiltonians have real eigenfunctions; then $\gamma_{\vec{n}}$ can only be real, as it must be, if it is zero.

If the geometric phase is nonzero, you may be able to play games with it. Suppose first that Hamiltonian changes with time because some single parameter $\lambda$ that it depends on changes with time. Then the geometric phase can be written as

$$
\gamma_{\vec{n}}=\mathrm{i} \int\left\langle\psi_{\vec{n}} \left\lvert\, \frac{\partial \psi_{\vec{n}}}{\partial \lambda}\right.\right\rangle \mathrm{d} \lambda \equiv \int f(\lambda) \mathrm{d} \lambda
$$

It follows that if you bring the system back to the state it started out at, the total geometric phase is zero, because the limits of integration will be equal.

But now suppose that not one, but a set of parameters $\vec{\lambda}=\left(\lambda_{1}, \lambda_{2}, \ldots\right)$ changes during the evolution. Then the geometric phase is

$$
\gamma_{\vec{n}}=\mathrm{i} \int\left\langle\psi_{\vec{n}} \mid \nabla_{\vec{\lambda}} \psi_{\vec{n}}\right\rangle \cdot \mathrm{d} \vec{\lambda} \equiv \int f_{1}\left(\lambda_{1}, \lambda_{2}, \ldots\right) \mathrm{d} \lambda_{1}+f_{2}\left(\lambda_{1}, \lambda_{2}, \ldots\right) \mathrm{d} \lambda_{2}+\ldots
$$

and that is not necessarily zero when the system returns to the same state it started out at. In particular, for two or three parameters, you can immediately see from the Stokes' theorem that the integral along a closed path will not normally be zero unless $\nabla_{\vec{\lambda}} \times \vec{f}=0$. The geometric phase that an adiabatic system picks up during such a closed path is called "Berry's phase."

You might assume that it is irrelevant since the phase of the wave function is not observable anyway. But if a beam of particles is sent along two different paths, the phase difference between the paths will produce interference effects when the beams merge again.

Systems that do not return to the same state when they are taken around a closed loop are not just restricted to quantum mechanics. A classical example is the Foucault pendulum, whose plane of oscillation picks up a daily angular deviation when the motion of the earth carries it around a circle. Such systems are called "nonholonomic" or "anholonomic."

## A. 17 The virial theorem

The virial theorem relates the expectation kinetic energy of a quantum system to the potential. That is of theoretical interest, as well as important for computational methods like "density functional theory."

Consider a quantum system in a state of definite energy $E$. In other words, consider a quantum system in a stationary state. It does not have to be the ground state. The quantum system will be assumed to be in infinite space.

To keep it simple, for now assume that there is a single particle with position vector $\vec{r}$ in a potential $V(\vec{r})$. That covers our previous examples of the harmonic oscillator and the hydrogen atom.

Then the virial theorem relates the expectation kinetic energy $\langle T\rangle$ to the potential $V$ as follows:

$$
\begin{equation*}
2\langle T\rangle=\langle\vec{r} \cdot \nabla V\rangle \tag{A.75}
\end{equation*}
$$

(Recall that nabla, $\nabla$, is just the multi-dimensional derivative $\partial / \partial \vec{r}$.) The above formula can be very useful.

For example, consider the harmonic oscillator. There

$$
V=\frac{1}{2} c_{x} x^{2}+\frac{1}{2} c_{y} y^{2}+\frac{1}{2} c_{z} z^{2}
$$

so in Cartesian coordinates

$$
\vec{r} \cdot \nabla V=x \frac{\partial V}{\partial x}+y \frac{\partial V}{\partial y}+z \frac{\partial V}{\partial z}=2 V
$$

Then according to the virial theorem $2\langle T\rangle=\langle 2 V\rangle$. So the expectation kinetic energy and the expectation potential energy are the same. Compute whichever is easiest, or just take half of the total energy $E$ if you know it.

Also consider the hydrogen atom. There

$$
V=-\frac{e^{2}}{4 \pi \epsilon_{0} r}
$$

so in polar coordinates

$$
\vec{r} \cdot \nabla V=r \frac{\partial V}{\partial r}=-V
$$

Then according to the virial theorem the expectation potential energy is minus twice the expectation kinetic energy. And their sum, the total energy $E$, is then minus the expectation kinetic energy. In short, $\langle T\rangle=-E$ and $\langle V\rangle=2 E$ with $E$ negative.

The virial theorem does not apply to the particle in a pipe, as that particle is in a bounded space. (You can assume infinite space if you take the potential infinite outside the pipe, but obviously by itself that does not help much. You could assume infinite space with a potential

$$
V=\left(x / \ell_{x}\right)^{p}+\left(y / \ell_{y}\right)^{p}+\left(z / \ell_{z}\right)^{p} \quad p \text { even }
$$

if you then take the limit $p \rightarrow \infty$ to get infinite potential outside the pipe and zero inside. That gives the correct but trivial result that all the energy is kinetic.)

But the virial theorem does apply to any number of particles, not just to one. Just sum over all the particles:

$$
2\left\langle\sum_{i} T_{i}\right\rangle=\left\langle\sum_{i} \vec{r}_{i} \cdot \nabla_{i} V\right\rangle
$$

where i is the particle number.
For example, consider the hydrogen molecule, where there are four particles, two protons and two electrons. Here

$$
V=\sum_{i \neq j} \frac{q_{i} q_{j}}{4 \pi \epsilon_{0}\left|\vec{r}_{i}-\vec{r}_{j}\right|}
$$

where $q_{i}$ is $e$ if particle $i$ is a proton and $-e$ if it is an electron. Like for the simple hydrogen atom,

$$
\left\langle\sum_{i} \vec{r}_{i} \cdot \nabla_{i} V\right\rangle=-\langle V\rangle
$$

so the total expectation potential energy of the system is still twice the total energy $E$ and the total kinetic energy is still minus $E$. And this continues to hold for much bigger systems of nuclei and electrons, which is why it is of interest for computational methods.

In some computations you might need to assume that the electrons are in a state of definite energy, like in the ground state, but the nuclei are not. In such computations the nuclei are at an assumed position and you will only compute the state of the electrons. So the summation in

$$
\left\langle\sum_{i} \vec{r}_{i} \cdot \nabla_{i} V\right\rangle
$$

now extends only over the electrons. But this summation does includes potentials of the electrons due to the attraction by the nuclei, and those terms are no longer equal to minus the corresponding potentials. You may need to evaluate these terms explicitly. But that is not too bad, as these potentials are now known functions of the individual electron positions only. The difficult term, due to the electron-electron interaction, is still given by minus the corresponding potential.

Finally, you might wonder where the virial theorem comes from. Well, one way to prove the virial theorem, as found in quantum textbooks and on Wikipedia, is to work out the commutator in

$$
\frac{\mathrm{d}\langle\vec{r} \cdot \vec{p}\rangle}{\mathrm{d} t}=\frac{\mathrm{i}}{\hbar}\langle[H, \vec{r} \cdot \vec{p}]\rangle
$$

using the formulae in chapter 4.5.4, to give

$$
\frac{\mathrm{d}\langle\vec{r} \cdot \vec{p}\rangle}{\mathrm{d} t}=2\langle T\rangle-\langle\vec{r} \cdot \nabla V\rangle
$$

and then note that the left hand side above is zero for stationary states, (in other words, for states with a precise total energy). This follows the classical way of deriving the classical virial theorem, but requires a messy purely mathematical derivation. The theorem then pops up out of the complex mathematics without any plausible physical reason why there would be such a theorem in the first place.

The original derivation by Fock in 1930 is much more physically appealing and more instructive. The idea is to slightly stretch the given quantum system: replace every position coordinate coordinate $\vec{r}$ by a slightly larger one $\vec{r}_{\mathrm{s}}=$ $(1+\varepsilon) \vec{r}$. Here $\varepsilon$ is assumed to be a vanishingly small number. We are interested in what the expectation potential and kinetic energy are in this slightly stretched system.

First however, recall that the square magnitude of the wave function gives the probability of that state, and that all probabilities must integrate together to 1 , certainty. Phrased differently, the expectation value of one must be one; $\langle 1\rangle=1$, what else? But clearly, if you integrate the same square wave function magnitude over a slightly larger domain, you will get a value slightly greater than one. This problem is easily fixed, however, by multiplying the wave function in the stretched system by a suitable constant slightly less than one. Then $\langle 1\rangle_{\mathrm{s}}=1$ too. (The precise value of the constant depends on the number of particles and is not important.)

Next, the expectation kinetic energy consists of terms like $-\hbar^{2} / 2 m_{i}$ times $\left\langle\partial^{2} / \partial x_{\mathrm{s}, \mathrm{i}}^{2}\right\rangle$ because of the form of the kinetic energy operator. Because of the stretching of the coordinate in the bottom of the derivative, each of these terms changes by a factor $1 /(1+\varepsilon)^{2}$, so

$$
\langle T\rangle_{\mathrm{s}}=\langle T\rangle \frac{1}{(1+\varepsilon)^{2}} \approx\langle T\rangle-2 \varepsilon\langle T\rangle+\ldots
$$

For the potential energy we can use a linear Taylor series to figure out how it changes:

$$
V\left(\vec{r}_{1}+\varepsilon \vec{r}_{1}, \vec{r}_{2}+\varepsilon \vec{r}_{2}, \ldots\right) \approx V+\nabla_{1} V \cdot \varepsilon \vec{r}_{1}+\nabla_{2} V \cdot \varepsilon \vec{r}_{2}+\ldots
$$

where in the right hand side $V$ and its derivatives are evaluated at $\left(\vec{r}_{1}, \vec{r}_{2}, \ldots\right)$. From that

$$
\langle V\rangle_{s}=\langle V\rangle+\varepsilon\left\langle\sum_{i} \vec{r}_{i} \cdot \nabla_{i} V\right\rangle+\ldots
$$

From the above expressions, it is seen that compared to the unstretched system, in the stretched system the sum of expectation kinetic and potential energies is different by an amount

$$
\varepsilon\left(-2\langle T\rangle+\left\langle\sum_{i} \vec{r}_{i} \cdot \nabla_{i} V\right\rangle\right)+\ldots
$$

But, as described in $\{$ A. 7$\}$, if you mess up an energy wave function by an amount of order $\varepsilon$, the expectation energy should only be messed up by an
amount proportional to $\varepsilon^{2}$, not $\varepsilon$. (In brief, the amounts of the other energy eigenfunctions found in the messed up wave function are proportional to $\varepsilon$. However, the probabilities of their energies are proportional to the squares of the amounts.) So the factor between parentheses in the expression above must be zero, and that is the virial theorem.

## A. 18 The energy-time uncertainty relationship

As mentioned in chapter 4.5.3, Heisenberg's formulae

$$
\Delta p_{x} \Delta x \geqslant \frac{1}{2} \hbar
$$

relating the typical uncertainties in momentum and position is often very convenient for qualitative descriptions of quantum mechanics, especially if you misread $\geqslant$ as $\approx$.

So, taking a cue from relativity, people would like to write a similar expression for the uncertainty in the time coordinate,

$$
\Delta E \Delta t \geqslant \frac{1}{2} \hbar
$$

The energy uncertainty can reasonably be defined as the standard deviation $\sigma_{E}$ in energy. However, if you want to formally justify the energy-time relationship, it is not at all obvious what to make of that uncertainty in time $\Delta t$.

To arrive at one definition, assume that the variable of real interest in a given problem has a time-invariant operator $A$. The generalized uncertainty relationship of chapter 4.5 .2 between the uncertainties in energy and $A$ is then:

$$
\sigma_{E} \sigma_{A} \geqslant \frac{1}{2}|\langle[H, A]\rangle| .
$$

But according to chapter $7.2|\langle[H, A]\rangle|$ is just $\hbar|\mathrm{d}\langle A\rangle / \mathrm{d} t|$.
So the Mandelshtam-Tamm version of the energy-time uncertainty relationship just defines the uncertainty in time to be

$$
\Delta t=\sigma_{A} /\left|\frac{\mathrm{d}\langle A\rangle}{\mathrm{d} t}\right|
$$

That corresponds to the typical time in which the expectation value of $A$ changes by one standard deviation. In other words, it is the time that it takes for $A$ to change to a value sufficiently different that it will clearly show up in measurements.

## A. 19 Conservation Laws and Symmetries

This note has a closer look at the relation between conservation laws and symmetries. As an example it derives the law of conservation of angular momentum directly from the rotational symmetry of physics. It then briefly explains how the arguments carry over to other conservation laws like linear momentum and parity. A simple example of a local gauge symmetry is also given. The final subsection has a few remarks about the symmetry of physics with respect to time shifts.

## A.19.1 An example symmetry transformation

The mathematician Weyl gave a simple definition of a symmetry. A symmetry exists if you do something and it does not make a difference. A circular cylinder is an axially symmetric object because if you rotate it around its axis over some arbitrary angle, it still looks exactly the same. However, this note is not concerned with symmetries of objects, but of physics. That are symmetries where you do something, like place a system of particles at a different position or angle, and the physics stays the same. The system of particles itself does not necessarily need to be symmetric here.

As an example, this subsection and the next ones will explore one particular symmetry and its conservation law. The symmetry is that the physics is the same if a system of particles is placed under a different angle in otherwise empty space. There are no preferred directions in empty space. The angle that you place a system under does not make a difference. The corresponding conservation law will turn out to be conservation of angular momentum.

First a couple of clarifications. Empty space should really be understood to mean that there are no external effects on the system. A hydrogen atom in a vacuum container on earth is effectively in empty space. Or at least it is as far as its electronic structure is concerned. The energies associated with the gravity of earth and with collisions with the walls of the vacuum container are negligible. Atomic nuclei are normally effectively in empty space because the energies to excite them are so large compared to electronic energies. As a macroscopic example, to study the internal motion of the solar system the rest of the galaxy can presumably safely be ignored. Then the solar system too can be considered to be in empty space.

Further, placing a system under a different angle may be somewhat awkward. Don't burn your fingers on that hot sun when placing the solar system under a different angle. And there always seems to be a vague suspicion that you will change something nontrivially by placing the system under a different angle.

There is a different, better, way. Note that you will always need a coordinate system to describe the evolution of the system of particles mathematically. Instead of putting the system of particles under an different angle, you can put
that coordinate system under a different angle. It has the same effect. In empty space there is no reference direction to say which one got rotated, the particle system or the coordinate system. And rotating the coordinate system leaves the system truly untouched. That is why the view that the coordinate system gets rotated is called the "passive view." The view that the system itself gets rotated is called the "active view."

Figure A.7: Effect of a rotation of the coordinate system on the spherical coordinates of a particle at an arbitrary location P .

Figure A. 7 shows graphically what happens to the position coordinates of a particle if the coordinate system gets rotated. The original coordinate system is indicated by primes. The $z^{\prime}$-axis has been chosen along the axis of the desired rotation. Rotation of this coordinate system over an angle $\gamma$ produces a new coordinate system indicated without primes. In terms of spherical coordinates, the radial position $r$ of the particle does not change. And neither does the "polar" angle $\theta$. But the "azimuthal" angle $\phi$ does change. As the figure shows, the relation between the azimuthal angles is

$$
\phi^{\prime}=\phi+\gamma
$$

That is the basic mathematical description of the symmetry transformation.
However, it must still be applied to the description of the physics. And in quantum mechanics, the physics is described by a wave function $\Psi$ that depends on the position coordinates of the particles;

$$
\Psi\left(r_{1}, \theta_{1}, \phi_{1}, r_{2}, \theta_{2}, \phi_{2}, \ldots ; t\right)
$$

where $1,2, \ldots$, is the numbering of the particles. Particle spin will be ignored for now.

Physically absolutely nothing changes if the coordinate system is rotated. So the values $\Psi$ of the wave function in the rotated coordinate system are exactly the same as the values $\Psi^{\prime}$ in the original coordinate system. But the particle coordinates corresponding to these values do change:

$$
\Psi\left(r_{1}, \theta_{1}, \phi_{1}, r_{2}, \theta_{2}, \phi_{2}, \ldots ; t\right)=\Psi^{\prime}\left(r_{1}^{\prime}, \theta_{1}^{\prime}, \phi_{1}^{\prime}, r_{2}^{\prime}, \theta_{2}^{\prime}, \phi_{2}^{\prime}, \ldots ; t\right)
$$

Therefore, considered as functions, $\Psi^{\prime}$ and $\Psi$ are different. However, only the azimuthal angles change. In particular, putting in the relation between the azimuthal angles above gives:

$$
\Psi\left(r_{1}, \theta_{1}, \phi_{1}, r_{2}, \theta_{2}, \phi_{2}, \ldots ; t\right)=\Psi^{\prime}\left(r_{1}, \theta_{1}, \phi_{1}+\gamma, r_{2}, \theta_{2}, \phi_{2}+\gamma, \ldots ; t\right)
$$

Mathematically, changes in functions are most conveniently written in terms of an appropriate operator, chapter 2.4. The operator here is called the "generator of rotations around the $z$-axis." It will be indicated as $\mathcal{R}_{z, \gamma}$. What it does is add $\gamma$ to the azimuthal angles of the function. By definition:

$$
\mathcal{R}_{z, \gamma} \Psi^{\prime}\left(r_{1}, \theta_{1}, \phi_{1}, r_{2}, \theta_{2}, \phi_{2}, \ldots ; t\right) \equiv \Psi^{\prime}\left(r_{1}, \theta_{1}, \phi_{1}+\gamma, r_{2}, \theta_{2}, \phi_{2}+\gamma, \ldots ; t\right)
$$

In terms of this operator, the relationship between the wave functions in the rotated and original coordinate systems can be written concisely as

$$
\Psi=\mathcal{R}_{z, \gamma} \Psi^{\prime}
$$

Using $\mathcal{R}_{z, \gamma}$, there is no longer a need for using primes on one set of coordinates. Take any wave function in terms of the original coordinates, written without primes. Application of $\mathcal{R}_{z, \gamma}$ will turn it into the corresponding wave function in the rotated coordinates, also written without primes.

So far, this is all mathematics. The above expression applies whether or not there is symmetry with respect to rotations. It even applies whether or not $\Psi$ is a wave function.

## A.19.2 Physical description of a symmetry

The next question is what it means in terms of physics that empty space has no preferred directions. According to quantum mechanics, the Schrödinger equation describes the physics. It says that the time derivative of the wave function can be found as

$$
\frac{\partial \Psi}{\partial t}=\frac{1}{\mathrm{i} \hbar} H \Psi
$$

where $H$ is the Hamiltonian. If space has no preferred directions, then the Hamiltonian must be the same regardless of angular orientation of the coordinate system used.

In particular, consider the two coordinate systems of the previous subsection. The second system differed from the first by a rotation over an arbitrary angle $\gamma$ around the $z$-axis. If one system had a different Hamiltonian than the other, then systems of particles would be observed to evolve in a different way in that coordinate system. That would provide a fundamental distinction between the two coordinate system orientations right there.

A couple of very basic examples can make this more concrete. Consider the electronic structure of the hydrogen atom as analyzed in chapter 4.3. The electron was not in empty space in that analysis. It was around a proton, which was assumed to be at rest at the origin. However, the electric field of the proton has no preferred direction either. (Proton spin was ignored). Therefore the current analysis does apply to the electron of the hydrogen atom. In terms of Cartesian coordinates, the Hamiltonian in the original $x^{\prime}, y^{\prime}, z^{\prime}$ coordinate system is

$$
H^{\prime}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}}\left[\frac{\partial}{\partial x^{\prime 2}}+\frac{\partial}{\partial y^{\prime 2}}+\frac{\partial}{\partial z^{\prime 2}}\right]-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{\sqrt{x^{\prime 2}+y^{\prime 2}+z^{\prime 2}}}
$$

The first term is the kinetic energy operator. It is proportional to the Laplacian operator, inside the square brackets. Standard vector calculus says that this operator is independent of the angular orientation of the coordinate system. So to get the corresponding operator in the rotated $x, y, z$ coordinate system, simply leave away the primes. The second term is the potential energy in the field of the proton. It is inversely proportional to the distance of the electron from the origin. The expression for the distance from the origin is the same in the rotated coordinate system. Once again, just leave away the primes. The bottom line is that you cannot see a difference between the two coordinate systems by looking at their Hamiltonians. The expressions for the Hamiltonians are identical.

As a second example, consider the analysis of the complete hydrogen atom as described in addendum \{A.5\}. The complete atom was assumed to be in empty space; there were no external effects on the atom included. The analysis still ignored all relativistic effects, including the electron and proton spins. However, it did include the motion of the proton. That meant that the kinetic energy of the proton had to be added to the Hamiltonian. But that too is a Laplacian, now in terms of the proton coordinates $x_{\mathrm{p}}^{\prime}, y_{\mathrm{p}}^{\prime}, z_{\mathrm{p}}^{\prime}$. Its expression too is the same regardless of angular orientation of the coordinate system. And in the potential energy term, the distance from the origin now becomes the distance between electron and proton. But the formula for the distance between two points is the same regardless of angular orientation of the coordinate system. So once again, the expression for the Hamiltonian does not depend on the angular orientation of the coordinate system.

The equality of the Hamiltonians in the original and rotated coordinate systems has a consequence. It leads to a mathematical requirement for the operator
$\mathcal{R}_{z, \gamma}$ of the previous subsection that describes the effect of a coordinate system rotation on wave functions. This operator must commute with the Hamiltonian:

$$
H \mathcal{R}_{z, \gamma}=\mathcal{R}_{z, \gamma} H
$$

That follows from examining the wave function of a system as seen in both the original and the rotated coordinate system. There are two ways to find the time derivative of the wave function in the rotated coordinate system. One way is to rotate the original wave function using $\mathcal{R}_{z, \gamma}$ to get the one in the rotated coordinate system. Then you can apply the Hamiltonian on that. The other way is to apply the Hamiltonian on the wave function in the original coordinate system to find the time derivative in the original coordinate system. Then you can use $\mathcal{R}_{z, \gamma}$ to convert that time derivative to the rotated system. The Hamiltonian and $\mathcal{R}_{z, \gamma}$ get applied in the opposite order, but the result must still be the same.

This observation can be inverted to define a symmetry of physics in general:

## A symmetry of physics is described by a unitary operator that commutes with the Hamiltonian.

If an operator commutes with the Hamiltonian, then the same Hamiltonian applies in the changed coordinate system. So there is no physical difference in how systems evolve between the two coordinate systems.

The qualification "unitary" means that the operator should not change the magnitude of the wave function. The wave function should remain normalized. It does for the transformations of interest in this note, like rotations of the coordinate system, shifts of the coordinate system, time shifts, and spatial coordinate inversions. All of these transformations are unitary. Like Hermitian operators, unitary operators have a complete set of orthonormal eigenfunctions. However, the eigenvalues are normally not real numbers.

For those who wonder, time reversal is somewhat of a special case. To understand the difficulty, consider first the operation "take the complex conjugate of the wave function." This operator preserves the magnitude of the wave function. And it commutes with the Hamiltonian, assuming a basic real Hamiltonian. But taking complex conjugate is not a linear operator. For a linear operator $(i \Psi)^{\prime}$ $=\mathrm{i}(\Psi)^{\prime}$. But $(\mathrm{i} \Psi)^{*}=-\mathrm{i} \Psi^{*}$. If constants come out of an operator as complex conjugates, the operator is called "antilinear." So taking complex conjugate is antilinear. Another issue: a linear unitary operator preserves the inner products between any two wave functions $\Psi_{1}$ and $\Psi_{2}$. (That can be verified by expanding the square magnitudes of $\Psi_{1}+\Psi_{2}$ and $\left.\Psi_{1}+\mathrm{i} \Psi_{2}\right)$. However, taking complex conjugate changes inner products into their complex conjugates. Operators that do that are called "antiunitary." So taking complex conjugate is both antilinear and antiunitary. (Of course, in normal language it is neither. The appropriate terms would have been conjugate-linear and conjugate-unitary. But if you got
this far in this book, you know how much chance appropriate terms have of being used in physics.)

Now the effect of time-reversal on wave functions turns out to be antilinear and antiunitary too, [49, p. 76]. One simple way to think about it is that a straightforward time reversal would change $e^{-\mathrm{i} E t / \hbar}$ into $e^{\mathrm{i} E t / \hbar}$. Then an additional complex conjugate will take things back to positive energies. For the same reason you do not want to add a complex conjugate to spatial transformations or time shifts.

## A.19.3 Derivation of the conservation law

The definition of a symmetry as an operator that commutes with the Hamiltonian may seem abstract. But it has a less abstract consequence. It implies that the eigenfunctions of the symmetry operation can be taken to be also eigenfunctions of the Hamiltonian, $\{$ D.18\}. And, as chapter 7.1.4 discussed, the eigenfunctions of the Hamiltonian are stationary. They change in time by a mere scalar factor $e^{\mathrm{i} E t / \hbar}$ of magnitude 1 that does not change their physical properties.

The fact that the eigenfunctions do not change is responsible for the conservation law. Consider what a conservation law really means. It means that there is some number that does not change in time. For example, conservation of angular momentum in the $z$-direction means that the net angular momentum of the system in the $z$-direction, a number, does not change.

And if the system of particles is described by an eigenfunction of the symmetry operator, then there is indeed a number that does not change: the eigenvalue of that eigenfunction. The scalar factor $e^{\mathrm{i} E t / \hbar}$ changes the eigenfunction, but not the eigenvalue that would be produced by applying the symmetry operator at different times. The eigenvalue can therefore be looked upon as a specific value of some conserved quantity. In those terms, if the state of the system is given by a different eigenfunction, with a different eigenvalue, it has a different value for the conserved quantity.

> The eigenvalues of a symmetry of physics describe the possible values of a conserved quantity.

Of course, the system of particles might not be described by a single eigenfunction of the symmetry operator. It might be a mixture of eigenfunctions, with different eigenvalues. But that merely means that there is quantum mechanical uncertainty in the conserved quantity. That is just like there may be uncertainty in energy. Even if there is uncertainty, still the mixture of eigenvalues does not change with time. Each eigenfunction is still stationary. Therefore the probability of getting a given value for the conserved quantity does not change with time. In particular, neither the expectation value of the conserved quantity, nor the amount of uncertainty in it changes with time.

The eigenvalues of a symmetry operator may require some cleaning up. They may not directly give the conserved quantity in the desired form. Consider for example the eigenvalues of the rotation operator $\mathcal{R}_{z, \gamma}$ discussed in the previous subsections. You would surely expect a conserved quantity of a system to be a real quantity. But the eigenvalues of $\mathcal{R}_{z, \gamma}$ are in general complex numbers.

The one thing that can be said about the eigenvalues is that they are always of magnitude 1. Otherwise an eigenfunction would change in magnitude during the rotation. But a function does not change in magnitude if it is merely viewed under a different angle. And if the eigenvalues are of magnitude 1 , then the Euler formula (2.5) implies that they can always be written in the form
$e^{\mathrm{i} \alpha}$
where $\alpha$ is some real number. If the eigenvalue does not change with time, then neither does $\alpha$, which is basically just its logarithm.

But although $\alpha$ is real and conserved, still it is not the desired conserved quantity. Consider the possibility that you perform another rotation of the axis system. Each rotation multiplies the eigenfunction by a factor $e^{\mathrm{i} \alpha}$ for a total of $e^{2 \mathrm{i} \alpha}$. In short, if you double the angle of rotation $\gamma$, you also double the value of $\alpha$. But it does not make sense to say that both $\alpha$ and $2 \alpha$ are conserved. If $\alpha$ is conserved, then so is $2 \alpha$; that is not a second conservation law. Since $\alpha$ is proportional to $\gamma$, it can be written in the form

$$
\alpha=m \gamma
$$

where the constant of proportionality $m$ is independent of the amount of coordinate system rotation.

The constant $m$ is the desired conserved quantity. For historical reasons it is called the "magnetic quantum number." Unfortunately, long before quantum mechanics, classical physics had already figured out that something was preserved. It called that quantity the "angular momentum" $L_{z}$. It turns out that what classical physics defines as angular momentum is simply a multiple of the magnetic quantum number:

$$
L_{z}=m \hbar
$$

So conservation of angular momentum is the same thing as conservation of magnetic quantum number.

But the magnetic quantum number is more fundamental. Its possible values are pure integers, unlike those of angular momentum. To see why, note that in terms of $m$, the eigenvalues of $\mathcal{R}_{z, \gamma}$ are of the form

Now if you rotate the coordinate system over an angle $\gamma=2 \pi$, it gets back to the exact same position as it was in before the rotation. The wave function
should not change in that case, which means that the eigenvalue must be equal to one. And that requires that the value of $m$ is an integer. If $m$ was a fractional number, $e^{\text {im } 2 \pi}$ would not be 1 .

It may be interesting to see how all this works out for the two examples mentioned in the previous subsection. The first example was the electron in a hydrogen atom where the proton is assumed to be at rest at the origin. Chapter 4.3 found the electron energy eigenfunctions in the form

$$
\psi_{n l m}(\vec{r})=R_{n l}(r) Y_{l}^{m}(\theta, \phi)=R_{n l}(r) \Theta_{l}^{m}(\theta) e^{\mathrm{i} m \phi}
$$

It is the final exponential that changes by the expected factor $e^{\mathrm{i} m \gamma}$ when $\mathcal{R}_{z, \gamma}$ replaces $\phi$ by $\phi+\gamma$.

The second example was the complete hydrogen atom in empty space. In addendum \{A.5\}, the energy eigenfunctions were found in the form

$$
\psi_{n l m, \text { red }}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right) \psi_{\mathrm{cg}}\left(\vec{r}_{\mathrm{cg}}\right)
$$

The first term is like before, except that it is computed with a "reduced mass" that is slightly different from the true electron mass. The argument is now the difference in position between the electron and the proton. It still produces a factor $e^{\mathrm{i} m \gamma}$ when $\mathcal{R}_{z, \gamma}$ is applied. The second factor reflects the motion of the center of gravity of the complete atom. If the center of gravity has definite angular momentum around whatever point is used as origin, it will produce an additional factor $e^{\mathrm{i} m_{\mathrm{cg}} \gamma}$. (See addendum $\{\mathrm{A} .6\}$ on how the energy eigenfunctions $\psi_{\mathrm{cg}}$ can be written as spherical Bessel functions of the first kind times spherical harmonics that have definite angular momentum. But also see chapter 7.9 about the nasty normalization issues with wave functions in infinite empty space.)

As a final step, it is desirable to formulate a nicer operator for angular momentum. The rotation operators $\mathcal{R}_{z, \gamma}$ are far from perfect. One problem is that there are infinitely many of them, one for every angle $\gamma$. And they are all related, a rotation over an angle $2 \gamma$ being the same as two rotations over an angle $\gamma$.

If you define a rotation operator over a very small angle, call it $\mathcal{R}_{z, \varepsilon}$, then you can approximate any other operator $\mathcal{R}_{z, \gamma}$ by just applying $\mathcal{R}_{z, \varepsilon}$ sufficiently many times. To make this approximation exact, you need to make $\varepsilon$ infinitesimally small. But when $\varepsilon$ becomes zero, $\mathcal{R}_{z, \varepsilon}$ would become just 1 . You have lost the nicer operator that you want by going to the extreme. The trick to avoid this is to subtract the limiting operator 1 , and in addition, to avoid that the resulting operator then becomes zero, you must also divide by $\varepsilon$. The nicer operator is therefore

$$
\lim _{\varepsilon \rightarrow 0} \frac{\mathcal{R}_{z, \varepsilon}-1}{\varepsilon}
$$

Now consider what this operator really means for a single particle with no spin:

$$
\lim _{\varepsilon \rightarrow 0} \frac{\mathcal{R}_{z, \varepsilon}-1}{\varepsilon} \Psi(r, \theta, \phi)=\lim _{\varepsilon \rightarrow 0} \frac{\Psi(r, \theta, \phi+\varepsilon)-\Psi(r, \theta, \phi)}{\varepsilon}
$$

By definition, the final term is the partial derivative of $\Psi$ with respect to $\phi$. So the new operator is just the operator $\partial / \partial \phi$ !

You can go one better still, because the eigenvalues of the operator just defined are

$$
\lim _{\varepsilon \rightarrow 0} \frac{e^{\mathrm{i} m \varepsilon}-1}{\varepsilon}=\mathrm{i} m
$$

If you add a factor $\hbar / \mathrm{i}$ to the operator, the eigenvalues of the operator are going to be $m \hbar$, the quantity defined in classical physics as the angular momentum. So you are led to define the angular momentum operator of a single particle as:

$$
\widehat{L}_{z} \equiv \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial \phi}
$$

This agrees perfectly with what chapter 4.2.2 got from guessing that the relationship between angular and linear momentum is the same in quantum mechanics as in classical mechanics.

The angular momentum operator of a general system can be defined using the same scale factor:

$$
\begin{equation*}
\widehat{L}_{z} \equiv \frac{\hbar}{\mathrm{i}} \lim _{\varepsilon \rightarrow 0} \frac{\mathcal{R}_{z, \varepsilon}-1}{\varepsilon} \tag{A.76}
\end{equation*}
$$

The system has definite angular momentum $m \hbar$ if

$$
\widehat{L}_{z} \Psi=m \hbar \Psi
$$

Consider now what happens if the angular operator $\widehat{L}_{z}$ as defined above is applied to the wave function of a system of multiple particles, still without spin. It produces

$$
\widehat{L}_{z} \Psi=\frac{\hbar}{\mathrm{i}} \lim _{\varepsilon \rightarrow 0} \frac{\Psi\left(r_{1}, \theta_{1}, \phi_{1}+\varepsilon, r_{2}, \theta_{2}, \phi_{2}+\varepsilon, \ldots\right)-\Psi\left(r_{1}, \theta_{1}, \phi_{1}, r_{2}, \theta_{2}, \phi_{2}, \ldots\right)}{\varepsilon}
$$

The limit in the right hand side is a total derivative. According to calculus, it can be rewritten in terms of partial derivatives to give

$$
\widehat{L}_{z} \Psi=\frac{\hbar}{\mathrm{i}}\left[\frac{\partial}{\partial \phi_{1}}+\frac{\partial}{\partial \phi_{2}}+\ldots\right] \Psi
$$

The scaled derivatives in the new right hand side are the orbital angular momenta of the individual particles as defined above, so

$$
\widehat{L}_{z} \Psi=\left[\widehat{L}_{z, 1}+\widehat{L}_{z, 2}+\ldots\right] \Psi
$$

It follows that the angular momenta of the individual particles just add, like they do in classical physics.

Of course, even if the complete system has definite angular momentum, the individual particles may not. A particle numbered $i$ has definite angular momentum $m_{i} \hbar$ if

$$
\widehat{L}_{z, i} \Psi \equiv \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial \phi_{i}} \Psi=m_{i} \hbar \Psi
$$

If every particle has definite momentum like that, then these momenta directly add up to the total system momentum. At the other extreme, if both the system and the particles have uncertain angular momentum, then the expectation values of the momenta of the particles still add up to that of the system.

Now that the angular momentum operator has been defined, the generator of rotations $\mathcal{R}_{z, \gamma}$ can be identified in terms of it. It turns out to be

$$
\begin{equation*}
\mathcal{R}_{z, \gamma}=\exp \left(\frac{\mathrm{i}}{\hbar} \widehat{L}_{z} \gamma\right) \tag{A.77}
\end{equation*}
$$

To check that it does indeed take the form above, expand the exponential in a Taylor series. Then apply it on an eigenfunction with angular momentum $L_{z}=$ $m \hbar$. The effect is seen to be to multiply the eigenfunction by the Taylor series of $e^{\mathrm{i} m \gamma}$ as it should. So $\mathcal{R}_{z, \gamma}$ as given above gets all eigenfunctions right. It must therefore be correct since the eigenfunctions are complete.

Now consider the generator of rotations in terms of the individual particles. Since $\widehat{L}_{z}$ is the sum of the angular momenta of the individual particles,

$$
\mathcal{R}_{z, \gamma}=\exp \left(\frac{\mathrm{i}}{\hbar} \widehat{L}_{z, 1} \gamma\right) \exp \left(\frac{\mathrm{i}}{\hbar} \widehat{L}_{z, 2} \gamma\right) \ldots
$$

So, while the contributions of the individual particles to total angular momentum add together, their contributions to the generator of rotations multiply together. In particular, if a particle $i$ has definite angular momentum $m_{i} \hbar$, then it contributes a factor $e^{\mathrm{i} m_{i} \gamma}$ to $\mathcal{R}_{z, \gamma}$.

How about spin? The normal angular momentum discussed so far suggests its true meaning. If a particle $i$ has definite spin angular momentum in the $z$ direction $m_{s, i} \hbar$, then presumably the wave function changes by an additional factor $e^{\mathrm{im} m_{s, i \gamma}}$ when you rotate the axis system over an angle $\gamma$.

But there is something curious here. If the axis system is rotated over an angle $2 \pi$, it is back in its original position. So you would expect that the wave function is also again the same as before the rotation. And if there is just orbital angular momentum, then that is indeed the case, because $e^{\mathrm{i} m 2 \pi}=1$ as long as $m$ is an integer, (2.5). But for fermions the spin angular momentum $m_{s}$ in a given direction is half-integer, and $e^{\mathrm{i} \pi}=-1$. Therefore the wave function of a fermion changes sign when the coordinate system is rotated over $2 \pi$ and is back in its original position. That is true even if there is uncertainty in the spin angular momentum. For example, the wave function of a fermion with spin $1 / 2$
can be written as, chapter 5.5.1,

$$
\Psi_{+} \uparrow+\Psi_{-\downarrow}
$$

where the first term has $\frac{1}{2} \hbar$ angular momentum in the $z$-direction and the second term $-\frac{1}{2} \hbar$. Each term changes sign under a turn of the coordinate system by $2 \pi$. So the complete wave function changes sign. More generally, for a system with an odd number of fermions the wave function changes sign when the coordinate system is rotated over $2 \pi$. For a system with an even number of fermions, the wave function returns to the original value.

Now the sign of the wave function does not make a difference for the observed physics. But it is still somewhat unsettling to see that on the level of the wave function, nature is only the same when the coordinate system is rotated over $4 \pi$ instead of $2 \pi$. (However, it may be only a mathematical artifact. The antisymmetrization requirement implies that the true system includes all electrons in the universe. Presumably, the number of fermions in the universe is infinite. That makes the question whether the number is odd or even unanswerable. If the number of fermions does turn out to be finite, this book will reconsider the question when people finish counting.)
(Some books now raise the question why the orbital angular momentum functions could not do the same thing. Why could the quantum number of orbital angular momentum not be half-integer too? But of course, it is easy to see why not. If the spatial wave function would be multiple valued, then the momentum operators would produce infinite momentum. You would have to postulate arbitrarily that the derivatives of the wave function at a point only involve wave function values of a single branch. Half-integer spin does not have the same problem; for a given orientation of the coordinate system, the opposite wave function is not accessible by merely changing position.)

## A.19.4 Other symmetries

The previous subsections derived conservation of angular momentum from the symmetry of physics with respect to rotations. Similar arguments may be used to derive other conservation laws. This subsection briefly outlines how.

Conservation of linear momentum can be derived from the symmetry of physics with respect to translations. The derivation is completely analogous to the angular momentum case. The translation operator $\mathcal{T}_{z, d}$ shifts the coordinate system over a distance $d$ in the $z$-direction. Its eigenvalues are of the form

$$
e^{\mathrm{i} k_{z} d}
$$

where $k_{z}$ is a real number, independent of the amount of translation $d$, that is called the wave number. Following the same arguments as for angular momentum, $k_{z}$ is a preserved quantity. In classical physics not $k_{z}$, but $p_{z}=\hbar k_{z}$ is
defined as the conserved quantity. To get the operator for this quantity, form the operator

$$
\begin{equation*}
\widehat{p}_{z}=\frac{\hbar}{\mathrm{i}} \lim _{\varepsilon \rightarrow 0} \frac{\mathcal{T}_{z, \varepsilon}-1}{\varepsilon} \tag{A.78}
\end{equation*}
$$

For a single particle, this becomes the usual linear momentum operator $\hbar \partial / \mathrm{i} \partial z$. For multiple particles, the linear momenta add up.

It may again be interesting to see how that works out for the two example systems introduced earlier. The first example was the electron in a hydrogen atom. In that example it is assumed that the proton is fixed at the origin. The energy eigenfunctions for the electron then were of the form

$$
\psi_{n l m}(\vec{r})
$$

with $\vec{r}$ the position of the electron. Shifting the coordinate system for this solution means replacing $\vec{r}$ by $\vec{r}+d \hat{k}$. That shifts the position of the electron without changing the position of the proton. The physics is not the same after such a shift. Correspondingly, the eigenfunctions do not change by a factor of the form $e^{\mathrm{i} k_{z} d}$ under the shift. Just looking at the ground state,

$$
\psi_{100}(\vec{r})=\frac{1}{\sqrt{\pi a_{0}^{3}}} e^{-|\vec{r}| / a_{0}}
$$

is enough to see that. An electron around a stationary proton does not have definite linear momentum. In other words, the linear momentum of the electron is not conserved.

However, the physics of the complete hydrogen atom as described in addendum $\{$ A. 5$\}$ is independent of coordinate shifts. A suitable choice of energy eigenfunctions in this context is

$$
\psi_{n l m, \text { red }}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right) e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{cg}}}
$$

where $\vec{k}$ is a constant wave number vector. The first factor does not change under coordinate shifts because the vector $\vec{r}-\vec{r}_{\mathrm{p}}$ from proton to electron does not. The exponential changes by the expected factor $e^{\mathrm{i} k_{z} d}$ because the position $\vec{r}_{\mathrm{cg}}$ of the center of gravity of the atom changes by an amount $d$ in the $z$ direction.

The derivation of linear momentum can be extended to conduction electrons in crystalline solids. In that case, the physics of the conduction electrons is unchanged if the coordinate system is translated over a crystal period $d$. (This assumes that the $z$-axis is chosen along one of the primitive vectors of the crystal structure.) The eigenvalues are still of the form $e^{i k_{z} d}$. However, unlike for linear momentum, the translation $d$ must be the crystal period, or an integer multiple of it. Therefore, the operator $\widehat{p}_{z}$ is not useful; the symmetry does not continue to apply in the limit $d \rightarrow 0$.

The conserved quantity in this case is just the $e^{\mathrm{i} k_{z} d}$ eigenvalue of $\mathcal{T}_{z, d}$. It is not possible from that eigenvalue to uniquely determine a value of $k_{z}$ and the corresponding crystal momentum $\hbar k_{z}$. Values of $k_{z}$ that differ by a whole multiple of $2 \pi / d$ produce the same eigenvalue. But Bloch waves have the same indeterminacy in their value of $k_{z}$ anyway. In fact, Bloch waves are eigenfunctions of $\mathcal{T}_{z, d}$ as well as energy eigenfunctions.

One consequence of the indeterminacy in $k_{z}$ is an increased number of possible electromagnetic transitions. Typical electromagnetic radiation has a wave length that is large compared to the atomic spacing. Essentially the electromagnetic field is the same from one atom to the next. That means that it has negligible crystal momentum, using the smallest of the possible values of $k_{x}$ as measure. Therefore the radiation cannot change the conserved eigenvalue $e^{\mathrm{i} k_{z} d}$. But it can still produce electron transitions between two Bloch waves that have been assigned different $k_{z}$ values in some "extended zone scheme," chapter 6.22.4. As long as the two $k_{z}$ values differ by a whole multiple of $2 \pi / d$, the actual eigenvalue $e^{\mathrm{i} k_{z} d}$ does not change. In that case there is no violation of the conservation law in the transition. The ambiguity in $k_{z}$ values may be eliminated by switching to a "reduced zone scheme" description, chapter 6.22.4.

The time shift operator $\mathcal{U}_{\tau}$ shifts the time coordinate over an interval $\tau$. In empty space, its eigenfunctions are exactly the energy eigenfunctions. Its eigenvalues are of the form

$$
e^{-\mathrm{i} \omega \tau}
$$

where classical physics defines $\hbar \omega$ as the energy $E$. The energy operator can be defined correspondingly, and is simply the Hamiltonian:

$$
\begin{equation*}
H=\mathrm{i} \hbar \lim _{\varepsilon \rightarrow 0} \frac{\mathcal{U}_{\varepsilon}-1}{\varepsilon}=\mathrm{i} \hbar \frac{\partial}{\partial t} \tag{A.79}
\end{equation*}
$$

In other words, we have reasoned in a circle and rederived the Schrödinger equation from time shift symmetry. But you could generalize the reasoning to the motion of particles in an external field that varies periodically in time.

Usually, nature is not just symmetric under rotating or translating it, but also under mirroring it. A transformation that creates a mirror image of a given system is called a parity transformation. The mathematically cleanest way to do it is to invert the direction of each of the three Cartesian axes. That is called spatial inversion. Physically it is equivalent to mirroring the system using some mirror passing through the origin, and then rotating the system $180^{\circ}$ around the axis normal to the mirror.
(In a strictly two-dimensional system, spatial inversion does not work, since the rotation would take the system into the third dimension. In that case, mirroring can be achieved by replacing just $x$ by $-x$ in some suitably chosen $x y$-coordinate system. Subsequently replacing $y$ by $-y$ would amount to a second mirroring that would restore a nonmirror image. In those terms, in
three dimensions it is replacing $z$ by $-z$ that produces the final mirror image in spatial inversion.)

The analysis of the conservation law corresponding to spatial inversion proceeds much like the one for angular momentum. One difference is that applying the spatial inversion operator a second time turns $-\vec{r}$ back into the original $\vec{r}$. Then the wave function is again the same. In other words, applying spatial inversion twice multiplies wave functions by 1. It follows that the square of every eigenvalue is 1 . And if the square of an eigenvalues is 1 , then the eigenvalue itself must be either 1 or -1 . In the same notation as used for angular momentum, the eigenvalues of the spatial inversion operator can therefore be written as

$$
\begin{equation*}
e^{\mathrm{i} m^{\prime} \pi}=(-1)^{m^{\prime}} \tag{A.80}
\end{equation*}
$$

where $m^{\prime}$ must be integer. However, it is pointless to give an actual value for $m^{\prime}$; the only thing that makes a difference for the eigenvalue is whether $m^{\prime}$ is even or odd. Therefore, parity is simply called "odd" or "minus one" or "negative" if the eigenvalue is -1 , and "even" or "one" or "positive" if the eigenvalue is 1 .

In a system, the $\pm 1$ parity eigenvalues of the individual particles multiply together. That is just like how the eigenvalues of the generator of rotation $\mathcal{R}_{z, \gamma}$ multiply together for angular momentum. Any particle with even parity has no effect on the system parity; it multiples the total eigenvalue by 1 . On the other hand, each particle with odd parity flips over the total parity from odd to even or vice-versa; it multiplies the total eigenvalue by -1 . Particles can also have intrinsic parity. However, there is no half-integer parity like there is half-integer spin.

## A.19.5 A gauge symmetry and conservation of charge

Modern quantum theories are build upon so-called "gauge symmetries." This subsection gives a simple introduction to some of the ideas.

Consider classical electrostatics. The force on charged particles is the product of the charge of the particle times the so-called electric field $\overrightarrow{\mathcal{E}}$. Basic physics says that the electric field is minus the derivative of a potential $\varphi$. The potential $\varphi$ is commonly known as the "voltage" in electrical applications. Now it too has a symmetry: adding some arbitrary constant, call it $C$, to $\varphi$ does not make a difference. Only differences in voltage can be observed physically. That is a very simple example of a gauge symmetry, a symmetry in an unobservable field, here the potential $\varphi$.

Note that this symmetry does not involve the gauges used to measure voltages in any way. Instead it is a reference point symmetry; it does not make a difference what voltage you want to declare to be zero. It is conventional to take the earth as the reference voltage, but that is a completely arbitrary choice. So the term "gauge symmetry" is misleading, like many other terms in physics. A
symmetry in a unobservable quantity should of course simply have been called an unobservable symmetry.

There is a relationship between this gauge symmetry in $\varphi$ and charge conservation. Suppose that, say, a few photons create an electron and an antineutrino. That can satisfy conservation of angular momentum and of lepton number, but it would violate charge conservation. Photons have no charge, and neither have neutrinos. So the negative charge $-e$ of the electron would appear out of nothing. But so what? Photons can create electron-positron pairs, so why not electron-antineutrino pairs?

The problem is that in electrostatics an electron has an electrostatic energy $-e \varphi$. Therefore the photons would need to provide not just the rest mass and kinetic energy for the electron and antineutrino, but also an additional electrostatic energy $-e \varphi$. That additional energy could be determined from comparing the energy of the photons against that of the electron-antineutrino pair. And that would mean that the value of $\varphi$ at the point of pair creation has been determined. Not just a difference in $\varphi$ values between different points. And that would mean that the value of the constant $C$ would be fixed. So nature would not really have the gauge symmetry that a constant in the potential is arbitrary.

Conversely, if the gauge symmetry of the potential is fundamental to nature, creation of lone charges must be impossible. Each negatively charged electron that is created must be accompanied by a positively charged particle so that the net charge that is created is zero. In electron-positron pair creation, the positive charge $+e$ of the positron makes the net charge that is created zero. Similarly, in beta decay, an uncharged neutron creates an electron-antineutrino pair with charge $-e$, but also a proton with charge $+e$.

You might of course wonder whether an electrostatic energy contribution $-e \varphi$ is really needed to create an electron. It is because of energy conservation. Otherwise there would be a problem if an electron-antineutrino pair was created at a location P and disintegrated again at a different location Q . The electron would pick up a kinetic energy $-e\left(\varphi_{\mathrm{P}}-\varphi_{\mathrm{Q}}\right)$ while traveling from P to Q . Without electrostatic contributions to the electron creation and annihilation energies, that kinetic energy would make the photons produced by the pair annihilation more energetic than those destroyed in the pair creation. So the complete process would create additional photon energy out of nothing.

The gauge symmetry takes on a much more profound meaning in quantum mechanics. One reason is that the Hamiltonian is based on the potential, not on the electric field itself. To appreciate the full impact, consider electrodynamics instead of just electrostatics. In electrodynamics, a charged particle does not just experience an electric field $\overrightarrow{\mathcal{E}}$ but also a magnetic field $\overrightarrow{\mathcal{B}}$. There is a corresponding additional so-called "vector potential" $\vec{A}$ in addition to the scalar potential $\varphi$. The relation between these potentials and the electric and magnetic
fields is given by, chapter 13.1:

$$
\overrightarrow{\mathcal{E}}=-\nabla \varphi-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A}
$$

Here $\nabla$, nabla, is the differential operator of vector calculus (calculus III in the U.S. system):

$$
\nabla \equiv \hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

The gauge property now becomes more general. The constant $C$ that can be added to $\varphi$ in electrostatics no longer needs to be constant. Instead, it can be taken to be the time-derivative of any arbitrary function $\chi(x, y, z, t)$. However, the gradient of this function must also be subtracted from $\vec{A}$. In particular, the potentials

$$
\varphi^{\prime}=\varphi+\frac{\partial \chi}{\partial t} \quad \vec{A}^{\prime}=\vec{A}-\nabla \chi
$$

produce the exact same electric and magnetic fields as $\varphi$ and $\vec{A}$. So they are physically equivalent. They produce the same observable motion.

However, the wave function computed using the potentials $\varphi^{\prime}$ and $\vec{A}^{\prime}$ is different from the one computed using $\varphi$ and $\vec{A}$. The reason is that the Hamiltonian uses the potentials rather than the electric and magnetic fields. Ignoring spin, the Hamiltonian of an electron in an electromagnetic field is, chapter 13.1:

$$
H=\frac{1}{2 m_{\mathrm{e}}}\left(\frac{\hbar}{\mathrm{i}} \nabla+e \vec{A}\right)^{2}-e \varphi
$$

It can be seen by crunching it out that if $\Psi$ satisfies the Schrödinger equation in which the Hamiltonian is formed with $\varphi$ and $\vec{A}$, then

$$
\begin{equation*}
\Psi^{\prime}=e^{\mathrm{i} e \chi / \hbar} \Psi \tag{A.81}
\end{equation*}
$$

satisfies the one in which $H$ is formed with $\varphi^{\prime}$ and $\vec{A}^{\prime}$.
To understand what a stunning result that is, recall the physical interpretation of the wave function. According to Born, the square magnitude of the wave function $|\Psi|^{2}$ determines the probability per unit volume of finding the electron at a given location. But the wave function is a complex number; it can always be written in the form

$$
\Psi=e^{\mathrm{i} \alpha}|\Psi|
$$

where $\alpha$ is a real quantity corresponding to a phase angle. This angle is not directly observable; it drops out of the magnitude of the wave function. And the gauge property above shows that not only is $\alpha$ not observable, it can be anything. For, the function $\chi$ can change $\alpha$ by a completely arbitrary amount $e \chi / \hbar$ and it remains a solution of the Schrödinger equation. The only variables that change are the equally unobservable potentials $\varphi$ and $\vec{A}$.

As noted earlier, a symmetry means that you can do something and it does not make a difference. Since $\alpha$ can be chosen completely arbitrary, varying with both location and time, this is a very strong symmetry. Zee writes, (Quantum Field Theory in a Nutshell, 2003, p. 135): "The modern philosophy is to look at [the equations of quantum electrodynamics] as a result of [the gauge symmetry above]. If we want to construct a gauge-invariant relativistic field theory involving a spin $1 / 2$ and a spin 1 field, then we are forced to quantum electrodynamics."

Geometrically, a complex number like the wave function can be shown in a two-dimensional complex plane in which the real and imaginary parts of the number form the axes. Multiplying the number by a factor $e^{i e x / \hbar}$ corresponds to rotating it over an angle $e \chi / \hbar$ around the origin in that plane. In those terms, the wave function can be rotated over an arbitrary, varying, angle in the complex plane and it still satisfies the Schrödinger equation.

For a relatively accessible derivation how the gauge invariance produces quantum electrodynamics, see [24, pp. 358ff]. To make some sense out of it, chapter 1.2 .5 gives a brief inroduction to relativistic index notation, chapter 12.12 to the Dirac equation and its matrices, addendum $\{$ A. 1$\}$ to Lagrangians, and $\{\mathrm{A} .21\}$ to photon wave functions. The $F^{\mu \nu}$ are derivatives of this wave function, [24, p. 239].

## A.19.6 Reservations about time shift symmetry

It is not quite obvious that the evolution of a physical system in empty space is the same regardless of the time that it is started. It is certainly not as obvious as the assumption that changes in spatial position do not make a difference. Cosmology does not show any evidence for a fundamental difference between different locations in space. For each spatial location, others just like it seem to exist elsewhere. But different cosmological times do show a major physical distinction. They differ in how much later they are than the time of the creation of the universe as we know it. The universe is expanding. Spatial distances between galaxies are increasing. It is believed with quite a lot of confidence that the universe started out extremely concentrated and hot at a "Big Bang" about 15 billion years ago.

Consider the cosmic background radiation. It has cooled down greatly since the universe became transparent to it. The expansion stretched the wave length of the photons of the radiation. That made them less energetic. You can look upon that as a violation of energy conservation due to the expansion of the universe.

Alternatively, you could explain the discrepancy away by assuming that the missing energy goes into potential energy of expansion of the universe. However, whether this "potential energy" is anything better than a different name for "energy that got lost" is another question. Potential energy is normally energy
that is lost but can be fully recovered. The potential energy of expansion of the universe cannot be recovered. At least not on a global scale. You cannot stop the expansion of the universe.

And a lack of exact energy conservation may not be such a bad thing for physical theories. Failure of energy conservation in the early universe could provide a possible way of explaining how the universe got all that energy in the first place.

In any case, for practical purposes nontrivial effects of time shifts seem to be negligible in the current universe. When astronomy looks at far-away clusters of galaxies, it sees them as they were billions of years ago. That is because the light that they emit takes billions of years to reach us. And while these galaxies look different from the current ones nearby, there is no evident difference in their basic laws of physics. Also, gravity is an extremely small effect in most other physics. And normal time variations are negligible compared to the age of the universe. Despite the Big Bang, conservation of energy remains one of the pillars on which physics is build.

## A. 20 Angular momentum of vector particles

This addendum is concerned with vector particles, particles whose wave functions are vectors. To be sure, the wave function of an electron can also be written as a vector, chapters 3.1 and 5.5.1:

$$
\text { electron: } \quad \vec{\Psi}(\vec{r} ; t) \equiv\binom{\Psi_{+}(\vec{r} ; t)}{\Psi_{-}(\vec{r} ; t)}
$$

But that is not a normal vector. It is a two-dimensional vector in three-dimensional space, and is known as a spinor. This addendum is concerned with wave functions that are normal three-dimensional vectors. That is of importance for understanding, for example, the spin angular momentum of photons. A photon is a vector particle, though a special one. It will be shown in this addendum that the spin of a vector particle is 1 . The parity of such a particle will also be discussed.

To really appreciate this addendum, you may want to read the previous addendum $\{\mathrm{A} .19\}$ first. In any case, according to that addendum angular momentum is related to what happens to the wave function under rotation of the coordinate system. In particular, the angular momentum in the $z$-direction is related to what happens if the coordinate system is rotated around the $z$-axis.

Consider first the simplest possible vector wave function:

$$
\vec{\Psi}=\vec{A}^{\prime} f(r) \quad \vec{A}^{\prime}=\left(\begin{array}{c}
A_{x}^{\prime} \\
A_{y}^{\prime} \\
A_{z}^{\prime}
\end{array}\right)
$$

Here $\vec{A}^{\prime}$ is a constant vector. Also $r$ is the distance from the origin around which the angular momentum is defined. Finally, $f(r)$ is any arbitrary function of $r$. The big question is now what happens to this wave function if the coordinate system is rotated over some angle $\gamma$ around the $z$-axis.

Figure A.8: Effect of rotation of the coordinate system on a vector. The vector is physically the same, but it has a different mathematical representation, different components, in the two coordinate systems.

The factor $f(r)$ does not change under rotations because the distance from the origin does not. But the vector $\overrightarrow{A^{\prime}}$ does change. Figure A. 8 shows what happens. The vector in the rotated coordinate system $x, y, z$ has components

$$
A_{x}=\cos (\gamma) A_{x}^{\prime}+\sin (\gamma) A_{y}^{\prime} \quad A_{y}=-\sin (\gamma) A_{x}^{\prime}+\cos (\gamma) A_{y}^{\prime} \quad A_{z}=A_{z}^{\prime}(\mathrm{A} .82)
$$

For example, the first relation expresses that $A_{x}^{\prime} \hat{\imath}^{\prime}$ has a component $\cos (\gamma) A_{x}^{\prime}$ in the direction of $\hat{\imath}$, while $A_{y}^{\prime} \hat{\jmath}^{\prime}$ has a component $\sin (\gamma) A_{y}^{\prime}$ in that direction. The second expression follows similarly. The $z$-component does not change under the rotation.

Now consider three very special vectors:

$$
\vec{Y}_{1}^{1}=\left(\begin{array}{c}
1 / \sqrt{2}  \tag{A.83}\\
\mathrm{i} / \sqrt{2} \\
0
\end{array}\right) \quad \vec{Y}_{1}^{0}=\left(\begin{array}{r}
0 \\
0 \\
-1
\end{array}\right) \quad \vec{Y}_{1}^{-1}=\left(\begin{array}{c}
-1 / \sqrt{2} \\
\mathrm{i} / \sqrt{2} \\
0
\end{array}\right)
$$

If you plug $\vec{A}^{\prime}=\vec{Y}_{1}^{1}$ into the relations (A.82) given above and use the Euler identity (2.5), you get $\vec{A}=e^{\mathrm{i} \gamma} \vec{Y}_{1}^{1}$. So the vector $\vec{Y}_{1}^{1}$ changes by a mere scalar factor, the exponential $e^{i \gamma}$, under the rotation of the coordinate system. According to the relationship between rotations and angular momentum, $\{\mathrm{A} .19\}$, that makes $\vec{Y}_{1}^{1}$ a state of definite angular momentum in the $z$-direction. Also, the magnetic quantum number $m_{s}$ of the momentum in the $z$-direction is by definition the coefficient of $\mathrm{i} \gamma$ in the exponential factor $e^{\mathrm{i} \gamma}=e^{1 \mathrm{i} \gamma}$. Here that
is 1 , so $m_{s}=1$. This value is shown as the superscript of the state $\vec{Y}_{1}^{1}$. The actual angular momentum in the $z$-direction is $m_{s} \hbar$, so it is $\hbar$ for this state. This angular momentum should be called spin, in analogy to the case for the electron. It is due to the fact that the wave function is a vector.

The vector $\vec{Y}_{1}^{0}$ has only a $z$-component, so it does not change under the rotation. Phrased differently, it changes by a unit factor $e^{0 i \gamma}$. That makes its magnetic quantum number $m_{s}$ zero, as the superscript in $\vec{Y}_{1}^{0}$ says. Then the angular momentum in the $z$-direction of this state is zero too. Finally, the vector $\vec{Y}_{1}^{-1}$ changes by a factor $e^{-1 i \gamma}$ under rotation, so it has $m_{s}=-1$, as its superscript says, and the angular momentum in the $z$-direction is $-\hbar$.

To get at square angular momentum, first the operator $\widehat{S}_{z}$ of spin angular momentum around the $z$-axis is needed. The relation between angular momentum and rotations shows that this operator takes the general form, $\{\mathrm{A} .19\}$ (A.76),

$$
\widehat{S}_{z}=\frac{\hbar}{\mathrm{i}} \lim _{\gamma \rightarrow 0} \frac{\mathcal{R}_{z, \gamma}-1}{\gamma}
$$

Here $\mathcal{R}_{z, \gamma}$ is the operator that describes the effect of the rotation of the coordinate system on the wave function. Applied on the vector $\vec{A}^{\prime}$ in the unrotated coordinate system, that means

$$
\widehat{S}_{z} \vec{A}^{\prime}=\frac{\hbar}{\mathrm{i}} \lim _{\gamma \rightarrow 0} \frac{\vec{A}-\vec{A}^{\prime}}{\gamma}
$$

Plugging in the components of $\vec{A}$ as given earlier, (A.82), and taking the limits using l'Hôpital, that produces

$$
\widehat{S}_{z}\left(\begin{array}{c}
A_{x}^{\prime} \\
A_{y}^{\prime} \\
A_{z}^{\prime}
\end{array}\right)=\frac{\hbar}{\mathrm{i}}\left(\begin{array}{c}
A_{y}^{\prime} \\
-A_{x}^{\prime} \\
0
\end{array}\right)
$$

So the operator $\widehat{S}_{z}$ drops the $z$-component and swaps the other two components, changing the sign of the first, and then adds a factor $\hbar / \mathrm{i}$. If the same operations are performed another time, the net result is:

$$
\widehat{S}_{z}^{2}\left(\begin{array}{c}
A_{x}^{\prime} \\
A_{y}^{\prime} \\
A_{z}^{\prime}
\end{array}\right)=\hbar^{2}\left(\begin{array}{c}
A_{x}^{\prime} \\
A_{y}^{\prime} \\
0
\end{array}\right)
$$

So the square operator just drops the $z$-component and adds a factor $\hbar^{2}$.
Of course, the operators $\widehat{S}_{x}^{2}$ and $\widehat{S}_{y}^{2}$ are defined similarly. There is nothing special about the $z$-axis. The operator of square spin angular momentum is defined as

$$
\widehat{S}^{2} \equiv \widehat{S}_{x}^{2}+\widehat{S}_{y}^{2}+\widehat{S}_{z}^{2}
$$

Since each of the operators in the right hand side drops a different component and adds a factor $\hbar^{2}$ to the other two, the total for any vector $\vec{A}^{\prime}$ is,

$$
\widehat{S}^{2} \vec{A}^{\prime}=2 \hbar^{2} \overrightarrow{A^{\prime}}
$$

So the square spin operator always produces a simple multiple of the original vector. That makes any vector an eigenvector of square spin angular momentum. Also, the azimuthal quantum number $s$, the spin, can by definition be found from equating the coefficient $2 \hbar^{2}$ of $\vec{A}^{\prime}$ in the right hand side above to $s(s+1) \hbar^{2}$. The only nonnegative value $s$ that can satisfy this condition is $s=$ 1.

That then means that the spin $s$ of vector particles is equal to 1 . So a vector particle is a boson of spin 1. The subscript on the special vectors $\vec{Y}_{1}^{m_{s}}$ indicates their spin $s=1$.

You can write the most general vector wave function in the form

$$
\vec{\Psi}(\vec{r} ; t)=\Psi_{1}(\vec{r} ; t) \vec{Y}_{1}^{1}+\Psi_{0}(\vec{r} ; t) \vec{Y}_{1}^{1}+\Psi_{-1}(\vec{r} ; t) \vec{Y}_{1}^{-1}
$$

Then you can put the coefficients in a vector much like the wave function of the electron, but now three-dimensional:

$$
\text { vector boson: } \vec{\Psi}(\vec{r} ; t) \equiv\left(\begin{array}{c}
\Psi_{1}(\vec{r} ; t) \\
\Psi_{0}(\vec{r} ; t) \\
\Psi_{-1}(\vec{r} ; t)
\end{array}\right)
$$

Like the electron, the vector particle can of course also have orbital angular momentum. That is due to the coefficients $\Psi_{m_{s}}$ in the wave function above. So far it has been assumed that these coefficients only depended on the distance $r$ from the origin. However, consider the following more general component of a vector wave function:

$$
\begin{equation*}
\vec{Y}_{1}^{m_{s}} f(r) Y_{l}^{m_{l}}(\theta, \phi) \tag{A.84}
\end{equation*}
$$

Here $\theta$ and $\phi$ are the position angles in spherical coordinates, and $Y_{l}^{m_{l}}$ is a socalled spherical harmonic of orbital angular momentum, chapter 4.2.3. For the above wave function to be properly normalized,

$$
\int_{r=0}^{\infty} r^{2} f(r) \mathrm{d} r=1
$$

(To check this, take a dot, or rather inner, product of the wave function with itself. Then integrate over all space using spherical coordinates and the orthonormality of the spherical harmonics.)

The wave function (A.84) above has orbital angular momentum in the $z$ direction equal to $m_{l} \hbar$ in addition to the spin angular momentum $m_{s} \hbar$. So the total angular momentum in the $z$-direction is $\left(m_{s}+m_{l}\right) \hbar$. To check that, note that under rotations of the coordinate system, the vector changes by a factor
$e^{m_{s} \mathrm{i} \gamma}$ while the spherical harmonic changes by an additional factor $e^{m_{l} \mathrm{i} \gamma}$. That makes the total change a factor $e^{\left(m_{s}+m_{l}\right) \mathrm{i} \gamma}$.

In general, then, the magnetic quantum number $m_{j}$ of the net angular momentum is simply the sum of the spin and orbital ones,

$$
\begin{equation*}
m_{j}=m_{s}+m_{l} \tag{A.85}
\end{equation*}
$$

However, the situation for the azimuthal quantum number $j$ of the net angular momentum is not so simple. In general the wave function (A.84) above will have uncertainty in the value of $j$. Combinations of wave functions of the form (A.84) are usually needed to get states of definite $j$.

That is a complicated issue best left to chapter 12. But a couple of special cases are worth mentioning already. First, if $m_{s}=1$ and $m_{l}=l$, or alternatively, if $m_{s}=-1$ and $m_{l}=-l$, then $j$ is simply the sum of the spin and orbital azimuthal quantum numbers $1+l$.

The other special case is that there is zero net angular momentum. Zero net angular momentum means that the wave function is exactly the same regardless how the coordinate system is rotated. And that only happens for a vector wave function if it is purely radial:

$$
\hat{\imath}_{r} f(r) \frac{1}{\sqrt{4 \pi}}
$$

Here $\hat{\imath}_{r}$ is the unit vector sticking radially outward away from the origin. The final constant is the spherical harmonic $Y_{0}^{0}$. It is needed the satisfy the normalization requirement unless you change the one on $f$.

The above state has zero net angular momentum. The question of interest is what can be said about its spin and orbital angular momentum. To answer that, it must be rewritten in terms of Cartesian components. Now the unit vector $\hat{\imath}_{r}$ has Cartesian components

$$
\hat{\imath}_{r}=\frac{x}{r} \hat{\imath}+\frac{y}{r} \hat{\jmath}+\frac{z}{r} \hat{k}
$$

The spatial factors in this expression can be written in terms of the spherical harmonics $Y_{1}^{m_{l}}$, chapter 4.2.3. That gives the state of zero net angular momentum as

$$
\hat{\imath}_{r} f(r) Y_{0}^{0}=\left(\sqrt{1 / 3} \vec{Y}_{1}^{1} Y_{1}^{-1}-\sqrt{1 / 3} \vec{Y}_{1}^{0} Y_{1}^{0}+\sqrt{1 / 3} \vec{Y}_{1}^{-1} Y_{1}^{1}\right) f(r)
$$

To check this, just plug in the expressions for the $\vec{Y}_{1}^{m_{s}}$ of (A.83), and for the $Y_{1}^{m_{l}}$ of table 4.3.

The bottom line is that by combining states of unit spin $s=1$, and unit orbital angular momentum $l=1$, you can create a state of zero net angular momentum, $j=0$. Note also that in each of the three terms in the right hand side above, $m_{s}$ and $m_{l}$ add up to zero. A state of zero angular momentum $j=$

0 must have $m_{j}=0$ without uncertainty. Further note that the values of both the spin and orbital angular momentum in the $z$-direction are uncertain. Each of the two has measurable values $\hbar, 0$, or $-\hbar$ with equal probability $\frac{1}{3}$.

The above relation may be written more neatly in terms of "ket notation." In ket notation, an angular momentum state with azimuthal quantum number $j$ and magnetic quantum number $m_{j}$ is indicated as $\left|j m_{j}\right\rangle$. Using this notation, and dropping the common factor $f(r)$, the above relation can be written as

$$
|00\rangle_{j}=\sqrt{1 / 3}|11\rangle_{s}|1-1\rangle_{l}-\sqrt{1 / 3}|10\rangle_{s}|10\rangle_{l}+\sqrt{1 / 3}|1-1\rangle_{s}|11\rangle_{l}
$$

Here the subscripts $j, s$, and $l$ indicate net, spin, and orbital angular momentum, respectively.

There is a quicker way to get this result than going through the above algebraic mess. You can simply read off the coefficients in the appropriate column of the bottom-right tabulation in figure 12.6. (In this figure take $a$ to stand for spin, $b$ for orbital, and $a b$ for net angular momentum.) Figure 12.6 also has the coefficients for many other net spin states that you might need. A derivation of the figure must wait until chapter 12.

The parity of vector wave functions is also important. Parity is what happens to a wave function if you invert the positive direction of all three Cartesian axes. What happens to a vector wave function under such an inversion can vary. A normal, or "polar," vector changes sign when you invert the axes. For example, a position vector $\vec{r}$ in classical physics is a polar vector. Each position coordinate $x, y$, and $z$ changes sign, and therefore so does the entire vector. Similarly, a velocity vector $\vec{v}$ is a polar vector; it is just the time derivative of position. A particle with a vector wave function that behaves like a normal vector has negative intrinsic parity. The sign of the wave function flips over under axes inversion. Particles of this type turn out to include the photon.

But now consider an example like a classical angular momentum vector, $\vec{r} \times$ $m \vec{v}$. Since both the position and the velocity change sign under spatial inversion, a classical angular momentum vector stays the same. A vector that does not change under axes inversion is called a "pseudovector" or "axial" vector. A particle whose wave function behaves like a pseudovector has positive intrinsic parity.

Note however that the orbital angular momentum of the particle also has an effect on the net parity. In particular, if the quantum number of orbital angular momentum $l$ is odd, then the net parity is the opposite of the intrinsic one. If the quantum number $l$ is even, then the net parity is the intrinsic one. The reason is that spherical harmonics change sign under spatial inversion if $l$ is odd, but not when $l$ is even, $\{\mathrm{D} .14\}$.

Particles of all types often have definite parity. Such a particle may still have uncertainty in $l$. But if parity is definite, the measurable values of $l$ will need to be all even or all odd.

## A. 21 Photon type 2 wave function

In quantum mechanics, photons are the particles of the electromagnetic field. To actually use photons, something like a wave function for them is needed. But that is not quite trivial for a purely relativistic particle with zero rest mass like the photon. That is the primary topic of this addendum. It will be assumed throughout that the photon is in empty space.

## A.21.1 The wave function

To see the problem with a photon wave function, a review of the wave function of the nonrelativistic electron is useful, chapters 3.1 and 5.5.1. The electron wave function can be written as a vector with two components:

$$
\text { electron: } \quad \vec{\Psi}(\vec{r} ; t) \equiv\binom{\Psi_{+}(\vec{r} ; t)}{\Psi_{-}(\vec{r} ; t)}
$$

This wave function takes on two different meanings

1. It gives the probability per unit volume of finding the electron at a given position with a given spin. For example, $\left|\Psi_{+}(\vec{r} ; t)\right|^{2} \mathrm{~d}^{3} \vec{r}$ gives the probability of finding the electron with spin-up in an vicinity of infinitesimal volume $\mathrm{d}^{3} \vec{r}$ around position $\vec{r}$. That is the Born statistical interpretation.
2. It is the unobservable function that nature seems to use to do its quantum "computations" of how physics behaves.
Now a wave function of type 1 is not really meaningful for a photon. What would it mean, find a photon? Since the photon has no rest mass, you cannot bring them to a halt: there would be nothing left. And anything you do to try to localize the electromagnetic field is likely to just produce new photons. (To be sure, with some effort something can be done towards a meaningful wave function of type 1, e.g. [Sype, J.E. 1995 Phys. Rev. A 52, 1875]. It would have two components like the electron, since the photon has two independent spin states. But wave functions of that type are not widely accepted, nor useful for the purposes here.)

So what? A wave function of type 1 is not that great anyway. For one, it only defines the magnitudes of the components of the wave function. If you only define the magnitude of a complex function, you define only half of it. True, even as a type 2 wave function the classical electron wave function is not quite unique. You can still multiply either component by a factor $e^{\mathrm{i} \alpha}$, with $\alpha$ a real constant, without changing any of the physics. But that is not by far as bad as completely ignoring everything else besides the magnitude.

Furthermore, relativistic quantum mechanics has discovered that what we call an electron is something cloaked in a cloud of virtual particles. It is anybody's guess what is inside that cloak, but it will not be anything resembling
what we would call an electron. So what does it really mean, finding an electron within an infinitesimal volume around a point? What happens to that cloak? And to really locate an electron in an infinitesimal volume requires infinite energy. If you try to locate the electron in a region that is small enough, you are likely to just create additional electron-positron pairs much like for photons.

For most practical purposes, classical physics understands the particle behavior of electrons very well, but not their wave behavior. Conversely, it understands the wave behavior of photons very well, but not their particle behavior. But when you go to high enough energies, that distinction becomes much less obvious.

The photon most definitely has a wave function of type 2 above. In quantum electrodynamics, it may simply be called the photon wave function, [24, p. 240]. However, since the term already seems to be used for type 1 wave functions, this book will use the term "photon type 2 wave function." It may not tell you where to find that elusive photon, but you will definitely need it to figure out how that photon interacts with, say, an electron.

What the type 2 wave function of the photon is can be guessed readily from classical electromagnetics. After all, the photon is supposed to be the particle of the electromagnetic field. So, consider first electrostatics. In classical electrostatics the forces on charged particles are described by an electric force per unit charge $\overrightarrow{\mathcal{E}}$. That is called the electric field.

But quantum mechanics uses potentials, not forces. For example, the solution of the hydrogen atom of chapter 4.3 used a potential energy of the electron $V$. In electrostatics, this potential energy is written as $V=-e \varphi$ where $-e$ is the charge of the electron and $\varphi$ is called the electrostatic potential. This potential is not directly observable nor unique; you can add any constant to it without changing the observed physics.

Clearly, an unobservable function $\varphi$ for the electromagnetic field sounds much like a wave function for the particle of that field, the photon. But actually, the electrostatic potential $\varphi$ is only part of it. In classical electromagnetics, there is not just an electric field $\overrightarrow{\mathcal{E}}$, there is also a magnetic field $\overrightarrow{\mathcal{B}}$. It is known that this magnetic field can be represented by a so-called "vector potential" $\vec{A}$.

The following relationships give the electric and magnetic fields in terms of these potentials:

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=-\nabla \varphi-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A} \tag{A.86}
\end{equation*}
$$

Here the operator

$$
\nabla=\hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

is called nabla or del. As an example, for the $z$ components of the fields:

$$
\mathcal{E}_{z}=-\frac{\partial \varphi}{\partial z}-\frac{\partial A_{z}}{\partial t} \quad \mathcal{B}_{z}=\frac{\partial A_{y}}{\partial x}-\frac{\partial A_{x}}{\partial y}
$$

When both potentials are allowed for, the nonuniqueness becomes much larger. In particular, for any arbitrary function $\chi$ of position and time, you can find two different potentials $\varphi^{\prime}$ and $\vec{A}^{\prime}$ that produce the exact same electric and magnetic fields as $\varphi$ and $\vec{A}$. These potentials are given by

$$
\begin{equation*}
\varphi^{\prime}=\varphi-\frac{\partial \chi}{\partial t} \quad \vec{A}^{\prime}=\vec{A}+\nabla \chi \tag{A.87}
\end{equation*}
$$

This indeterminacy in potentials is the famous "gauge property" of the electromagnetic field.

Finally, it turns out that classical relativistic mechanics likes to combine the four scalar potentials in a four-dimensional vector, or four-vector, chapter 1.3.2:

$$
\overleftrightarrow{A}=\binom{\varphi / c}{\vec{A}}=\left(\begin{array}{c}
\varphi / c \\
A_{x} \\
A_{y} \\
A_{z}
\end{array}\right)
$$

That is the one. Quantum mechanics takes a four-vector potential of this form to be the type 2 wave function of the photon $\vec{A}_{\gamma}$. It keeps the gauge property (A.87) for this wave function. However, note the following important caveat:

The photon wave function $\overleftrightarrow{A}_{\gamma}$ should not be confused with the clas-
sical four-potential $\stackrel{\rightharpoonup}{A}$. sical four-potential $\vec{A}$.

Wave functions are in general complex. The classical four-potential, and especially its physically observable derivatives, the electric and magnetic fields, must be real. Indeed, according to quantum mechanics, observable quantities correspond to eigenvalues of Hermitian operators, not to wave functions. What the operators of the observable electric and magnetic fields are will be discussed in addendum \{A.23\}.

## A.21.2 Simplifying the wave function

To use the photon wave function in practical applications, it is essential to simplify it. That can be done by choosing a clever gauge function $\chi$ in the gauge property (A.87).

One very helpful simplification is to choose $\chi$ so that

$$
\begin{equation*}
\frac{1}{c} \frac{\partial \varphi_{\gamma} / c}{\partial t}+\nabla \cdot \vec{A}_{\gamma}=0 \tag{A.88}
\end{equation*}
$$

where $c$ is the speed of light. This is called the "Lorenz condition." A corresponding gauge function is a "Lorenz gauge." The reason why the Lorenz condition is a good one is because all observers in inertial motion will agree
it is true. (You can crunch that out using the Lorentz transform as given in chapter 1.2.1 (1.6). The four-vector $\breve{A}_{\gamma}$ transforms the same way as the fourvector $\vec{r}$. However, you will need to use the inverse transform for one of the two four-vectors. Alternatively, those familiar with index notation as briefly described in chapter 1.2.5 recognize the Lorenz condition as being simply $\partial_{\mu} A_{\gamma}^{\mu}$ $=0$. That is unchanged going from one observer to the next, because the upper index transforms under the Lorentz transform and the lower index under the inverse Lorentz transform.)

To achieve the Lorenz condition, assume an initial wave function $\left(\varphi_{\gamma}^{\prime}, \vec{A}_{\gamma}^{\prime}\right)$ that does not satisfy it. Then plug the gauge property (A.87) into the Lorenz condition above. That shows that the needed gauge function $\chi$ must satisfy

$$
-\frac{1}{c^{2}} \frac{\partial^{2} \chi}{\partial t^{2}}+\nabla^{2} \chi=\frac{1}{c} \frac{\partial \varphi_{\gamma}^{\prime} / c}{\partial t}+\nabla \cdot \vec{A}_{\gamma}^{\prime}
$$

This equation for $\chi$ is called an inhomogeneous Klein-Gordon equation. (More generically, it is called an inhomogeneous wave equation.)

There is another reason why you want to satisfy the Lorenz condition. The photon is a purely relativistic particle with zero rest mass. Then following the usual ideas of quantum mechanics, in empty space its wave function should satisfy the homogeneous Klein-Gordon equation, $\{\mathrm{A} .14\}$ (A.43):

$$
\begin{equation*}
-\frac{1}{c^{2}} \frac{\partial^{2} \overleftrightarrow{A}_{\gamma}}{\partial t^{2}}+\nabla^{2} \overleftrightarrow{A}_{\gamma}=0 \tag{A.89}
\end{equation*}
$$

Unfortunately, that is not automatic. In general, gauge transforms mess up this equation. However, as long as gauge transforms respect the Lorenz condition, they also respect the Klein-Gordon equation. So reasonably speaking, "normal" photon wave functions, the ones that do satisfy the Klein-Gordon equation, should be exactly the ones that also satisfy the Lorenz condition.

Maxwell's classical electromagnetics provides additional support for that idea. There the Klein-Gordon equation for the potentials also requires that the Lorenz condition is satisfied, $\{$ A. 37$\}$.

Since the inhomogeneous Klein-Gordon equation for the gauge function $\chi$ is second order in time, it still leaves two initial conditions to be chosen. These can be chosen such as to make the initial values for $\varphi_{\gamma}$ and its time-derivative zero. That then makes $\varphi_{\gamma}$ completely zero, because it satisfies the homogeneous Klein-Gordon equation.

And so the fully simplified photon wave function becomes:

$$
\begin{array}{|cc|}
\hline \text { Coulomb-Lorenz gauge: } & \overleftrightarrow{A}_{\gamma}=\binom{0}{\vec{A}_{\gamma}} \quad \nabla \cdot \vec{A}_{\gamma}=0  \tag{A.90}\\
\hline
\end{array}
$$

The final condition applies because of the Lorenz condition (A.88). Using an expensive word, the final condition says that $\vec{A}_{\gamma}$ must be "solenoidal." A gauge function that makes $\vec{A}_{\gamma}$ solenoidal is called a "Coulomb gauge."

It should be noted that the Coulomb gauge is not Lorentz invariant. A moving observer will not agree that the potential $\varphi_{\gamma}$ is zero and that $\vec{A}_{\gamma}$ is solenoidal. In real life that means that if you want to study a process in say a center-of-mass system, first switch to that system and then assume the Coulomb gauge. Not the other way around. The Coulomb-Lorenz gauge is too helpful not to use, although that is possible, [24, p. 241].

## A.21.3 Photon spin

Now that the photon wave function has been simplified the photon spin can be determined. Recall that for the electron, the two components of the wave function correspond to its two possible values of the spin angular momentum $\widehat{S}_{z}$ in the chosen $z$-direction. In particular, $\Psi_{+}$corresponds to $\widehat{S}_{z}=\frac{1}{2} \hbar$, and $\Psi_{-}$to $\widehat{S}_{z}=-\frac{1}{2} \hbar$. Since the wave function of the photon is a four-dimensional vector, at first it might therefore look like the photon should have spin $3 / 2$. That would make $\widehat{S}_{z}$ one of $\frac{3}{2} \hbar, \frac{1}{2} \hbar,-\frac{1}{2} \hbar$, or $-\frac{3}{2} \hbar$. But that is not true.

The simplified wave function (A.90) has only three nontrivial components. And the gauge property requires that this simplified wave function still describes all the physics. Since the only nontrivial part left is the three-dimensional vector $\vec{A}_{\gamma}$, the spin of the photon must be 1 . The possible values of the spin in the $z$ direction $\widehat{S}_{z}$ are $\hbar, 0$, and $-\hbar$. The photon is a vector boson like discussed in addendum $\{$ A. 20$\}$.

However, that is not quite the end of the story. There is still that additional condition $\nabla \cdot \vec{A}_{\gamma}=0$ to satisfy. In principle this constraint allows another component of the wave function to be eliminated. However, all three remaining components are spatial ones. So it does not make much sense to eliminate one and not the other. More importantly, it is known from relativity that $\vec{A}$ behaves like a normal three-dimensional vector under rotations of the coordinate system, not like a two-dimensional spinor like the electron wave function. That is implicit in the fact that the complete four-vector transforms according to the Lorentz transform, chapter 1.3.2. The spin is really 1.

Still, the additional constraint does limit the angular momentum of the photon. In particular, a photon does not have independent spin and orbital angular momentum. The two are intrinsically linked. What that means for the net angular momentum of photons is worked out in subsection A.21.7.

For now it may already be noted that the photon has no state of zero net angular momentum. A state of zero angular momentum needs to look the same from all directions. That is a consequence of the relationship between angular momentum and symmetry, chapter 7.3. Now the only vector wave functions that look the same from all directions are of the form $\hat{\imath}_{r} f(r)$. Here $r$ is the distance from the origin around which the angular momentum is measured and $\hat{\imath}_{r}$ the unit vector pointing away from the origin. Such a wave function cannot
satisfy the condition $\nabla \cdot \hat{\imath}_{r} f(r)=0$. That follows from applying the divergence theorem for a sphere around the origin.

## A.21.4 Energy eigenstates

Following the rules of quantum mechanics, $\{\mathrm{A} .14\}$, photon states of definite energy $E$ take the form

$$
\vec{A}_{\gamma}=c_{0} \vec{A}_{\gamma}^{\mathrm{e}} e^{-\mathrm{i} E t / \hbar}
$$

Here $c_{0}$ is an arbitrary constant. More importantly $\vec{A}_{\gamma}^{\text {e }}$ is the energy eigenfunction, which is independent of time.

Substitution in the Klein-Gordon equation and cleaning up shows that this eigenfunction needs to satisfy the eigenvalue problem, \{A.14\},

$$
\begin{equation*}
-\nabla^{2} \vec{A}_{\gamma}^{\mathrm{e}}=k^{2} \vec{A}_{\gamma}^{\mathrm{e}} \quad k \equiv \frac{E}{\hbar c}=\frac{p}{\hbar} \quad E=\hbar \omega \quad p=\hbar k \tag{A.91}
\end{equation*}
$$

Here $p$ is the magnitude of the linear momentum of the photon. The so-called Planck-Einstein relation gives the energy $E$ in terms of the photon frequency $\omega$, while the de Broglie relation gives the momentum $p$ in terms of the photon wave number $k$.

## A.21.5 Normalization of the wave function

A classical wave function for a particle is normalized by demanding that the square integral of the wave function is 1 . That does not work for a relativistic particle like the photon, since the Klein-Gordon equation does not preserve the square integral of the wave function, $\{A .14\}$.

However, the Klein-Gordon equation does preserve the following integral, \{D.36.1\},

$$
\int_{\text {all }}\left(\left|\frac{\partial \vec{A}_{\gamma}}{\partial t}\right|^{2}+c^{2}\left|\nabla \vec{A}_{\gamma}\right|^{2}\right) \mathrm{d}^{3} \vec{r}=\text { the same for all time }
$$

Reasonably speaking, you would expect this integral to be related to the energy in the electromagnetic field. After all, what other scalar physical quantity is there to be preserved?

Consider for a second the case that $\vec{A}_{\gamma}$ was a classical potential $\vec{A}$ instead of a photon wave function. Then the above integral can be rewritten in terms of the electric and magnetic fields $\overrightarrow{\mathcal{E}}$ and $\overrightarrow{\mathcal{B}}$ as, $\{$ D.36.1\},

$$
\int_{\text {all }}\left(|\overrightarrow{\mathcal{E}}|^{2}+c^{2}|\overrightarrow{\mathcal{B}}|^{2}\right) \mathrm{d}^{3} \vec{r}=\text { the same for all time }
$$

Now classical physics does not have photons of energy $\hbar \omega$. All it has are electric and magnetic fields. Then surely the integral above must be a measure for the energy in the electromagnetic field? What is more logical than that the energy in the electromagnetic field per unit volume would be given by the square magnitudes of the electric and magnetic fields? No fields, no energy.

Of course, there needs to be an additional constant; the integral above does not have units of energy. If you check, you find that the "permittivity of space" $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ has the right units to be the constant. Actually, it turns out that the correct constant is $\frac{1}{2} \epsilon_{0}$. But that is not a fundamental issue; classical physics could just as well have defined $\epsilon_{0}$ as half of what it did.

Now the photon wave function is not physically observable and does not have to conform to the rules of classical physics. But if you have to choose a normalization constant anway? Why not choose it so that what classical physics would take to be the energy is in fact the correct energy $\hbar \omega$ ? It is likely to simplify your life a lot.

So, the photon wave function normalization that will be used in this book is:

$$
\begin{equation*}
\frac{1}{2} \epsilon_{0} \int_{\text {all }}\left(\left|\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right|^{2}+c^{2}\left|\overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}\right|^{2}\right) \mathrm{d}^{3} \vec{r}=\hbar \omega \tag{A.92}
\end{equation*}
$$

Here $\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}$ and $\overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}$ are what classical physics would take to be the electric and magnetic fields for the normalized photon energy eigenfunction $\vec{A}_{\gamma}^{\text {n }}$. Specifically,

$$
\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\mathrm{i} k c \vec{A}_{\gamma}^{\mathrm{n}} \quad \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\nabla \times \vec{A}_{\gamma}^{\mathrm{n}}
$$

(To be sure, classical physics would take $\overrightarrow{\mathcal{E}}$ to be minus the time derivative of the potential $\vec{A}$. But for an energy eigenstate, the time derivative gives a simple factor $-\mathrm{i} \omega=-\mathrm{i} k c$.) The functions $\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}$ and $\overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}$ will be referred to as "unobservable fields" to avoid confusion with the observable electric and magnetic fields.

Assume that you start with an unnormalized energy eigenfunction $\vec{A}_{\gamma}^{e}$. Then the normalized functions are usually most conveniently written as

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \vec{A}_{\gamma}^{\mathrm{e}} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \vec{A}_{\gamma}^{\mathrm{e}} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k} \nabla \times \vec{A}_{\gamma}^{\mathrm{e}} \tag{A.93}
\end{equation*}
$$

Here the constant $\varepsilon_{k}$ is to be found by substitution into the normalization condition (A.92).

## A.21.6 States of definite linear momentum

The simplest quantum states for photons are states of definite linear momentum $\vec{p}$. And to make it even simpler, it will be assumed that the $z$-axis is chosen in the direction of the linear momentum.

In that case, the photon wave function takes the form

$$
\vec{A}_{\gamma}^{e}=\vec{A}^{0} e^{\mathrm{i} k z} \quad \vec{p}=\hat{k} \hbar k
$$

Here $\vec{A}^{0}$ is a constant vector. That this wave function has definite linear momentum $\vec{p}$ may be verified by applying the linear momentum operator $\vec{p}=\hbar \nabla / \mathrm{i}$ on it. And substitution into the eigenvalue problem (A.91) verifies that it is an energy eigenfunction.

The vector $\vec{A}^{0}$ is not completely arbitrary; its $z$-component must be zero. That is in order that $\nabla \cdot \vec{A}_{\gamma}^{e}$ is zero as the Coulomb-Lorenz gauge requires. So the wave function can be written as

$$
\vec{A}_{\gamma}^{\mathrm{e}}=A_{x}^{0} \hat{i} e^{\mathrm{i} k z}+A_{y}^{0} \hat{\jmath} e^{\mathrm{i} k z}
$$

The bottom line is that there are only two independent states, even though the wave function is a three-dimensional vector. The wave function cannot have a component in the direction of motion. It may be noted that the first term in the right hand side above is called a wave that is "linearly polarized" in the $x$ direction. Similarly, the second term is a wave that is linearly polarized in the $y$-direction. There is no longitudinal polarization of photons possible.

There is another useful way to write the wave function:

$$
\vec{A}_{\gamma}^{\mathrm{e}}=c_{1}(\hat{\imath}+\mathrm{i} \hat{\jmath}) e^{\mathrm{i} k z}+c_{2}(-\hat{\imath}+\mathrm{i} \hat{\jmath}) e^{\mathrm{i} k z}
$$

where $c_{1}$ and $c_{2}$ are constants. The first term in this expression is called "rightcircularly polarized." It has angular momentum $\hbar$ in the $z$-direction. (To see why is a matter of rotating the coordinate system around the $z$-axis, $\{\mathrm{A} .20\}$. The exponential does not change in such a rotation.) Similarly, the second state has angular momentum $-\hbar$ in the $z$-direction and is called left-circularly polarized. There is no state with angular momentum zero in the $z$-direction. In fact, it is exactly the missing $z$-component of $\vec{A}^{0}$ that would provide such a state, $\{$ A. 20$\}$.

There are still only two independent states. But another way of thinking about that is that the spin angular momentum in the direction of motion cannot be zero. The relative spin in the direction of motion, $m_{s} / s$ is called the "helicity." It turns out that for a particle with zero rest mass like the photon, the helicity can only be 1 (right handed) or -1 (left handed), [24, p. 65].

Note further that the angular momenta in the $x$ and $y$ directions are uncertain. It so happens that the angular momentum in the direction of motion commutes with all three components of linear momentum, chapter 4.5.4. So it can have definite values. But the $x$ and $y$ angular momenta do not commute.

For later use, it is necessary to normalize the wave function using the procedure described in the previous subsection. To do so, it must be assumed that the photon is in a periodic box of volume $\mathcal{V}$, like in chapter 6.17. In infinite
space the wave function cannot be normalized, as it does not become zero at infinity. For the right-circularly polarized wave function as given above,

$$
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \frac{\hat{\imath}+\mathrm{i} \hat{\mathrm{j}}}{\sqrt{2}} e^{\mathrm{i} k z} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \frac{\hat{\imath}+\mathrm{i} \hat{\jmath}}{\sqrt{2}} e^{\mathrm{i} k z} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \frac{-\mathrm{i} \hat{\imath}+\hat{\jmath}}{\sqrt{2}} e^{\mathrm{i} k z} \quad \varepsilon_{k}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}}
$$

In order to compare to the classical electromagnetic wave in chapter 7.7.1, another example is needed. This photon wave function has its linear momentum in the $y$-direction, and it is linearly polarized in the $z$-direction. Then an unnormalized energy eigenfunction is

$$
\vec{A}_{\gamma}^{\mathrm{e}}=\hat{k} e^{\mathrm{i} k y}
$$

The normalized eigenfunction and unobservable fields are in that case

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \hat{k} e^{\mathrm{i} k y} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \hat{k} e^{\mathrm{i} k y} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \hat{i} e^{\mathrm{i} k y} \quad \varepsilon_{k}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}} \tag{A.95}
\end{equation*}
$$

Note that $\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}, \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}$, and the linear momentum are all orthogonal. That will reflect in the observable fields associated with the photon state. For the circularly polarized state, the electric and magnetic fields are not orthogonal. However, the observable fields will be.

For a general direction of the wave motion and its linear polarization, the above expession becomes

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \hat{\imath}_{\mathcal{E}} e^{\mathrm{i} \vec{k} \cdot \vec{r}} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \hat{\imath} \mathcal{\mathcal { L }} e^{\mathrm{i} \cdot \vec{r}} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \hat{\imath} \mathcal{B} e^{\mathrm{i} \vec{k} \cdot \vec{r}} \quad \varepsilon_{k}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}} \tag{A.96}
\end{equation*}
$$

Here $\vec{k}$ and the unit vectors $\hat{\imath}_{\mathcal{E}}$ and $\hat{\imath}_{\mathcal{B}}=\vec{k} \times \hat{\imath}_{\mathcal{E}} / k$ are all orthogonal
For convenience, the density of states as needed for Fermi's golden rule will be listed here. It was given earlier in chapter 6.3 (6.7) and 6.19:

$$
\frac{\mathrm{d} N}{\mathrm{~d} E}=\frac{\omega^{2}}{\hbar \pi^{2} c^{3}} \mathcal{V}
$$

## A.21.7 States of definite angular momentum

It is often convenient to describe photons in terms of states of definite net angular momentum. That makes it much easier to apply angular momentum conservation in the emission of radiation by atoms or atomic nuclei. Unfortunately, angular momentum states are a bit of a mess compared to the linear momentum states of the previous subsection. Fortunately, engineers are brave.

Before diving in, it is a good idea to look first at a spinless particle. Assume that this hypothetical particle is in an energy eigenstate. Also assume that this
state has square orbital angular momentum $l(l+1) \hbar^{2}$ where $l$ is called the azimuthal quantum number. And that the state has orbital angular momentum in the $z$-direction $m_{l} \hbar$ where $m_{l}$ is called the magnetic quantum number. Then according to quantum mechanics, chapter 4.2.3, $l$ must be a nonnegative integer and $m_{l}$ must be an integer no larger in magnitude than $l$. Also, in spherical coordinates $(r, \theta, \phi)$, figure 4.7, the angular dependence of the energy eigenfunction must be given by the so-called spherical harmonic $Y_{l}^{m_{l}}(\theta, \phi)$. If in addition the particle is in empty space, the energy eigenfunction takes the general form, \{A.6\},

$$
\psi=j_{l}(k r) Y_{l}^{m_{l}}(\theta, \phi) \quad \text { with } \quad-\nabla^{2} \psi=k^{2} \psi
$$

Here $k$ is a constant related to the energy of the particle and whether it is relativistic or not, $\{\mathrm{A} .14\}$ (A.44). Further $j_{l}$ is the so-called "spherical Bessel function of the first kind of order $l, "\{A .6\}$. The parity of the eigenfunction is positive if $l$ is even and negative if $l$ is odd, \{D.14\}. The eigenfunction is of order $r^{l}$ near the origin. That is only nonzero at the origin $r=0$ if $l=0$. That is important if there is, say, a vanishingly small atom is located at the origin. All states except $l=0$ are virtually zero at such an atom. So the atom only has a decent chance to interact with the particle if the particle is in a state $l=$ 0 . End discussion of the hypothetical spinless particle.

Now the photon is a particle with spin 1. Its wave function is essentially a vector $\vec{A}_{\gamma}$. The angular momentum states and parity for such particles were discussed in $\{$ A. 20$\}$. But the photon is a special case because it must be solenoidal, it must satisfy $\nabla \cdot \vec{A}_{\gamma}=0$. Normally, for three-dimensional vectors you expect three types of angular momentum states, like in \{A.20\}. But for the photon there are only two types.

The two types of photon energy eigenfunctions with definite net angular momentum are, $\{\mathrm{D} .36 .2\}$ and with drums please,

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{E}}=\nabla \times \vec{r} \times \nabla j_{\ell}(k r) Y_{\ell}^{m_{\ell}}(\theta, \phi) \quad \vec{A}_{\gamma}^{\mathrm{M}}=\vec{r} \times \nabla j_{\ell}(k r) Y_{\ell}^{m_{\ell}}(\theta, \phi) \tag{A.97}
\end{equation*}
$$

Here $\ell$ is the azimuthal quantum number of the net photon angular momentum, orbital plus spin. And $m_{\ell}$ is the corresponding net magnetic quantum number.

The azimuthal quantum number $\ell$ is at least 1 ; the expressions above produce zero for $\ell=0$. ( $Y_{0}^{0}$ is just a constant and the gradient of a radial function is in the direction of $\vec{r}$.) The photon energy is related to the wave number $k$ as $\hbar k c$ with $c$ the speed of light, (A.91). That is really the Planck-Einstein relation, because $k c$ is the photon frequency $\omega$.

The parity of the electric multipole wave functions is negative if $\ell$ is odd and positive if $\ell$ is even, $\{\mathrm{D} .36 .2 .7\}$. The parity of the magnetic multipole wave functions is exactly the other way around. From that it can be seen, $\{D .36 .2 .8\}$, that magnetic multipole wave functions have orbital angular momentum $l=\ell$. The electric ones have uncertainty in orbital angular momentum, with nonzero probabilities for both $l=\ell-1$ and $l=\ell+1$.

Atomic or nuclear transitions in which a photon in a state $\vec{A}_{\gamma}^{\mathrm{E}}$ is emitted or absorbed are called "electric multipole" transitions. They are indicated as El transitions.

In particular, for net angular momentum $\ell=1$, they are called E1 or electric dipole transitions. That is the normal kind. However, as discussed in chapter 7.4, such transitions may not be able to satisfy conservation of angular momentum and parity. Since the photon in the state has $\ell=1$, transitions in which the atomic angular momentum changes by more than one unit cannot be accomodated. Neither can transitions in which the atomic or nuclear momentum parity does not change, because the E1 photon has odd parity.

Such transitions may be accomodated by transitions in which photons in different states are emitted or absorbed, using the photon angular momenta and parities as noted above. Electric multipole transitions with $\ell=2$ are called E2 or electric quadrupole transitions. Those with $\ell=3$ are E3 or electric octupole ones, with $\ell=4 \mathrm{E} 4$ or electric hexadecapole ones, with $\ell=5 \mathrm{E} 5$ or electric triakontadipole ones, for $\ell=6 \mathrm{E} 6$ or electric hexacontatetrapole ones and so on until your knowledge of latin and greek powers of 2 runs out.

Similarly, transitions in which photons in a state $\vec{A}_{\gamma}^{\mathrm{M}}$ are emitted or absorbed are called "magnetic multipole transitions." The same latin applies.

Like the states of definite linear momentum in the previous subsection, the states of definite angular momentum cannot be normalized in infinite space. To deal with that, it will be assumed that the photon is confined inside a sphere of a very large radius $r_{\text {max }}$. As a "boundary condition" on the sphere, it will be assumed that the Bessel function is zero. In terms of the wave functions, that works out to mean that the magnetic ones are zero on the sphere, but only the radial component of the electric ones is.

The normalized wave function and unobservable fields for electric multipole photons are then, subsection A. 21.5 and $\{\mathrm{D} .36\}$,

$$
\vec{A}_{\gamma}^{\mathrm{En}}=\frac{\varepsilon_{k}^{\mathrm{E}}}{\mathrm{i} k c} \vec{A}_{\gamma}^{\mathrm{E}} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{En}}=\varepsilon_{k}^{\mathrm{E}} \vec{A}_{\gamma}^{\mathrm{E}} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{En}}=\frac{\varepsilon_{k}^{\mathrm{E}} k}{\mathrm{i}} \vec{A}_{\gamma}^{\mathrm{M}} \quad \varepsilon_{k}^{\mathrm{E}} \sim \sqrt{\frac{2 \hbar \omega}{\ell(\ell+1) \epsilon_{0} r_{\max }}}
$$

(The expression for the magnetic field arises because for a solenoidal vector $\nabla$ $\times \nabla \times=-\nabla^{2}$, and that produces a factor $k^{2}$ according to the energy eigenvalue problem.)

The normalized wave function and unobservable fields for magnetic multipole photons are

$$
\vec{A}_{\gamma}^{\mathrm{Mn}}=\frac{\varepsilon_{k}^{\mathrm{E}}}{\mathrm{i} c} \vec{A}_{\gamma}^{\mathrm{M}} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{Mn}}=k \varepsilon_{k}^{\mathrm{E}} \vec{A}_{\gamma}^{\mathrm{M}} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{Mn}}=\frac{\varepsilon_{k}^{\mathrm{E}}}{\mathrm{i}} \vec{A}_{\gamma}^{\mathrm{E}} \quad \varepsilon_{k}^{\mathrm{E}} \sim \sqrt{\frac{2 \hbar \omega}{\ell(\ell+1) \epsilon_{0} r_{\max }}}
$$

Assume now that there is an atom or atomic nucleus at the origin that interacts with the photon. An atom or nucleus is typically very small compared to the wave length of the photon that it interacts with. Phrased more appropriately, if $R$ is the typical size of the atom or nucleus, then $k R$ is typically small. The atom or nucleus is just a tiny speck at the origin.

Now the wave functions $\vec{A}_{\gamma}^{\mathrm{E}}$ are larger at small radii than the $\vec{A}_{\gamma}^{\mathrm{M}}$. In particular, the $\vec{A}_{\gamma}^{\mathrm{E}}$ are of order $r^{\ell-1}$ while the $\vec{A}_{\gamma}^{\mathrm{M}}$ are of order $r^{\ell}$, one power of $r$ smaller. These powers of $r$ reflect the lowest measurable orbital angular momentum of the states.

A glance at the unobservable fields of electric multipole photons above then shows that for these photons, the field is primarily electric at the atom or nucleus. And even the electric field will be small unless $\ell=1$, in other words, unless it is an electric dipole photon.

For the magnetic multipole photons, it is the magnetic field that dominates at the atom or nucleus. And even that will be small unless $\ell=1$, which means a magnetic dipole photon. Note that the magnetic field acts as if it had one unit or orbital angular momentum less than the photon; the magnetic field is essentially the wave function of an electric multipole photon.

For later reference, the density of states as needed for Fermi's golden rule will be listed here, $\{\mathrm{D} .36 .2 .6\}$ :

$$
\begin{equation*}
\frac{\mathrm{d} N}{\mathrm{~d} E} \approx \frac{1}{\hbar \pi c} r_{\max } \tag{A.100}
\end{equation*}
$$

This approximation applies for large cut-off radius $r_{\text {max }}$, which should always be valid.

## A. 22 Forces by particle exchange

As noted in chapter 7.5.2, the fundamental forces of nature arise from the exchange of particles. This addendum will illustrate the general idea. It will first derive the hypothetical "Koulomb" force due to the exchange of equally hypothetical particles called "fotons."

The Koulomb potential provides a fairly simple model of a quantum field. It also provides a simple context to introduce some key concepts in quantum field theories, such as Green's functions, variational calculus, Lagrangians, the limitation of the speed of light, description in terms of momentum modes, Fock space kets, annihilation and creation operators, antiparticles, special relativity, the imperfections of physicists, and Lorentz invariance. The Koulomb potential can also readily be modified to explain nuclear forces. However, that will have to wait until a later addendum, $\{\mathrm{A} .42\}$.

In the current addendum, the Koulomb potential provides the starting point for a discussion of the electromagnetic field. The classical Maxwell equations for
the electromagnetic field will be derived in a slightly unconventional way. Who needs to know classical electromagnetics when all it takes is quantum mechanics, relativity, and a few plausible guesses to derive electromagnetics from scratch?

To quantize the electromagnetic field is not that straightforward; it has unexpected features that do not occur for the Koulomb field. This book follows the derivation as formulated by Fermi in 1932. This derivation is the basis for more advanced modern quantum field approaches. These advanced theories will not be covered, however.

Essentially, the Fermi derivation splits off the Coulomb potential from the electromagnetic field. What is left is then readily described by a simple quantum field theory much like for the Koulomb potential. This is sufficient to handle important applications such as the emission or absorption of radiation by atoms and atomic nuclei. That, however, will again be done in subsequent addenda.

A word to the wise. While this addendum is on the calculus level like virtually everything else in this book, there is just quite a lot of mathematics. Some mathematical maturity may be needed not to get lost. Note that this addendum is not needed to understand the discussion of the emission and absorption of radiation in the subsequent addenda.

## A.22.1 Classical selectostatics

The Koulomb force holds the sarged spotons and selectons together in satoms. The force is due to the exchange of massless particles called fotons between the sarged particles. (It will be assumed that the spoton is an elementary particle, though really it consists of three skarks.)

This subsection will derive the selectostatic Koulomb force by representing the fotons by a classical field, not a quantum field. The next subsection will explain classical selectodynamics, and how it obeys the speed of light. Subsection A. 22.3 will eventually fully quantize the selectic field. It will show how quantum effects modify some of the physics expected from the classical analysis.

Physicists have some trouble measuring the precise properties of the selectic field. However, a few basic quantum ideas and some reasonable guesses readily substitute for the lack of empirical data. And guessing is good. If you can guess a self-consistent Koulomb field, you have a lot of insight into its nature.

Consider first the wave function for the exchanged foton in isolation. A foton is a boson without spin. That means that its wave function is a simple function, not some vector. But since the foton is massless, the Schrödinger equation does not apply to it. The appropriate equation follows from the relativistic expression for the energy of a massless particle as given by Einstein, chapter 1.1.2 (1.2):

$$
E^{2}=\vec{p}^{2} c^{2}
$$

Here $E$ is the foton energy, $\vec{p}$ its linear momentum, and $c$ the speed of light. The squares are used because momentum is really a vector, not a number like energy.

Quantum mechanics replaces the momentum vector by the operator

$$
\widehat{\vec{p}}=\frac{\hbar}{\mathrm{i}} \nabla \quad \nabla \equiv \hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

Note the vector operator $\nabla$, called "nabla" or "del." This operator is treated much like an ordinary vector in various computations. Its properties are covered in Calculus III in the U.S. system. (Brief summaries of properties of relevance here can be found in the notations section.)

The Hamiltonian eigenvalue problem for a foton wave function $\varphi_{\mathrm{f}}$ then takes the form

$$
\widehat{\vec{p}}^{2} c^{2} \varphi_{\mathrm{f}}=E^{2} \varphi_{\mathrm{f}}
$$

A solution $\varphi_{\mathrm{f}}$ to this equation is an energy eigenstate. The corresponding value of $E$ is the energy of the state. (To be picky, the above is an eigenvalue problem for the square Hamiltonian. But eigenfunctions of an operator are also eigenfunctions of the square operator. The reverse is not always true, but that is not a concern here.)

Using the momentum operator as given above and some rearranging, the eigenvalue problem becomes

$$
\begin{equation*}
-\nabla^{2} \varphi_{\mathrm{f}}=\frac{E^{2}}{\hbar^{2} c^{2}} \varphi_{\mathrm{f}} \quad \nabla^{2} \equiv \frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}} \tag{A.101}
\end{equation*}
$$

This is called the "time-independent Klein-Gordon equation" for a massless particle.

For foton wave functions that are not necessarily energy eigenstates, quantum mechanics replaces the energy $E$ by the operator i $\hbar \partial / \partial t$. That gives the time-dependent Klein-Gordon equation as:

$$
\begin{equation*}
-\nabla^{2} \varphi_{\mathrm{f}}=-\frac{1}{c^{2}} \frac{\partial^{2} \varphi_{\mathrm{f}}}{\partial t^{2}} \tag{A.102}
\end{equation*}
$$

Now consider solutions of this equation of the form

$$
\varphi_{\mathrm{f}}(\vec{r} ; t)=e^{-\mathrm{i} \omega t} \varphi_{\mathrm{fs}}(\vec{r})
$$

Here $\omega$ is a positive constant called the angular frequency. Substitution in the time-dependent Klein-Gordon equation shows that this solution also satisfies the time-independent Klein-Gordon equation, with energy

$$
E=\hbar \omega
$$

That is the famous "Planck-Einstein" relation. It is implicit in the association of $E$ with $\mathrm{i} \hbar \partial / \partial t$.

Note however that there will also be a solution of the form

$$
\varphi_{\mathrm{f}}(\vec{r} ; t)=e^{\mathrm{i} \omega t} \varphi_{\mathrm{fs}}(\vec{r})
$$

This solution too has energy $\hbar \omega$. The difference in sign in the exponential is taken to mean that the particle moves backwards in time. Note that changing the sign in the exponential is equivalent to changing the sign of the time $t$. At least it is if you require that $\omega=E / \hbar$ cannot be negative. If a particle moves backwards in time, it is called an "antiparticle." So the wave function above describes an "antifoton."

There is really no physical difference between a foton and an antifoton. That is not necessarily true for other types of particles. Quantities such as electric charge, lepton number, baryon number, strangeness, etcetera take opposite values for a particle and its antiparticle.

There is a very important difference between the Klein-Gordon equation and the Schrödinger equation. The Schrödinger equation describes nonrelativistic physics where particles can neither be destroyed nor created. Mass must be conserved. But the Klein-Gordon equation applies to relativistic physics. In relativistic physics particles can be created out of pure energy or destroyed following Einstein's famous relationship $E=m c^{2}$, chapter 1 .

There is a mathematical consequence to this. It concerns the integral

$$
\int\left|\varphi_{\mathrm{f}}\right|^{2} \mathrm{~d}^{3} \vec{r}
$$

(In this addendum, integrals like this are over all space unless explicitly stated otherwise. It is also assumed that the fields vanish quickly enough at large distances that such integrals are finite. Alternatively, for particles confined in a large box it is assumed that the box is periodic, chapter 6.17.) Now for solutions of the Schrödinger equation, the integral $\int\left|\varphi_{\mathrm{f}}\right|^{2} \mathrm{~d}^{3} \vec{r}$ keeps the same value, 1 , for all time. Physically, the integral represent the probability of finding the particle. The probability of finding the particle if you look in all space must be 1 .

But fotons are routinely destroyed or created by sarged particles. So the probability of finding a foton is not a preserved quantity. (It is not even clear what finding a foton would mean in the first place.) The Klein-Gordon equation reflects that. It does not preserve the integral $\int\left|\varphi_{\mathrm{f}}\right|^{2} \mathrm{~d}^{3} \vec{r}$. (There is one exception: if the wave function is purely described by particle states or purely described by antiparticle states, the integral is still preserved.)

But the Klein-Gordon equation does preserve an other integral, $\{\mathrm{D} .32\}$. That is

$$
\int\left|\frac{1}{c} \frac{\partial \varphi_{\mathrm{f}}}{\partial t}\right|^{2}+\left|\nabla \varphi_{\mathrm{f}}\right|^{2} \mathrm{~d}^{3} \vec{r}
$$

Now if the number of fotons is not a preserved quantity, what can this preserved integral stand for? Not momentum or angular momentum, which
are vectors. The integral must obviously stand for the energy. Energy is still preserved in relativity, even if the number of particles of a given type is not.

Of course, the energy of a foton wave function $\varphi_{\mathrm{f}}$ is also given by the PlanckEinstein relation. But wave functions are not observable. Still, fotons do affect spotons and selectons. That is observable. So there must be an observable foton field. This observable field will be called the foton potential. It will be indicated by simply $\varphi$, without a subscript f. Quantum uncertainty in the values of the field will be ignored in this subsection. So the field will be modeled as a classical (i.e. nonquantum) field.

And if there is an observable field, there must be an observable energy associated with that field. Now what could the expression for the energy in the field be? Obviously it will have to take the form of the integral above. What other options are there that are plausible? Of course, there will be some additional empirical constant. If the integral is constant, then any multiple of it will be constant too. And the above integral will not have units of energy as it is. The needed empirical constant is indicated by $\epsilon_{1}$ and is called, um no, the permissivity of space. It is a measure of how efficient the foton field is in generating energy. To be precise, for arcane historical reasons the constant in the energy is actually defined as half the permissivity. The bottom line is that the expression for the energy in the observable foton field is:

$$
\begin{equation*}
E_{\varphi}=\frac{\epsilon_{1}}{2} \int\left|\frac{1}{c} \frac{\partial \varphi}{\partial t}\right|^{2}+|\nabla \varphi|^{2} \mathrm{~d}^{3} \vec{r} \tag{A.103}
\end{equation*}
$$

That is really all that is needed to figure out the properties of classical selectostatics in this subsection. It will also be enough to figure out classical selectodynamics in the next subsection.

The first system that will be considered here is that of a foton field and a single spoton. It will be assumed that the spoton is pretty much located at the origin. Of course, in quantum mechanics a particle must have some uncertainty in position, or its kinetic energy would be infinite. But it will be assumed that the spoton wave function is only nonzero within a small distance $\varepsilon$ of the origin. Beyond that distance, the spoton wave function is zero.

However, since this is a classical derivation and not a quantum one, the term "spoton wave function" must not be used. So imagine instead that the spoton sarge $s_{\mathrm{p}}$ is smeared out over a small region of radius $\varepsilon$ around the origin.

For a smeared out sarge, there will be a "sarge density" $\sigma_{\mathrm{p}}$, defined as the local sarge per unit volume. This sarge density can be expressed mathematically as

$$
\sigma_{\mathrm{p}}(\vec{r})=s_{\mathrm{p}} \delta_{\varepsilon}^{3}(\vec{r})
$$

Here $\delta_{\varepsilon}^{3}(\vec{r})$ is some function that describes the detailed shape of the smeared-out sarge distribution. The integral of this function must be 1 , because the sarge
density $\sigma_{\mathrm{p}}$ must integrate to the total spoton sarge $s_{\mathrm{p}}$. So:

$$
\int \delta_{\varepsilon}^{3}(\vec{r}) \mathrm{d}^{3} \vec{r}=1
$$

To ensure that the sarge density is zero for distances from the origin $r$ greater than the given small value $\varepsilon, \delta_{\varepsilon}^{3}(\vec{r})$ must be zero at these distances. So:

$$
\delta_{\varepsilon}^{3}(\vec{r})=0 \quad \text { if } \quad r \equiv|\vec{r}| \geqslant \varepsilon
$$

In the limit that $\varepsilon$ becomes zero, $\delta_{\varepsilon}^{3}(\vec{r})$ becomes the so-called three-dimensional "Dirac delta function" $\delta^{3}(\vec{r})$. This function is totally concentrated at a single point, the origin. But its integral over that single point is still 1 . That is only possible if the function value at the point is infinite. Now infinity is not a proper number, and so the Dirac delta function is not a proper function. However, mathematicians have in fact succeeded in generalizing the idea of functions to allow delta functions. That need not concern the discussion here because "Physicists are sloppy about mathematical rigor," as Zee [53, p. 22] very rightly states. Delta functions are named after the physicist Dirac. They are everywhere in quantum field theory. That is not really surprising as Dirac was one of the major founders of the theory. See section 7.9 for more on delta functions.

Here the big question is how the spoton manages to create a foton field around itself. That is not trivial. If there was a nonzero probability of finding an energetic foton well away from the spoton, surely it would violate energy conservation. However, it turns out that the time-independent Klein-Gordon equation (A.101) actually has a very simple solution where the foton energy $E$ appears to be zero away from the origin. In spherical coordinates, it is

$$
\varphi_{\mathrm{f}}=\frac{C}{r} \quad \text { if } \quad r \neq 0
$$

Here $C$ is some constant which is still arbitrary about this stage. To check the above solution, plug it into the energy eigenvalue problem (A.101) with $E$ zero.

This then seems to be a plausible form for the observable potential $\varphi$ away from the spoton at the origin. However, while the energy of a $C / r$ potential appears to be zero, it is not really. Such a potential is infinite at the origin, and you cannot just ignore that. The correct foton field energy is given by the earlier integral (A.103). For a steady potential, it can be written as

$$
\begin{equation*}
E_{\varphi}=\frac{\epsilon_{1}}{2} \int(\nabla \varphi)^{2} \mathrm{~d}^{3} \vec{r}=-\frac{\epsilon_{1}}{2} \int \varphi\left(\nabla^{2} \varphi\right) \mathrm{d}^{3} \vec{r} \tag{A.104}
\end{equation*}
$$

The final integral comes from an integration by parts. (See \{A. 2$\}$ and $\{\mathrm{D} .32\}$ for examples how to do such integrations by parts.) Note that it looks like the energy could be zero according to this final integral: $\nabla^{2} \varphi$ is zero if $\varphi=C / r$.

That is true outside the small vicinity around the origin. But if you look at the equivalent first integral, it is obvious that the energy is not zero: its integrand is everywhere positive. So the energy must be positive. It follows that in the final integral, the region around the origin, while small, still produces an energy that is not small. The integrand must be not just nonzero, but large in this region.

All that then raises the question why there is a foton field in the first place. The interest in this subsection is in the selectostatic field. That is supposed to be the stable ground state of lowest energy. According to the above, the state of lowest energy would be when there is no foton field; $\varphi=0$.

And so it is. The only reasonable way to explain that there is a nontrivial foton field in the ground state of the spoton-foton system is if the foton field energy is compensated for by something else. There must be an energy of interaction between the foton field and the spoton.

Consider the mathematical form that this energy could take in a given volume element $\mathrm{d}^{3} \vec{r}$. Surely the simplest possibility is that it is proportional to the potential $\varphi$ at the location times the sarge $\sigma_{\mathrm{p}} \mathrm{d}^{3} \vec{r}$. Therefore the total energy of spoton-foton interaction is presumably

$$
\begin{equation*}
E_{\varphi \mathrm{p}}=-\int \varphi(\vec{r}) \sigma_{\mathrm{p}}(\vec{r}) \mathrm{d}^{3} \vec{r}=-\int \varphi(\vec{r}) s_{\mathrm{p}} \delta_{\varepsilon}^{3}(\vec{r}) \mathrm{d}^{3} \vec{r} \tag{A.105}
\end{equation*}
$$

Note that this expression really defines the sarge $s_{\mathrm{p}}$. Sarge gives the strength of the coupling between spoton and foton field. Its units and sign follow from writing the energy as the expression above.

The question is now, what is the ground state foton field? In other words, for what potential $\varphi$ is the complete system energy minimal? To answer that requires "variational calculus." Fortunately, variational calculus is just calculus. And you need to understand how it works if you want to make any sense at all out of books on quantum field theory.

Suppose that you wanted an equation for the minimum of some function $f$ depending on a single variable $x$. The equation would be that $\mathrm{d} f / \mathrm{d} x=0$ at the position of the minimum $x_{\text {min }}$. In terms of differentials, that would mean that the function does not change going from position $x_{\text {min }}$ to a slightly different position $x_{\text {min }}+\mathrm{d} x$ :

$$
\mathrm{d} f=\frac{\mathrm{d} f}{\mathrm{~d} x} \mathrm{~d} x=0 \quad \text { at } \quad x=x_{\min }
$$

It is the same for the change in net energy $E_{\varphi}+E_{\varphi \mathrm{p}}$. Assume that $\varphi_{\text {min }}$ is the desired potential at minimum net energy. Then at $\varphi_{\text {min }}$ the net energy should not change when you change $\varphi$ by an infinitesimal amount $\mathrm{d} \varphi$. Or rather, by an infinitesimal amount $\delta \varphi$ : the symbol $\delta$ is used in variational calculus instead of d. That is to avoid confusion with any symbol d that may already be around. So the requirement for the ground state potential is

$$
\delta\left(E_{\varphi}+E_{\varphi \mathrm{p}}\right)=0 \quad \text { when } \quad \varphi=\varphi_{\min } \rightarrow \varphi=\varphi_{\min }+\delta \varphi
$$

Using the expressions (A.104) and (A.105) for the energies, that means that
$\delta\left[\frac{\epsilon_{1}}{2} \int(\nabla \varphi)^{2} \mathrm{~d}^{3} \vec{r}-\int s_{\mathrm{p}} \delta_{\varepsilon}^{3} \varphi \mathrm{~d}^{3} \vec{r}\right]=0 \quad$ when $\quad \varphi=\varphi_{\text {min }} \rightarrow \varphi=\varphi_{\min }+\delta \varphi$
The usual rules of calculus can be used, (see \{A.2\} for more details). The only difference from basic calculus is that the change $\delta \varphi$ may depend on the point that you look at. In other words, it is some arbitrary but small function of the position $\vec{r}$. For example,

$$
\delta(\nabla \varphi)^{2}=2(\nabla \varphi) \delta(\nabla \varphi) \quad \delta(\nabla \varphi)=\nabla\left(\varphi_{\min }+\delta \varphi\right)-\nabla\left(\varphi_{\min }\right)=\nabla \delta \varphi
$$

Also, $\varphi$ by itself is validly approximated as $\varphi_{\min }$, but $\delta \varphi$ is a completely separate quantity that can be anything. Working it out gives

$$
\frac{\epsilon_{1}}{2} \int 2\left(\nabla \varphi_{\min }\right) \cdot(\nabla \delta \varphi) \mathrm{d}^{3} \vec{r}-\int s_{\mathrm{p}} \delta_{\varepsilon}^{3} \delta \varphi \mathrm{~d}^{3} \vec{r}=0
$$

Performing an integration by parts moves the $\nabla$ from $\delta \varphi$ to $\nabla \varphi_{\min }$ and adds a minus sign. Then the two integrals combine as

$$
-\int\left(\epsilon_{1} \nabla^{2} \varphi_{\min }+s_{\mathrm{p}} \delta_{\varepsilon}^{3}\right) \delta \varphi \mathrm{d}^{3} \vec{r}=0
$$

If this is supposed to be zero for whatever you take the small change $\delta \varphi$ in field to be, then the parenthetical expression in the integral will have to be zero. If the parenthetical expression is nonzero somewhere, you can easily make up a nonzero change $\delta \varphi$ in that region so that the integral is nonzero.

The parenthetical expression can now be rearranged to give the final result:

$$
\begin{equation*}
-\nabla^{2} \varphi=\frac{s_{\mathrm{p}}}{\epsilon_{1}} \delta_{\varepsilon}^{3} \tag{A.106}
\end{equation*}
$$

Here the subscript "min" was left away again as the ground state is the only state of interest here anyway.

The above equation is the famous "Poisson equation" for the selectostatic potential $\varphi$. The same equation appears in electrostatics, chapter 13.3.4. So far, this is all quite encouraging. Note also that the left hand side is the steady Klein-Gordon equation. The right hand side is mathematically a "forcing" term; it forces a nonzero solution for $\varphi$.

Beyond the small vicinity of radius $\varepsilon$ around the origin, the spoton sarge density in the right hand side is zero. That means that away from the spoton, you get the time-independent Klein-Gordon equation (A.101) with $E=0$. That was a good guess, earlier. Assuming spherical symmetry, away from the spoton the solution to the Poisson equation is then indeed

$$
\varphi=\frac{C}{r} \quad \text { if } \quad r \geqslant \varepsilon
$$

But now that the complete Poisson equation (A.106) is known, the constant $C$ can be figured out, $\{\mathrm{D} .2\}$. The precise field turns out to be

$$
\varphi=\frac{s_{\mathrm{p}}}{4 \pi \epsilon_{1} r} \quad \text { if } \quad r \geqslant \varepsilon
$$

For unit value of $s_{\mathrm{p}} / \epsilon_{1}$ the above solution is called the "fundamental solution" or "Green's function" of the Poisson equation. It is the solution due to a delta function.

If the spoton is not at the origin, but at some position $\vec{r}_{\mathrm{p}}$, you simply replace $r$ by the distance from that point:

$$
\begin{equation*}
\varphi^{\mathrm{p}}=\frac{s_{\mathrm{p}}}{4 \pi \epsilon_{1}\left|\vec{r}-\vec{r}_{\mathrm{p}}\right|} \tag{A.107}
\end{equation*}
$$

The superscript $p$ indicates that this potential is created by a spoton at a position $\vec{r}_{\mathrm{p}}$. This solution of the Poisson equation will become very important in the Fermi derivation.

Now the net energy is of interest. It can be simplified by substituting the Poisson equation (A.106) in the expression (A.104) for the foton field energy and adding the interaction energy (A.105). That gives

$$
E_{\varphi}+E_{\varphi \mathrm{p}}=\frac{1}{2} \int \varphi(\vec{r}) s_{\mathrm{p}} \delta_{\varepsilon}^{3}(\vec{r}) \mathrm{d}^{3} \vec{r}-\int \varphi(\vec{r}) s_{\mathrm{p}} \delta_{\varepsilon}^{3}(\vec{r}) \mathrm{d}^{3} \vec{r}
$$

which simplifies to

$$
\begin{equation*}
E_{\varphi}+E_{\varphi \mathrm{p}}=-\frac{1}{2} \int \varphi(\vec{r}) s_{\mathrm{p}} \delta_{\varepsilon}^{3}(\vec{r}) \mathrm{d}^{3} \vec{r} \tag{A.108}
\end{equation*}
$$

Note that the spoton-foton interaction energy is twice the foton field energy, and negative instead of positive. That means that the total energy has been lowered by an amount equal to the foton field energy, despite the fact that the field energy itself is positive.

The fact that there is a foton field in the ground state has now been explained. The interaction with the spoton lowers the energy more than the field itself raises it.

Note further from the solution for $\varphi$ above that $\varphi$ is large in the vicinity of the spoton. As a result, the energy in the foton field becomes infinite when the spoton sarge contracts to a point. (That is best seen from the original integral for the foton field energy in (A.104).) This blow up is very similar to the fact that the energy in a classical electromagnetic field is infinite for a point charge. For the Koulomb field, the interaction energy blows up too, as it is twice the foton field energy. All these blow ups are a good reason to use a sarge density rather than a point sarge. Then all energies are normal finite numbers.

The final step to derive the classical Koulomb force is to add a selecton. The selecton is also sarged, so it too generates a field. To avoid confusion, from now
on the field generated by the spoton will always be indicated by $\varphi^{\mathrm{p}}$, and the one generated by the selecton by $\varphi^{e}$. The variational analysis can now be repeated including the selecton, $\{\mathrm{D} .37 .1\}$. That shows that there are three effects that produce the Koulomb force between the spoton and selecton:

1. the selecton sarge interacts with the potential $\varphi^{\mathrm{p}}$ generated by the spoton;
2. the spoton sarge interacts with the potential $\varphi^{e}$ generated by the selecton;
3. the energy in the combined foton field $\varphi^{\mathrm{p}}+\varphi^{\mathrm{e}}$ is different from the sum of the energies of the separate fields $\varphi^{\mathrm{p}}$ and $\varphi^{\mathrm{e}}$.
All three effects turn out to produce the same energy, but the first two energies are negative and the third positive. So the net energy change is the same as if there was just item 1, the interaction of the selecton sarge density $\sigma_{\mathrm{e}}$ with the potential $\varphi^{\mathrm{p}}$ produced by the spoton. That is of course given by a similar expression as before:

$$
V_{\mathrm{ep}}=-\int \varphi^{\mathrm{p}}(\vec{r}) \sigma_{\mathrm{e}}(\vec{r}) \mathrm{d}^{3} \vec{r}
$$

The expression for $\varphi^{\mathrm{p}}(\vec{r})$ was given above in (A.107) for any arbitrary position of the spoton $\vec{r}_{\mathrm{p}}$. And it will be assumed that the selecton sarge density $\sigma_{\mathrm{e}}$ is spread out a bit just like the spoton one, but around a different location $\vec{r}_{\mathrm{e}}$. Then the interaction energy becomes

$$
V_{\mathrm{ep}}=-\int \frac{s_{\mathrm{p}}}{4 \pi \epsilon_{1}\left|\vec{r}-\vec{r}_{\mathrm{p}}\right|} s_{\mathrm{e}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{e}}\right) \mathrm{d}^{3} \vec{r}
$$

Since $\varepsilon$ is assumed small, the selecton sarge density is only nonzero very close to the nominal position $\vec{r}_{\mathrm{e}}$. Therefore you can approximate $\vec{r}$ as $\vec{r}_{\mathrm{e}}$ in the fraction and take it out of the integral as a constant. Then the delta function integrates to 1 , and you get

$$
\begin{equation*}
V_{\mathrm{ep}}=-\frac{s_{\mathrm{p}} s_{\mathrm{e}}}{4 \pi \epsilon_{1}\left|\vec{r}_{\mathrm{e}}-\vec{r}_{\mathrm{p}}\right|} \tag{A.109}
\end{equation*}
$$

That then is the final energy of the Koulomb interaction between the two sarged particles. Because the spoton and the selecton both interact with the foton field, in effect it produces a spoton-selecton interaction energy.

Of course, in classical physics you would probably want to know the actual force on say the selecton. To get it, move the origin of the coordinate system to the spoton and rotate it so that the selecton is on the positive $x$-axis. Now give the selecton a small displacement $\partial x_{\mathrm{e}}$ in the $x$-direction. Slowly of course; this is supposed to be selectostatics. Because of energy conservation, the work done by the force $F_{x \text { e }}$ during this displacement must cause a corresponding small decrease in energy. So:

$$
F_{x_{\mathrm{e}}} \partial x_{\mathrm{e}}=-\partial V_{\mathrm{ep}}
$$

But on the positive $x$-axis, $\left|\vec{r}_{\mathrm{e}}-\vec{r}_{\mathrm{p}}\right|$ is just the $x$-position of the selecton $x_{\mathrm{e}}$, so

$$
F_{x_{\mathrm{e}}}=-\frac{\partial V_{\mathrm{ep}}}{\partial x_{\mathrm{e}}}=-\frac{s_{\mathrm{p}} s_{\mathrm{e}}}{4 \pi \epsilon_{1} x_{\mathrm{e}}^{2}}
$$

It is seen that if the sarges have equal sign, the force is in the negative $x$ direction, towards the spoton. So sarges of the same sign attract.

More generally, the force on the selecton points towards the spoton if the sarges are of the same sign. It points straight away from the spoton if the sarges are of opposite sign.

The Koulomb energy $V_{\text {ep }}$ looks almost exactly the same as the Coulomb energy in electrostatics. Recall that the Coulomb energy was used in chapter 4.3 to describe the attraction between the proton and electron in a hydrogen atom. The difference is that the Coulomb energy has no minus sign. That means that while like sarges attract, like charges repel each other. For example, two spotons attract, but two protons repel.

Now a spoton must necessarily create a foton field that is attractive to spotons. Otherwise there should be no field at all in the ground state. And if spotons create fields that attract spotons, then spotons attract. So the Koulomb force is clearly right.

It is the Coulomb force that does not seem to make any sense. Much more will be said about that in later subsections.

## A.22.2 Classical selectodynamics

According to the previous section the Koulomb energy between a spoton and a selecton is given by

$$
V_{\mathrm{ep}}=-\frac{s_{\mathrm{p}} s_{\mathrm{e}}}{4 \pi \epsilon_{1}\left|\vec{r}_{\mathrm{e}}-\vec{r}_{\mathrm{p}}\right|}
$$

However, this result can only be correct in a stationary state like a ground state, or maybe some other energy state.

To see the problem, imagine that the spoton is suddenly given a kick. According to the Koulomb potential given above, the selecton notices that instantly. There is no time in the Koulomb potential, so there is no time delay. But Einstein showed that no observable effect can move faster than the speed of light. So there should be a time delay.

Obviously then, to discuss unsteady evolution will require the full governing equations for selectodynamics. The big question is how to find these equations.

The quantum mechanics in this book is normally based on some Hamiltonian $H$. But there is a more basic quantity for a system than the Hamiltonian. That quantity is called the "Lagrangian" $\mathcal{L}$. If you can guess the correct Lagrangian of a system, its equations of motion follow. That is very important for quantum field theories. In fact, a lot of what advanced quantum field theories really do is guess Lagrangians.

To get at the Lagrangian for selectodynamics, consider first the motion of the spoton for a given foton field $\varphi$. The Hamiltonian of the spoton by itself is just the energy of the spoton. As discussed in the previous subsection, a spoton has a potential energy of interaction with the given foton field

$$
\begin{equation*}
E_{\varphi \mathrm{p}}=-\int \varphi(\vec{r} ; t) \sigma_{\mathrm{p}}(\vec{r} ; t) \mathrm{d}^{3} \vec{r} \tag{A.110}
\end{equation*}
$$

Here $\sigma_{\mathrm{p}}$ was the sarge density of the spoton. The foton potential and sarge density can now of course also depend on time.

However, to discuss the dynamics of the spoton, it is easier to consider it a point particle located at a single moving point $\vec{r}_{\mathrm{p}}$. Therefore it will be assumed that the sarge density is completely concentrated at that one point. That means that the only value of the foton field of interest is the value at $\vec{r}_{\mathrm{p}}$. And the sarge distribution integrates to the net spoton sarge $s_{\mathrm{p}}$. So the above energy of interaction becomes approximately

$$
\begin{equation*}
E_{\varphi \mathrm{p}} \approx-\varphi_{\mathrm{p}} s_{\mathrm{p}} \quad \varphi_{\mathrm{p}} \equiv \varphi\left(\vec{r}_{\mathrm{p}} ; t\right) \tag{A.111}
\end{equation*}
$$

In terms of the components of position, this can be written out fully as

$$
E_{\varphi \mathrm{p}} \approx-\varphi\left(r_{\mathrm{p}_{1}}, r_{\mathrm{p}_{2}}, r_{\mathrm{p}_{3}} ; t\right) s_{\mathrm{p}}
$$

Note that in this addendum the position components are indicated as $r_{\mathrm{p}_{1}}, r_{\mathrm{p}_{2}}$, and $r_{\mathrm{P}_{3}}$ instead of the more familiar $r_{\mathrm{p}_{x}}, r_{\mathrm{p}_{y}}$, and $r_{\mathrm{p}_{z}}$ or $x_{\mathrm{p}}, y_{\mathrm{p}}$, and $z_{\mathrm{p}}$. That is in order that a generic position component can be indicated by $r_{\mathrm{P}_{i}}$ where $i$ can be 1,2 , or 3 .

In addition to the interaction energy above there is the kinetic energy of the spoton,

$$
E_{\mathrm{p}, \mathrm{kin}}=\frac{1}{2} m_{\mathrm{p}} \vec{v}_{\mathrm{p}}^{2}
$$

Here $m_{\mathrm{p}}$ is the mass of the spoton and $\vec{v}_{\mathrm{p}}$ its velocity,

$$
\vec{v}_{\mathrm{p}} \equiv \frac{\mathrm{~d} \vec{r}_{\mathrm{p}}}{\mathrm{~d} t}
$$

The kinetic energy can be written out in terms of the velocity components as

$$
E_{\mathrm{p}, \text { kin }}=\frac{1}{2} m_{\mathrm{p}}\left[\left(v_{\mathrm{p}_{1}}\right)^{2}+\left(v_{\mathrm{p}_{2}}\right)^{2}+\left(v_{\mathrm{p}_{3}}\right)^{2}\right] \quad \text { with } v_{\mathrm{p}_{i}}=\frac{\mathrm{d} r_{\mathrm{p}_{i}}}{\mathrm{~d} t} \text { for } i=1,2,3
$$

Now the Hamiltonian of the spoton is the sum of the kinetic and potential energies. But the Lagrangian is the difference between the kinetic and potential energies:

$$
\mathcal{L}_{\mathrm{p}}\left(\vec{v}_{\mathrm{p}}, \vec{r}_{\mathrm{p}}\right)=\frac{1}{2} m_{\mathrm{p}} \vec{v}_{\mathrm{p}}^{2}+\varphi\left(\vec{r}_{\mathrm{p}} ; t\right) s_{\mathrm{p}}
$$

This Lagrangian can now be used to find the equation of motion of the spoton. This comes about in a somewhat weird way. Suppose that there is some range of times, from a time $t_{1}$ to a time $t_{2}$, during which you want to know the motion of the spoton. (Maybe the spoton is at rest at time $t_{1}$ and becomes again at rest at time $t_{2}$.) Suppose further that you now compute the so-called "action" integral

$$
\mathcal{S} \equiv \int_{t_{1}}^{t_{2}} \mathcal{L}_{\mathrm{p}}\left(\vec{v}_{\mathrm{p}}, \vec{r}_{\mathrm{p}}\right) \mathrm{d} t
$$

If you use the correct velocity and position of the spoton, you will get some number. But now suppose that you use a slightly different (wrong) spoton path. Suppose it is different by a small amount $\delta \vec{r}_{\mathrm{p}}$, which of course depends on time. You would think that the value of the action integral would change by a corresponding small amount. But that is not true. Assuming that the path used in the original integral was indeed the right one, and that the change in path is infinitesimally small, the action integral does not change. Mathematically

$$
\delta \mathcal{S}=0 \quad \text { at the correct path }
$$

Yes, this is again variational calculus. The action may not be minimal at the correct spoton path, but it is definitely stationary at it.

Probably this sounds like a stupid mathematical trick. But in the so-called path integral approach to quantum field theory, the action is central to the formulation.

For classical physics the action by itself is pretty useless. However, with some manipulations, you can get the evolution equations for your system out of it, $\{$ A. 1$\}$. They are found as

$$
\begin{equation*}
\frac{\mathrm{d}}{\mathrm{~d} t}\left(\frac{\partial \mathcal{L}}{\partial v_{\mathrm{p}_{i}}}\right)=\left(\frac{\partial \mathcal{L}}{\partial r_{\mathrm{p}_{i}}}\right) \tag{A.112}
\end{equation*}
$$

Here $i=1,2$, or 3 gives the equation in the $x, y$, or $z$ direction, respectively.
Note that for the governing equations it does not matter at all what you take the times $t_{1}$ and $t_{2}$ in the action to be. They are pretty vaguely defined anyway. You might want to let them go to minus and plus infinity to get rid of them.

The next step is to write out the governing equation (A.112) in terms of physical quantities. To do that correctly, the trick is that the Lagrangian must be treated as a function of velocity and position, as independent variables. In reality velocity and position are not independent; velocity is the derivative of position. But when differentiating the Lagrangian you are supposed to forget about that. Consider how this works out for the $x$-component, $i=1$,

$$
\frac{\partial \mathcal{L}}{\partial v_{\mathrm{p}_{1}}}=m_{\mathrm{p}} v_{\mathrm{p}_{1}} \quad \frac{\partial \mathcal{L}}{\partial r_{\mathrm{p}_{1}}}=\frac{\partial \varphi\left(r_{\mathrm{p}_{1}}, r_{\mathrm{p}_{2}}, r_{\mathrm{p}_{3}} ; t\right)}{\partial r_{\mathrm{p}_{1}}} s_{\mathrm{p}}
$$

That are simple differentiations taking the given Lagrangian at face value.
However, when you do the remaining time derivative in (A.112) you have to do it properly, treating the velocity as the function of time that it is. That gives the final equation of motion as

$$
\begin{equation*}
m_{\mathrm{p}} \frac{\mathrm{~d} v_{\mathrm{p}_{1}}}{\mathrm{~d} t}=\frac{\partial \varphi\left(r_{\mathrm{p}_{1}}, r_{\mathrm{p}_{2}}, r_{\mathrm{p}_{3}} ; t\right)}{\partial r_{\mathrm{p}_{1}}} s_{\mathrm{p}} \tag{A.113}
\end{equation*}
$$

Note that the left hand side is mass times acceleration in the $x$-direction. So the right hand side must be the selectic force on the spoton. This force is called the "Sorentz force." It is seen that the Sorentz force is proportional to the derivative of the foton potential, evaluated at the position of the spoton. If you compare the Sorentz force with the force in electrostatics, you see that the force in electrostatics has an additional minus sign. That reflects again that equal sarges attract, while equal charges repel.

So far, it was assumed that the foton field was given. But in reality the foton field is not given, it depends on the motion of the spoton. To describe the field, its energies must be added to the Lagrangian too. The total energy in the foton field was given in the previous subsection as (A.103). Using some shorthand notation, this becomes

$$
E_{\varphi}=\frac{\epsilon_{1}}{2} \int \frac{1}{c^{2}} \varphi_{t}^{2}+\sum_{i=1}^{3} \varphi_{i}^{2} \mathrm{~d}^{3} \vec{r}
$$

The shorthand is to indicate derivatives by subscripts, as in

$$
\varphi_{t} \equiv \frac{\partial \varphi}{\partial t} \quad \varphi_{i} \equiv \frac{\partial \varphi}{\partial r_{i}}
$$

with $i=1,2$, or 3 for the $x, y$, and $z$ derivatives respectively. For example, $\varphi_{1}$ would be the partial $x$-derivative of $\varphi$.

Actually, even more concise shorthand will be used. If an index like $i$ occurs twice in a term, summation over that index is to be understood. The summation symbol will then not be shown. That is called the Einstein summation convention. So the energy in the foton field will be indicated briefly as

$$
E_{\varphi}=\frac{\epsilon_{1}}{2} \int \frac{1}{c^{2}} \varphi_{t}^{2}+\varphi_{i}^{2} \mathrm{~d}^{3} \vec{r}
$$

(Note that $\varphi_{i}^{2}=\varphi_{i} \varphi_{i}$, so $i$ occurs twice in the second term of the integrand.) All this is done as a service to you, the reader. You are no doubt getting tired of having to look at all these mathematical symbols.

Now the first term in the energy above is a time derivative, just like $\vec{v}_{\mathrm{p}}$ was the time derivative of the spoton position. So this term has presumably the
same sign in the Lagrangian, while the sign of the other term flips over. That makes the total selectodynamic Lagrangian equal to

$$
\mathcal{L}_{\varphi \mathrm{p}}=\frac{\epsilon_{1}}{2} \int \frac{1}{c^{2}} \varphi_{t}^{2}-\varphi_{i}^{2} \mathrm{~d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} \vec{v}_{\mathrm{p}}^{2}+\varphi_{\mathrm{p}} s_{\mathrm{p}}
$$

The last two terms are as before for a given field.
However, for the final term it is now desirable to go back to the representation of the spoton in terms of a sarge density $\sigma_{\mathrm{p}}$, as in (A.110). The final term as written would lead to a nasty delta function in the analysis of the field. In the sarge density form the term can be brought inside the integral to give the complete Lagrangian as

$$
\begin{equation*}
\mathcal{L}_{\varphi \mathrm{p}}=\int \frac{\epsilon_{1}}{2}\left(\frac{1}{c^{2}} \varphi_{t}^{2}-\varphi_{i}^{2}\right)+\varphi \sigma_{\mathrm{p}} \mathrm{~d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} \overrightarrow{\mathrm{v}}_{\mathrm{p}}^{2} \tag{A.114}
\end{equation*}
$$

Note that there is no longer a subscript $p$ on $\varphi$; it is the integration against the sarge density that picks out the value of $\varphi$ at the spoton.

An integrand of a spatial integral in a Lagrangian is called a "Lagrangian density" and indicated by the symbol $£$. In this case:

$$
\begin{equation*}
£=\frac{\epsilon_{1}}{2}\left(\frac{1}{c^{2}} \varphi_{t}^{2}-\varphi_{i}^{2}\right)+\varphi \sigma_{\mathrm{p}} \tag{A.115}
\end{equation*}
$$

When differentiating this Lagrangian density, $\varphi$ and its derivatives $\varphi_{t}$ and $\varphi_{i}$, (with $i=1,2$, and 3 ), are to be considered 5 separate independent variables.

The action principle can readily be extended to allow for Lagrangian densities, $\{\mathrm{D} .37\}$. The equations of motion for the field are then found to be

$$
\frac{\partial}{\partial t}\left(\frac{\partial £}{\partial \varphi_{t}}\right)+\frac{\partial}{\partial r_{i}}\left(\frac{\partial £}{\partial \varphi_{i}}\right)=\frac{\partial £}{\partial \varphi}
$$

Working this out much like for the equation of motion of the spoton gives, taking $\varepsilon_{1}$ to the other side,

$$
\begin{equation*}
\frac{1}{c^{2}} \frac{\partial^{2} \varphi}{\partial t^{2}}-\frac{\partial^{2} \varphi}{\partial r_{i}^{2}}=\frac{\sigma_{\mathrm{p}}}{\epsilon_{1}} \tag{A.116}
\end{equation*}
$$

This is the so-called "Saxwell wave equation" of selectodynamics. If there is also a selecton, say, its sarge density can simply be added to the spoton one in the right hand side.

To check the Saxwell equation, first consider the case that the system is steady, i.e. independent of time. In that case the Saxwell wave equation becomes the Poisson equation of the previous subsection as it should. (The second term is summed over the three Cartesian directions $i$. That gives $\nabla^{2} \varphi$.) So the spoton produces the same steady Koulomb field (A.107) as before. So far, so good.

How about the force on a selecton in this field? Of course, the force on a selecton is a Sorentz force of the same form as (A.113),

$$
\begin{equation*}
F_{x_{\mathrm{e}}}=\frac{\partial \varphi\left(r_{\mathrm{e}_{1}}, r_{\mathrm{e}_{2}}, r_{\mathrm{e}_{3}} ; t\right)}{\partial r_{\mathrm{e}_{1}}} s_{\mathrm{e}} \tag{A.117}
\end{equation*}
$$

In the steady case, the relevant potential at the selecton is the electrostatic one (A.107) produced by the spoton as given in the previous subsection (Strictly speaking you should also include the field produced by the selecton itself. But this "self-interaction" produces no net force. That is fortunate because if the selecton was really a point sarge, the self-interaction is mathematically singular.) Now minus the potential (A.107) times the selecton sarge $s_{\mathrm{e}}$ gave the energy $V_{\text {ep }}$ of the spoton-selecton interaction in the previous subsection. And minus the derivative of that gave the force on the selecton. A look at the force above then shows it is the same.

So in the steady case the Saxwell equation combined with the Sorentz force does reproduce selectostatics correctly. That means that the given Lagrangian (A.114) contains all of selectostatics in a single concise mathematical expression. At the minimum. Neat, isn't it?

Consider next the case that the time dependence cannot be ignored. Then the time derivative in the Saxwell equation (A.116) cannot be ignored. In that case the left hand side in the equation is the complete unsteady Klein-Gordon equation. Since there is a nonzero right-hand side, mathematically the Saxwell equation is an inhomogeneous Klein-Gordon equation. Now it is known from the theory of partial differential equations that the Klein-Gordon equation respects the speed of light. As an example, imagine that at time $t=0$ you briefly shake the spoton at the origin and then put it back where it was. The right hand side of the Saxwell equation is then again back to what it was. But near the origin, the foton field $\varphi$ will now contain additional disturbances. These disturbances evolve according to the homogeneous Saxwell equation, i.e. the equation with zero right hand side. And it is easy to check by substitution that the homogeneous equation has solutions of the form

$$
\varphi=f(x-c t)
$$

That are waves traveling in the x -direction with the speed of light $c$. The wave shape is the arbitrary function $f$ and is preserved in time. And note that the $x$-direction is arbitrary. So waves like this can travel in any direction. The perturbations near the origin caused by shaking the spoton will consist of such waves. Since they travel with the speed of light, they need some time to reach the selecton. The selecton will not notice anything until this happens. However, when the perturbations in the foton field do reach the selecton, they will change the foton field $\varphi$ at the selecton. That then will change the force (A.117) on the selecton.

It follows that selectodynamics, as described by the Lagrangian (A.114), also respects the speed of light limitation.

## A.22.3 Quantum selectostatics

The previous subsections derived the Koulomb force between sarged particles. This force was due to foton exchange. While the derivations used some ideas from quantum mechanics, they were classical. The effect of the fotons took the form of a potential $\varphi$ that the sarged particles interacted with. This potential was a classical field; it had a definite numerical value at each point. To be picky, there really was an undetermined constant in the potential $\varphi$. But its gradient $\nabla \varphi$ produced the fully determined Sorentz force per unit sarge (A.117). This force can be "observed" by a sarged spoton or selecton.

However, that very fact violates the fundamental postulates of quantum mechanics as formulated at the beginning of this book, chapter 3.4. Observable values should be the eigenvalues of Hermitian operators that act on wave functions. While the foton potential was loosely associated with a foton wave function, wave functions should not be observable.

Now if classically every position has its own observable local potential $\varphi$, then in a proper quantum description every position must be associated with its own Hermitian operator $\widehat{\varphi}$. In the terminology of addendum $\{$ A.15.9\}, the foton field $\widehat{\varphi}$ must be a "quantum field;" an infinite amount of operators, one for each position.

The objective in this subsection is to deduce the form of this quantum field. And the type of wave function that it operates on. The results will then be used to verify the Koulomb force between stationary sarges as found the first subsection. It is imperative to figure out whether like sarges still attract in a proper quantum description.

Doing this directly would not be easy. It helps a lot if the field is written in terms of linear momentum eigenstates.

In fact, typical quantum field theories depend very heavily on this trick. However, often such theories use relativistic combined energy-momentum states in four-dimensional space-time. This subsection will use simpler purely spatial momentum states. The basic idea is the same. And it is essential for understanding the later Fermi derivation of the Coulomb potential.

Linear momentum states are complex exponentials of the form $e^{i \vec{k} \cdot \vec{r}}$. Here $\vec{k}$ is a constant vector called the wave number vector. The momentum of such a state is given in terms of the wave number vector by the de Broglie relation as $\vec{p}=\hbar \vec{k}$. (It may be noted that the $e^{\mathrm{i} \vec{k} \cdot \vec{r}}$ states need an additional constant to properly normalize them, chapter 6.18. But for conciseness, in this addendum that normalization constant will be absorbed in the constants multiplying the exponentials.)

If a field $\varphi$ is written in terms of linear momentum states, its value at any point $\vec{r}$ is given by:

$$
\varphi(\vec{r})=\sum_{\text {all } \vec{k}} c_{\vec{k}} e^{\mathrm{i} \vec{k} \cdot \vec{r}}
$$

Note that if you know the coefficients $c_{\vec{k}}$ of the momentum states, it is equivalent to knowing the field $\varphi$. Then the field at any point can in principle be found by doing the sum.

The expression above assumes that the entire system is confined to a very large periodic box, as in chapter 6.17. In infinite space the sum becomes an integral, section 7.9. That would be much more messy. (But that is the way you will usually find it in a typical quantum field analysis.) The precise values of the wave number vectors to sum over for a given periodic box were given in chapter 6.18 (6.28); they are all points in figure 6.17.

The first subsection found the selectostatic potential $\varphi^{\mathrm{p}}$ that was produced by a spoton, (A.107). This potential was a classical field; it had a definite numerical value for each position. The first step will be to see how this potential looks in terms of momentum states. While the final objective is to rederive the classical potential using proper quantum mechanics, the correct answer will need to be recognized when written in terms of momentum states. Not to mention that the answer will reappear in the discussion of the Coulomb potential. For simplicity it will be assumed that the spoton is at the origin.

According to the first subsection, the classical potential was the solution to a Poisson equation; a steady Klein-Gordon equation with forcing by the spoton:

$$
-\nabla^{2} \varphi_{\mathrm{cl}}^{\mathrm{p}}=\frac{s_{\mathrm{p}}}{\epsilon_{1}} \psi_{\mathrm{p}}^{*} \psi_{\mathrm{p}}
$$

As a reminder that $\varphi^{\mathrm{p}}$ is a classical potential, not a quantum one, a subscript "cl" has been added. Also note that since this is a now a quantum description, the spoton sarge density $\sigma_{\mathrm{p}}$ has been identified as the spoton sarge $s_{\mathrm{p}}$ times the square magnitude of the spoton wave function $\left|\psi_{\mathrm{p}}\right|^{2}=\psi_{\mathrm{p}}^{*} \psi_{\mathrm{p}}$.

Now the classical potential is to be written in the form

$$
\varphi_{\mathrm{cl}}^{\mathrm{p}}(\vec{r})=\sum_{\text {all } \vec{k}} c_{\vec{k}} e^{\mathrm{i} \cdot \vec{r}}
$$

To figure out the coefficients $c_{\vec{k}}$, plug it in the Poisson equation above. That gives

$$
\sum_{\text {all } \vec{k}} k^{2} c_{\vec{k}} e^{\mathrm{i} \vec{k} \cdot \vec{r}}=\frac{s_{\mathrm{p}}}{\epsilon_{1}} \psi_{\mathrm{p}}^{*} \psi_{\mathrm{p}}
$$

Note that in the left hand side each $\nabla$ produced a factor $\mathrm{i} \vec{k}$ for $-k^{2}$ total.
Now multiply this equation at both sides by some sample complex-conjugate momentum eigenfunction $e^{-\mathrm{i} \underline{\vec{k}} \cdot \vec{r}}$ and integrate over the entire volume $\mathcal{V}$ of the
periodic box. In the left hand side, you only get something nonzero for the term in the sum where $\vec{k}=\underline{k}$ because eigenfunctions are orthogonal. For that term, the exponentials multiply to 1 . So the result is

$$
\underline{k}^{2} c_{\underline{\underline{k}}} \mathcal{V}=\frac{s_{\mathrm{p}}}{\epsilon_{1}} \int e^{-\mathrm{i} \cdot \underline{\vec{k}} \cdot \vec{r}} \psi_{\mathrm{p}}^{*} \psi_{\mathrm{p}} \mathrm{~d}^{3} \vec{r}
$$

Now in the right hand side, assume again that the spoton is almost exactly at the origin. In other words, assume that its wave function is zero except very close to the origin. In that case, the exponential in the integral is approximately 1 when the spoton wave function is not zero. Also, the square wave function integrates to 1 . So the result is, after clean up,

$$
c_{\underline{\vec{k}}}=\frac{s_{\mathrm{p}}}{\epsilon_{1} \mathcal{V} \underline{k}^{2}}
$$

This expression applies for any wave number vector $\underline{\vec{k}}$, so you can leave the underline away. It fully determines $\varphi_{\mathrm{cl}}^{\mathrm{p}}$ in terms of the momentum states:

$$
\begin{equation*}
\varphi_{\mathrm{cl}}^{\mathrm{p}}(\vec{r})=\sum_{\text {all } \vec{k}} \frac{s_{\mathrm{p}}}{\epsilon_{1} \mathcal{V} k^{2}} e^{\mathrm{i} \vec{k} \cdot \vec{r}} \tag{A.118}
\end{equation*}
$$

This solution is definitely one to remember. Note in particular that the coefficients of the momentum states are a constant divided by $k^{2}$. Recall also that for a unit value of $s_{\mathrm{p}} / \epsilon_{1}$, this solution is the fundamental solution, or Green's function, of the Poisson equation with point wise forcing at the origin.

If the requirement that the spoton wave function is completely at the origin is relaxed, the integral involving the spoton wave function stays:

$$
\begin{equation*}
\varphi_{\mathrm{cl}}^{\mathrm{p}}(\vec{r})=\sum_{\text {all } \vec{k}} \frac{s_{\mathrm{p}}}{\epsilon_{1} \mathcal{V} k^{2}}\left\langle\psi_{\mathrm{p}} \mid e^{-\mathrm{i} \overrightarrow{\mathrm{k}} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle e^{\mathrm{i} \vec{k} \cdot \vec{r}} \tag{A.119}
\end{equation*}
$$

where

$$
\left\langle\psi_{\mathrm{p}} \mid e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle \equiv \int \psi_{\mathrm{p}}^{*}\left(\vec{r}_{\mathrm{p}}\right) e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\left(\vec{r}_{\mathrm{p}}\right) \mathrm{d}^{3} \vec{r}_{\mathrm{p}}
$$

Note that the integration variable over the spoton wave function has been renamed $\vec{r}_{\mathrm{p}}$ to avoid confusion with the position $\vec{r}$ at which the potential is evaluated. The above result is really better to work with in this subsection, since it does not suffer from some convergence issues that the Green's function solution has. And it is exact for a spoton wave function that is somewhat spread out.

Now the objective is to reproduce this classical result using a proper quantum field theory. And to find the force when a selecton is added to the system.

To do so, consider initially a system of fotons and a single spoton. The spoton will be treated as a nonrelativistic particle. Then its wave function $\psi_{\mathrm{p}}$ describes exactly one spoton. The spoton wave function will be treated as given.

Imagine something keeping the spoton in a ground state squeezed around the origin. Maxwell's demon would work. He has not been doing much anyway after he failed his thermo test.

Next the fotons. Their description will be done based upon linear momentum states. Such a state corresponds to a single-foton wave function of the form $e^{i \vec{k} \cdot \vec{r}}$.

To keep it simple, for now only a single momentum state will be considered. In other words, only a single wave number vector $\vec{k}$ will be considered. But there might be multiple fotons in the state, or even uncertainty in the number of fotons.

Of course, at the end of the day the results must still be summed over all values of $\vec{k}$.

Some notations are needed now. A situation in which there are no fotons in the considered state will be indicated by the "Fock space ket" $|0\rangle$. If there is one foton in the state, it is indicated by $|1\rangle$, two by $|2\rangle$, etcetera. In the mathematics of quantum field theory, kets are taken to be orthonormal, $\{$ A.15\}:

$$
\left\langle i_{1} \| i_{2}\right\rangle=\left\{\begin{array}{l}
1 \text { if } i_{1}=i_{2}  \tag{A.120}\\
0 \text { otherwise }
\end{array}\right.
$$

In words, the inner product of kets is 0 unless the numbers of fotons are equal. Then it is 1 .

The ground state wave function for the combined spoton-fotons system is then assumed to be of the form

$$
\begin{equation*}
\psi_{\varphi \mathrm{p}}=C_{0} \psi_{\mathrm{p}}|0\rangle+C_{1} \psi_{\mathrm{p}}|1\rangle+C_{2} \psi_{\mathrm{p}}|2\rangle+\ldots \quad\left|C_{0}\right|^{2}+\left|C_{1}\right|^{2}+\left|C_{2}\right|^{2}+\ldots=1 \tag{A.121}
\end{equation*}
$$

That is a linear combination of system states with $0,1,2, \ldots$ fotons. So it is assumed that there may be uncertainty about the number of fotons in the considered foton state. The normalization condition for the constants expresses that the total probability of finding the system in some state or the other is 1 .
(It may be noted that in typical quantum field theories, a charged relativistic particle would also be described in terms of kets and some quantum field $\widehat{\psi}$. However, unlike for a photon, for a charged particle $\widehat{\psi}$ would normally be a complex quantum field. Then $\widehat{\psi}^{*} \widehat{\psi}$ or something along these lines provides a real probability for a photon to "observe" the particle. That resembles the Born interpretation of the nonrelativistic wave function somewhat, especially for a spinless particle. Compare $\llbracket 17, \mathrm{pp} .49,136,144 \rrbracket$. The field $\widehat{\psi}$ will describe both the particle and its oppositely charged antiparticle. The spoton wave function $\psi_{\mathrm{p}}$ as used here represents some nonrelativistic limit in which the antiparticle has been approximated away from the field, $\llbracket 17$, pp. 41-45】. Such a nonrelativistic limit simply does not exist for a real scalar field like the Koulomb one.)

Now, of course, the Hamiltonian is needed. The Hamiltonian determines the energy. It consists of three parts:

$$
H=H_{\mathrm{p}}+H_{\varphi}+H_{\varphi \mathrm{p}}
$$

The first part is the Hamiltonian for the spoton in isolation. It consists of the kinetic energy of the spoton, as well as the potential provided by the fingers of the demon. By definition

$$
\begin{equation*}
H_{\mathrm{p}} \psi_{\mathrm{p}}=E_{\mathrm{p}} \psi_{\mathrm{p}} \tag{A.122}
\end{equation*}
$$

where $E_{\mathrm{p}}$ is the energy of the spoton in isolation.
The second part is the Hamiltonian of the free foton field. Each foton in the considered state should have an energy $\hbar \omega$ with $\omega=k c$. That is the energy that you get if you substitute the momentum eigenfunction $e^{i \vec{k} \cdot \vec{r}}$ into the KleinGordon eigenvalue problem (A.101) for a massless particle. And if one foton has an energy $\hbar \omega$, then $i$ of them should have energy $i \hbar \omega$, so

$$
\begin{equation*}
H_{\varphi}|i\rangle=i \hbar \omega|i\rangle \tag{A.123}
\end{equation*}
$$

Note that specifying what the Hamiltonian does to each separate ket tells you all you need to know about it. (Often there is an additional ground state energy shown in the above expression, but that does not make a difference here. It reflects the choice of the zero of energy.)

Finally, the third part of the total Hamiltonian is the interaction between the spoton and the foton field. This is the tricky one. First recall the classical expression for the interaction energy. According to the previous subsection, (A.111), it was $-s_{\mathrm{p}} \varphi_{\mathrm{p}}$. Here $\varphi_{\mathrm{p}}$ was the classical foton potential, evaluated at the position of the spoton.

In quantum field theory, the observable field $\varphi$ gets replaced by a quantum field $\widehat{\varphi}$. The interaction Hamiltonian then becomes

$$
\begin{equation*}
H_{\varphi \mathrm{p}}=-s_{\mathrm{p}} \widehat{\varphi}_{\mathrm{p}} \tag{A.124}
\end{equation*}
$$

This Hamiltonian needs to operate on the wave function (A.121) involving the spoton wave function and Fock space kets for the fotons. The big question is now: what is that quantum field $\widehat{\varphi}$ ?

To answer that, first note that sarged particles can create and destroy fotons. The above interaction Hamiltonian must express that somehow. After all, it is the Hamiltonian that determines the time evolution of systems in quantum mechanics.

Now in quantum field theories, creation and destruction of particles are accounted for through creation and annihilation operators, $\{\mathrm{A} .15\}$. A creation operator $\widehat{a}_{\vec{k}}$ creates a single particle in a momentum state $e^{i k \cdot \vec{r}}$. An annihilation operator $\widehat{a}_{\vec{k}}$ annihilates a single particle from such a state. More precisely, the operators are defined as

$$
\begin{equation*}
\widehat{a}_{\vec{k}}|i\rangle=\sqrt{i}|i-1\rangle \quad \widehat{a}_{\vec{k}}^{\dagger}|i-1\rangle=\sqrt{i}|i\rangle \tag{A.125}
\end{equation*}
$$

Here $|i\rangle$ is the Fock-space ket that indicates that there are $i$ fotons in the considered momentum state. Except for the numerical factor $\sqrt{i}$, the annihilation
operator takes a foton out of the state. The creation operator puts it back in, adding another numerical factor $\sqrt{i}$.

Note incidentally that the foton field Hamiltonian given earlier can now be rewritten as

$$
\begin{equation*}
H_{\varphi}=\hbar \omega \widehat{a}_{\vec{k}}^{\dagger} \widehat{a}_{\vec{k}} \tag{A.126}
\end{equation*}
$$

That is because

$$
\hbar \omega \widehat{a}_{\vec{k}}^{\dagger} \widehat{a}_{\vec{k}}|i\rangle=\hbar \omega \widehat{a}_{\vec{k}}^{\dagger} \sqrt{i}|i-1\rangle=\hbar \omega \sqrt{i}^{2}|i\rangle=i \hbar \omega|i\rangle=H_{\varphi}|i\rangle
$$

In general this Hamiltonian will still need to be summed over all values of $\vec{k}$.
But surely, the creation and annihilation of particles should also depend on where the spoton is. Fotons in the considered state have a spatially varying wave function. That should be reflected in the quantum field $\widehat{\varphi}$ somehow. To find the correct expression, it is easiest to first perform a suitable normalization of the foton state. Now the full wave function corresponding to the single-foton momentum eigenstate in empty space is

$$
\varphi_{\mathrm{f}}=C e^{-\mathrm{i} \omega t} e^{\mathrm{i} \vec{k} \cdot \vec{r}}
$$

Here $C$ is some normalization constant to be chosen. The above wave function can be verified by putting it into the Klein-Gordon equation (A.102). The energy of the foton is given in terms of its wave function above as $\hbar \omega$. But the energy in the foton field is also related to the observable field $\varphi$; classical selectostatics gives that relation as (A.103). If you plug the foton wave function above into that classical expression, you do not normally get the correct energy $\hbar \omega$. There is no need for it; the foton wave function is not observable. However, it makes things simpler if you choose $C$ so that the classical energy does equal $\hbar \omega$. That gives a energy-normalized wave function

$$
\begin{equation*}
\varphi_{\vec{k}}=\frac{\varepsilon_{k}}{k} e^{\mathrm{i} \vec{k} \cdot \vec{r}} \quad \varepsilon_{k} \equiv \sqrt{\frac{\hbar \omega}{\epsilon_{1} \mathcal{V}}} \tag{A.127}
\end{equation*}
$$

In those terms, the needed quantum field turns out to be

$$
\begin{equation*}
\widehat{\varphi}=\frac{1}{\sqrt{2}}\left(\varphi_{\vec{k}} \widehat{a}_{\vec{k}}+\varphi_{\vec{k}}^{*} \widehat{a}_{\vec{k}}^{\dagger}\right)=\frac{\varepsilon_{k}}{\sqrt{2} k}\left(e^{\mathrm{i} \vec{k} \cdot \vec{r}} \widehat{a}_{\vec{k}}+e^{-\mathrm{i} \cdot \vec{k} \cdot \vec{r}} \widehat{a}_{\vec{k}}^{\dagger}\right) \quad \varepsilon_{k} \equiv \sqrt{\frac{\hbar \omega}{\epsilon_{1} \mathcal{V}}} \tag{A.128}
\end{equation*}
$$

The first term in the right hand side is the normalized single-foton wave function at wave number $\vec{k}$ times the corresponding annihilation operator. The second term is the complex-conjugate foton wave function times the creation operator. There is also the usual factor $1 / \sqrt{2}$ that appears when you take a linear combination of two states.

You might of course wonder about that second term. Mathematically it is needed to make the operator Hermitian. Recall that operators in quantum
mechanics need to be Hermitian to ensure that observable quantities have real, rather than complex values, chapter 2.6. To check whether an operator is Hermitian, you need to check that it is unchanged when you take it to the other side of an inner product. Now the wave function is a numerical quantity that changes into its complex conjugate when taken to the other side. And $\widehat{a}$ changes into $\widehat{a}^{\dagger}$ and vice-versa when taken to the other side, $\{$ A.15.2\}. So each term in $\widehat{\varphi}$ changes into the other one, leaving the sum unchanged. So the operator as shown is indeed Hermitian.

But what to make physically of the two terms? One way of thinking about it is that the observed field is real because it does not just involve an interaction with an $e^{\mathrm{i}(\vec{k} \cdot \vec{r}-\omega t)}$ foton, but also with an $e^{-\mathrm{i}(\vec{k} \cdot \vec{r}-\omega t)}$ antifoton.

In general, the quantum field above would still need to be summed over all wave numbers $\vec{k}$. (Or integrated over $\vec{k}$ in infinite space). It may be noted that for given $\vec{r}$ the sum of the creation operator terms over all $\vec{k}$ can be understood as a field operator that creates a particle at position $\vec{r},[35, \mathrm{p} .24]$. That is a slightly different definition of the creation field operator than given in \{A.15.9\}, [43, pp. 22]. But for nonrelativistic particles (which have nonzero rest mass) it would not make a difference.

With the quantum field $\varphi$ now identified, the Hamiltonian of the spotonfotons interaction becomes finally

$$
\begin{equation*}
H_{\varphi \mathrm{p}}=-s_{\mathrm{p}} \widehat{\varphi}_{\mathrm{p}}=-\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left(e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \widehat{a}_{\vec{k}}+e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \widehat{a}_{\vec{k}}^{\dagger}\right) \quad \varepsilon_{k} \equiv \sqrt{\frac{\hbar \omega}{\epsilon_{1} \mathcal{V}}} \tag{A.129}
\end{equation*}
$$

Note that the spoton has uncertainty in position. The spoton position in the Hamiltonian above is just a possible spoton position. In usage it will still get multiplied by the square spoton wave function magnitude that gives the probability for that position. Still, at face value the interaction of the spoton with the field takes place at the location of the spoton. Interactions in quantum field theories are "local." At least on macroscopic scales that is needed to satisfy the limitation of the speed of light.

Having a Hamiltonian allows quantum selectodynamics to be explored. That will be done to some detail for the case of the electromagnetic field in subsequent addenda. However, here the only question that will be addressed is whether classical selectostatics as described in the first subsection was correct. In particular, do equal sarges still attract in the quantum description?

Selectostatics of the spoton-fotons system should correspond to the ground state of the system. The ground state has the lowest possible energy. You can therefore find the ground state by finding the state of lowest possible system energy. That is the same trick as was used to find the ground states of the hydrogen molecular ion and the hydrogen molecule in chapters 4.6 and 5.2. The "expectation value" of the system energy is defined by the inner product

$$
\langle E\rangle=\left\langle\psi_{\varphi \mathrm{p}} \mid\left(H_{\mathrm{p}}+H_{\varphi}+H_{\varphi \mathrm{p}}\right) \psi_{\varphi \mathrm{p}}\right\rangle
$$

Here the Hamiltonians have already been described above.
Now to find the ground state, the lowest possible value of the expectation energy above is needed. To get that, the inner products between the kets in the factors $\psi_{\varphi \mathrm{p}}$ must be multiplied out. First apply the Hamiltonians (A.122), (A.123), and (A.129) on the wave function $\psi_{\varphi \mathrm{p}}$, (A.121), using (A.125). Then apply the orthogonality relations (A.120) of kets. Do not forget the complex conjugate on the left side of an inner product. That produces

$$
\begin{aligned}
\langle E\rangle= & E_{\mathrm{p}} \\
& +\left|C_{1}\right|^{2} \hbar \omega+\left|C_{2}\right|^{2} 2 \hbar \omega+\ldots \\
& -\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left\langle\psi_{\mathrm{p}} \mid \mathrm{e}^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle\left(C_{0}^{*} C_{1}+\sqrt{2} C_{1}^{*} C_{2}+\ldots\right) \\
& -\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left\langle\psi_{\mathrm{p}} \mid e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle\left(C_{1}^{*} C_{0}+\sqrt{2} C_{2}^{*} C_{1}+\ldots\right)
\end{aligned}
$$

Here the dots stand for terms involving the coefficients $C_{3}, C_{4}, \ldots$ of states with three or more fotons.

Note that the first term in the right hand side above is the energy $E_{\mathrm{p}}$ of the spoton by itself. That term is a given constant. The question is what foton states produce the lowest energy for the remaining terms. The answer is easy if the spoton sarge $s_{\mathrm{p}}$ is zero. Then the terms in the last two lines are zero. So the second line shows that $C_{1}, C_{2}, \ldots$ must all be zero. Then there are no fotons; only the state with zero fotons is then left in the system wave function (A.121).

If the spoton sarge is nonzero however, the interaction terms in the last two lines can lower the energy for suitable nonzero values of the constants $C_{1}, C_{2}$, $\ldots$... To simplify matters, it will be assumed that the spoton sarge is nonzero but small. Then so will be the constants. In that case only the $C_{1}$ terms need to be considered; the other terms in the last two lines involve the product of two small constants, and those cannot compete. Further the normalization condition in (A.121) shows that $\left|C_{0}\right|$ will be approximately 1 since even $C_{1}$ is small. Then $C_{0}$ may be assumed to be 1 , because any eigenfunction is indeterminate by a factor of magnitude 1 anyway.

Further, since any complex number may always be written as its magnitude times some exponential of magnitude 1 , the second last line of the energy above can be written as

$$
-\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} k \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle C_{1}=-\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left|\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle\right| e^{\mathrm{i} \alpha}\left|C_{1}\right| e^{\mathrm{i} \beta}
$$

Replacing i everywhere by -i gives the corresponding expression for the last line. The complete expression for the energy then becomes

$$
\begin{aligned}
E= & E_{\mathrm{p}}+\left|C_{1}\right|^{2} \hbar \omega \\
& -\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left|\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle\right|\left|C_{1}\right| e^{\mathrm{i}(\alpha+\beta)}-\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left|\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle\right|\left|C_{1}\right| e^{-\mathrm{i}(\alpha+\beta)}
\end{aligned}
$$

In the last term, note that the sign of i inside an absolute value does not make a difference. Using the Euler formula (2.5) on the trailing exponentials gives

$$
E=E_{\mathrm{p}}+\left|C_{1}\right|^{2} \hbar \omega-2 \frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k}\left|\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \cdot \overrightarrow{r_{\mathrm{r}}^{\mathrm{p}}}} \psi_{\mathrm{p}}\right\rangle\right|\left|C_{1}\right| \cos (\alpha+\beta)
$$

But in the ground state, the energy should be minimal. Clearly, that requires that the cosine is at its maximum value 1 . So it requires taking $C_{1}$ so that $\beta=$ $-\alpha$.

That still leaves the magnitude $\left|C_{1}\right|$ to be found. Note that the final terms in expression above are now of the generic form

$$
a\left|C_{1}\right|^{2}-2 b\left|C_{1}\right|
$$

where $a$ and $b$ are positive constants. That is a quadratic function of $\left|C_{1}\right|$. By differentiation, it is seen that the minimum occurs at $\left|C_{1}\right|=b / a$ and has a value $-b^{2} / a$. Putting in what $a$ and $b$ are then gives

$$
C_{1}=\frac{s_{\mathrm{p}} \varepsilon_{k}}{\sqrt{2} k \hbar \omega}\left\langle\psi_{\mathrm{p}} \mid e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle \quad E=E_{\mathrm{p}}-\frac{s_{\mathrm{p}}^{2}}{2 \epsilon_{1} \mathcal{V} k^{2}}\left|\left\langle\psi_{\mathrm{p}} \mid e^{i \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle\right|^{2}
$$

The second part of the energy is the energy lowering achieved by having a small probability $\left|C_{1}\right|^{2}$ of a single foton in the considered momentum state.

This energy-lowering still needs to be summed over all states $\vec{k}$ to get the total:
$E-E_{\mathrm{p}}=-\sum_{\vec{k}} \frac{s_{\mathrm{p}}^{2}}{2 \epsilon_{1} \mathcal{V} k^{2}}\left|\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \cdot \overrightarrow{r_{\mathrm{p}}}} \psi_{\mathrm{p}}\right\rangle\right|^{2}=-\sum_{\vec{k}} \frac{s_{\mathrm{p}}^{2}}{2 \epsilon_{1} \mathcal{V} k^{2}}\left\langle\psi_{\mathrm{p}} \mid e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \vec{k} \cdot \vec{r}} \psi_{\mathrm{p}}\right\rangle$
Note that the final two inner products represent separate integrations. Therefore to avoid confusion, the subscript p was dropped from one integration variable. In the sum, the classical field (A.119) can now be recognized:

$$
E-E_{\mathrm{p}}=-\frac{s_{\mathrm{p}}}{2}\left\langle\psi_{\mathrm{p}} \mid \varphi_{\mathrm{cl}}^{\mathrm{p}}(\vec{r}) \psi_{\mathrm{p}}\right\rangle=-\frac{1}{2} \int \varphi_{\mathrm{cl}}^{\mathrm{p}}(\vec{r}) s_{\mathrm{p}} \psi_{\mathrm{p}}^{*}(\vec{r}) \psi_{\mathrm{p}}(\vec{r}) \mathrm{d}^{3} \vec{r}
$$

Ignoring the differences in notation, the energy lowering is exactly the same as (A.108) found in the classical analysis. The classical analysis, while not really justified, did give the right answer.

However now an actual picture of the quantum ground state has been obtained. It is a quantum superposition of system states. The most likely state is the one where there are no fotons at all. But there are also small probabilities for system states where there is a single foton in a single linear momentum foton state. This picture does assume that the spoton sarge is small. If that was not true, things would get much more difficult.

Another question is whether the observable values of the foton potential are the same as those obtained in the classical analysis. This is actually a trick question because even the classical foton potential is not observable. There is still an undetermined constant in it. What is observable are the derivatives of the potential: they give the observable selectic force per unit sarge on sarged particles.

Now, in terms of momentum modes, the derivatives of the classical potential can be found by differentiating (A.119). That gives

$$
\varphi_{i_{\mathrm{p}, \mathrm{cl}}}=\sum_{\text {all } \vec{k}} \frac{s_{\mathrm{p}}}{\epsilon_{1} \mathcal{V} k^{2}}\left\langle\psi_{\mathrm{p}} \mid e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle \mathrm{i} k_{i} e^{\mathrm{i} \vec{k} \cdot \vec{r}}
$$

Recall again the convention introduced in the previous subsection that a subscript $i$ on $\varphi$ indicates the derivative $\partial / \partial r_{i}$, where $r_{1}, r_{2}$, and $r_{3}$ correspond to $x, y$, and $z$ respectively. So the above expression gives the selectic force per unit sarge in the $x, y$, or $z$ direction, depending on whether $i$ is 1,2 , or 3 .

The question is now whether the quantum analysis predicts the same observable forces. Unfortunately, the answer here is no. The observable forces have quantum uncertainty that the classical analysis missed. However, the Ehrenfest theorem of chapter 7.2.1 suggests that the expectation forces should still match the classical ones above.

The quantum expectation force per unit sarge in the $i$-direction is given by

$$
\left\langle\varphi_{i}\right\rangle=\left\langle\Psi_{\varphi \mathrm{p}} \mid \widehat{\varphi}_{i} \Psi_{\varphi \mathrm{p}}\right\rangle \quad \Psi_{\varphi \mathrm{p}}=e^{-\mathrm{i} E t / \hbar} \psi_{\varphi \mathrm{p}}
$$

Here $E$ is the ground state energy. Note that in this case the full, time-dependent wave function $\Psi_{\varphi \mathrm{p}}$ is used. That is done because in principle an observed field could vary in time as well as in space. Substituting in the $r_{i}$-derivative of the quantum field (A.128) gives

$$
\left\langle\varphi_{i}\right\rangle=\frac{\varepsilon_{k}}{\sqrt{2} k}\left\langle\psi_{\varphi \mathrm{p}} \mid\left(\mathrm{i} k_{i} e^{\mathrm{i} \vec{k} \cdot \vec{r}} \widehat{a}_{\vec{k}}-\mathrm{i} k_{i} e^{-\mathrm{i} \vec{k} \cdot \vec{r}} \widehat{a}_{\vec{k}}^{\dagger}\right) \psi_{\varphi \mathrm{p}}\right\rangle
$$

Note that here $\vec{r}$ is not a possible position of the spoton, but a given position at which the selectic force per unit sarge is to be found. Also note that the time dependent exponentials have dropped out against each other; the expectation forces are steady like for the classical field.

The above expression can be multiplied out as before. Using the obtained expression for $C_{1}$, and the fact that $\left\langle\psi_{\mathrm{p}} \mid \psi_{\mathrm{p}}\right\rangle=1$ because wave functions are normalized, that gives.

$$
\left\langle\varphi_{i}\right\rangle=\frac{s_{\mathrm{p}}}{2 \epsilon_{1} \mathcal{V} k^{2}}\left\langle\psi_{\mathrm{p}} \mid e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle \mathrm{i} k_{i} e^{\mathrm{i} \overrightarrow{\mathrm{i}} \cdot \vec{r}}-\frac{s_{\mathrm{p}}}{2 \epsilon_{1} \mathcal{V} k^{2}}\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \overrightarrow{\mathrm{k}} \cdot \vec{r}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle \mathrm{i} k_{i} e^{-\mathrm{i} \vec{k} \cdot \vec{r}}
$$

Summed over all $\vec{k}$, the two terms in the right hand side produce the same result, because opposite values of $\vec{k}$ appear equally in the summation. In other words,
for every $\vec{k}$ term in the first sum, there is a $-\vec{k}$ term in the second sum that produces the same value. And that then means that the expectation selectic forces are the same as the classical ones. The classical analysis got that right, too.

To see that there really is quantum uncertainty in the forces, it suffices to look at the expectation square forces. If there was no uncertainty in the forces, the expectation square forces would be just the square of the expectation forces. To see that that is not true, it is sufficient to simply take the spoton sarge zero. Then the expectation field is zero too. But the expectation square field is given by

Multiplying this out gives

$$
\left\langle\varphi_{i}^{2}\right\rangle=\frac{\varepsilon_{k}^{2} k_{i}^{2}}{2 k^{2}}=\frac{\hbar \omega k_{i}^{2}}{2 \epsilon_{1} \mathcal{V} k^{2}}
$$

Since Planck's constant is not zero, this is not zero either. So even without the spoton, a selectic force measurement will give a random, but nonzero value. The average of a large number of such force measurements will be zero, but not the individual measurements.

The above expression can be compared with the corresponding $\left|\varphi_{\vec{k}, i}\right|^{2}$ of a single foton, as given by (A.127). That comparison indicates that even in the ground state in empty space, there is still half a foton of random field energy left. Recall now the Hamiltonian (A.126) for the foton field. Usually, this Hamiltonian would be defined as

$$
H_{\varphi}=\sum_{\vec{k}} \hbar \omega\left(\hat{a}_{\vec{k}}^{\dagger} \widehat{a}_{\vec{k}}+\frac{1}{2}\right)
$$

The additional $\frac{1}{2}$ expresses the half foton of energy left in the ground state. The ground state energy does not change the dynamics. However, it is physically reflected in random nonzero values if the selectic field is measured in vacuum.

The bad news is that if you sum these ground state energies over all values of $\vec{k}$, you get infinite energy. The exact same thing happens for the photons of the electromagnetic field. Quantum field theories are plagued by infinite results; this "vacuum energy" is just a simple example. What it really means physically is as yet not known either. More on this can be found in $\{\mathrm{A} .23 .4\}$.

The final issue to be addressed is the attraction between a spoton and a selecton. That can be answered by simply adding the selecton to the spoton-fotons analysis above, $\{\mathrm{D} .37 .2\}$. The answer is that the spoton-selecton interaction energy is the same as found in the classical analysis.

So equal sarges still attract.

## A.22.4 Poincaré and Einstein try to save the universe

The Koulomb universe is a grim place. In selectodynamics, particles with the same sarge attract. So all selectons clump together into one gigantic ball. Assuming that spotons have the opposite sarge, they clump together into another big ball at the other end of the universe. But actually there is no justification to assume that spotons would have a different sarge from selectons. That then means that all matter clumps together into a single gigantic satom. A satom like that will form one gigantic, obscene, black hole. It is hardly conductive to the development of life as we know it.

Unfortunately, the Koulomb force is based on highly plausible, apparently pretty unavoidable assumptions. The resulting force simply makes sense. None of these things can be said about the Coulomb force.

But maybe, just maybe, the Koulomb juggernaut can be tripped up by some legal technicality. Things like that have happened before.

Now in a time not really that very long ago, there lived a revolutionary of mathematics called Poincaré. Poincaré dreamt of countless shining stars that would sweep through a gigantic, otherwise dark universe. And around these stars there would be planets populated by living beings called "observers." But if the stars all moved in random directions, with random speeds, then which star would be the one at rest? Which star would be the king around which the other stars danced? Poincaré thought long and hard about that problem. "No!" he thundered eventually; "It shall not be. I hereby proclaim that all stars are created equal. Any observer at any star can say at any given time that its star is at rest and that the other stars are moving. On penalty of dead, nothing in physics may indicate that observer to be wrong."

Now nearby lived a young physicist called Einstein who was very lazy. For example, he almost never bothered to write the proper summation symbols in his formulae. Of course, that made it difficult for him to find a well paying job in some laboratory where they smash spotons into each other. Einstein ended up working in some patent office for little pay. But, fortunate for our story, working in a patent office did give Einstein a fine insight in legal technicalities.

First Einstein noted that the Proclamation of Poincaré meant that observers at different stars had to disagree seriously about the locations and times of events. However, it would not be complete chaos. The locations and times of events as perceived by different observers would still be related. The relation would be a transformation that the famous physicist Lorentz had written down earlier, chapter 1.2.1 (1.6).

And the Proclamation of Poincaré also implied that different observers had to agree about the same laws of physics. So the laws of physics should remain the same when you change them from one observer to the next using the Lorentz transformation. Nowadays we would say that the laws of physics should be "Lorentz invariant." But at the time, Einstein did not want to use the name of

## Lorentz in vain.

Recall now the classical "action principle" of subsection A.22.2. The socalled action integral had to be unchanged under small deviations from the correct physics. The Proclamation of Poincaré demands that all observers must agree that the action is unchanged. If the action is unchanged for an observer at one star, but not for one at another star, then not all stars are created equal.

To see what that means requires a few fundamental facts about special relativity, the theory of systems in relative motion.

The Lorentz transformation badly mixes up spatial positions and times of events as seen by different observers. To deal with that efficiently, it is convenient to combine the three spatial coordinates and time into a single fourdimensional vector, a four-vector, chapter 1.2.4. Time becomes the "zeroth coordinate" that joins the three spatial coordinates. In various notations, the four-vector looks like

$$
\stackrel{\rightharpoonup}{r} \equiv\binom{c t}{\vec{r}} \equiv\left(\begin{array}{c}
c t \\
x \\
y \\
z
\end{array}\right) \equiv\left(\begin{array}{c}
r_{0} \\
r_{1} \\
r_{2} \\
r_{3}
\end{array}\right) \equiv\binom{r_{0}}{\left\{r_{i}\right\}} \equiv\left(\begin{array}{c}
x^{0} \\
x^{1} \\
x^{2} \\
x^{3}
\end{array}\right) \equiv\left\{x^{\mu}\right\} \rightarrow x^{\mu}
$$

First of all, note that the zeroth coordinate receives an additional factor $c$, the speed of light. That is to ensure that it has units of length just like the other components. It has already been noted before that the spatial coordinates $x, y$, and $z$ are indicated by $r_{1}, r_{2}$, and $r_{3}$ in this addendum. That allows a generic component to be indicated by $r_{i}$ for $i=1,2$, or 3 . Note also that curly brackets are a standard mathematical way of indicating a set or collection. So $\left\{r_{i}\right\}$ stands for the set of all three $r_{i}$ values; in other words, it stands for the complete position vector $\vec{r}$. That is the primary notation that will be used in this addendum.

However, in virtually any quantum field book, you will find four-vectors indicated by $x^{\mu}$. Here $\mu$ is an index that can have the values $0,1,2$, or 3 . (Except that some books make time the fourth component instead of the zeroth.) An $x^{\mu}$ by itself probably really means $\left\{x^{\mu}\right\}$, in other words, the complete four-vector. Physicists have trouble typing curly brackets, so they leave them away. When more than one index is needed, another Greek symbol will be used, like $x^{\nu}$. However, $x^{i}$ would stand for just the spatial components, so for the position vector $\left\{r_{i}\right\}$. The give-away is here that a roman superscript is used. Roman superscript $j$ would mean the same thing as $i$; the spatial components only.

There are similar notations for the derivatives of a function $f$ :
$\stackrel{\rightharpoonup}{\nabla} f \equiv\binom{\partial f / c \partial t}{\nabla f} \equiv\left(\begin{array}{c}\partial f / c \partial t \\ \partial f / \partial x \\ \partial f / \partial y \\ \partial f / \partial z\end{array}\right) \equiv\binom{f_{t} / c}{\left\{f_{i}\right\}} \equiv\left(\begin{array}{c}\partial_{0} f \\ \partial_{1} f \\ \partial_{2} f \\ \partial_{3} f\end{array}\right) \equiv\left\{\partial_{\mu} f\right\} \rightarrow \partial_{\mu} f$

Note again that time derivatives in this addendum are indicated by a subscript $t$ and spatial derivatives by a subscript $i$ for $i=1,2$, or 3 .

Quantum field books use $\partial_{\mu} f$ for derivatives. They still have problems with typing curly brackets, so $\partial_{\mu} f$ by itself probably means the set of all four derivatives. Similarly $\partial_{i} f$ would probably mean the spatial gradient $\nabla f$.

The final key fact to remember about special relativity is:

> In dot products between four-vectors, the product of the zeroth components gets a minus sign.

Dot products between four-vectors are very important because all observers agree about the values of these dot products. They are Lorentz invariant. (In nonrelativistic mechanics, all observers agree about the usual dot products between spatial vectors. That is no longer true at relativistic speeds.)

One warning. In almost all modern quantum field books, the products of the spatial components get the minus sign instead of the time components. The purpose is to make the relativistic dot product incompatible with the nonrelativistic one. After all, "backward compatibility" is so, well, backward. (One source that does use the compatible dot product is [49]. This is a truly excellent book written by a Nobel Prize winning pioneer in quantum field theory. It may well be the best book on the subject available. Unfortunately it is also very mathematical and the entire thing spans three volumes. Then again, you could certainly live without supersymmetry.)

One other convention might be mentioned. Some books put a factor $\mathrm{i}=$ $\sqrt{-1}$ in the zeroth components of four-vectors. That takes care of the minus sign in dot products automatically. But modern quantum field books do not this.

Armed with this knowledge about special relativity, the Koulomb force can now be checked. Action is defined as

$$
\mathcal{S} \equiv \int_{t_{1}}^{t_{2}} \mathcal{L} \mathrm{~d} t
$$

Here the time range from $t_{1}$ to $t_{2}$ should be chosen to include the times of interest. Further $\mathcal{L}$ is the so-called Lagrangian.

If all observers agree about the value of the action in selectodynamics, then selectodynamics is Lorentz invariant. Now the Lagrangian of classical selectodynamics was of the form, subsection A.22.2,

$$
\mathcal{L}_{\varphi \mathrm{p}}=\int £_{\varphi} \mathrm{d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} \vec{v}_{\mathrm{p}}^{2}+\varphi_{\mathrm{p}} s_{\mathrm{p}}
$$

Here the Lagrangian density of the foton field $\varphi$ was

$$
£_{\varphi}=-\frac{\epsilon_{1}}{2}\left(-\frac{1}{c^{2}} \varphi_{t}^{2}+\varphi_{i}^{2}\right)
$$

To this very day, a summation symbol may not be used to reveal to nonphysicists that the last term needs to be summed over all three values of $i$. That is in honor of the lazy young physicist, who tried to save the universe.

Note that the parenthetical term in the Lagrangian density is simply the square of the four-vector of derivatives of $\varphi$. Indeed, the relativistic dot product puts the minus sign in front of the product of the time derivatives. Since all observers agree about dot products, they all agree about the values of the Lagrangian density. It is Lorentz invariant.

To be sure, it is the action and not the Lagrangian density that must be Lorentz invariant. But note that in the action, the Lagrangian density gets integrated over both space and time. Such integrals are the same for any two observers. You can easily check that from the Lorentz transformation chapter 1.2.1 (1.6) by computing the Jacobian of the $\mathrm{d} x \mathrm{~d} t$ integration between observers.
(OK, the limits of integration are not really the same for different observers. One simple way to get around that is to assume that the field vanishes at large negative and positive times. Then you can integrate over all space-time. A more sophisticated argument can be given based on the derivation of the action principle \{A.1.5\}. From that derivation it can be seen that it suffices to consider small deviations from the correct physics that are localized in both space and time. It implies that the limits of integration in the action integral are physically irrelevant.)
(Note that this subsection does no longer mention periodic boxes. In relativity periodicity is not independent of the observer, so the current arguments really need to be done in infinite space.)

The bottom line is that the first, integral, term in the Lagrangian produces a Lorentz-invariant action. The second term in the Lagrangian is the nonrelativistic kinetic energy of the spoton. Obviously the action produced by this term will not be Lorentz invariant. But you can easily fix that up by substituting the corresponding relativistic term as given in chapter 1.3.2. So the lack of Lorentz invariance of this term will simply be ignored in this addendum. If you want, you can consider the spoton mass to be the moving mass in the resulting equations of motion.

The final term in the Lagrangian is the problem. It represents the spotonfotons interaction. The term by itself would be Lorentz invariant, but it gets integrated with respect to time. Now in relativity time intervals $\mathrm{d} t$ are not the same for different observers. So the action for this term is not Lorentz invariant. Selectodynamics cannot be correct. The Koulomb juggernaut has been stopped by a small legal technicality.
(To be sure, any good lawyer would have pointed out that there is no problem if the spoton sarge density, instead of the spoton sarge $s_{\mathrm{p}}$, is the same for different observers. But the Koulomb force was so sure about its invincibility that it never bothered to seek competent legal counsel.)

The question is now of course how to fix this up. That will hopefully produce
a more appealing universe. One in which particles like protons and electrons have charges $q$ rather than sarges $s$. Where these charges allow them to interact with the photons of the electromagnetic field. And where these photons assure that particles with like charges repel, rather than attract.

Consider the form of the problem term in the Koulomb action:

$$
\int_{t_{1}}^{t_{2}} \varphi_{\mathrm{p}} s_{\mathrm{p}} \mathrm{~d} t
$$

It seems logical to try to write this in relativistic terms, like

$$
\int_{t_{1}}^{t_{2}}\left(\frac{\varphi_{\mathrm{p}}}{c}\right)\left(s_{\mathrm{p}} \mathrm{~d} c t\right)=\int_{t_{1}}^{t_{2}}\left(\frac{\varphi_{\mathrm{p}}}{c}\right)\left(s_{\mathrm{p}} \mathrm{~d} r_{\mathrm{p}_{0}}\right)
$$

Here $\mathrm{d} r_{\mathrm{p}_{0}}$ is the zeroth component of the change in spoton four-vector $\mathrm{d} \vec{r}_{\mathrm{p}}$. The product of the two parenthetical factors is definitely not Lorentz invariant. But suppose that you turn each of the factors into a complete four-vector? Dot products are Lorentz invariant. And the four-vector corresponding to $\mathrm{d} r_{\mathrm{p}_{0}}$ is clearly $\mathrm{d} \vec{r}_{\mathrm{p}}$.

But the photon potential must also become a four-vector, instead of a scalar. That is what it takes to achieve Lorentz invariance. So electrodynamics defines a four-vector of potentials of the form

$$
\overleftrightarrow{A} \equiv\binom{\varphi / c}{\vec{A}} \equiv\left(\begin{array}{c}
\varphi / c \\
A_{x} \\
A_{y} \\
A_{z}
\end{array}\right) \equiv\left(\begin{array}{c}
A_{0} \\
A_{1} \\
A_{2} \\
A_{3}
\end{array}\right) \equiv\left(\begin{array}{c}
A^{0} \\
A^{1} \\
A^{2} \\
A^{3}
\end{array}\right) \equiv\left\{A^{\mu}\right\} \rightarrow A^{\mu}
$$

Here $\vec{A}$ is the so-called "vector potential" while $\varphi$ is now the electrostatic potential.

The interaction term in the action now becomes, replacing the spoton sarge $s_{\mathrm{p}}$ by minus the proton charge $q_{\mathrm{p}}$,

In writing out the dot product, note that the spatial components of $\mathrm{d} \stackrel{\rightharpoonup}{\mathrm{p}}_{\mathrm{p}} / \mathrm{d} t$ are simply the proton velocity components $v_{\mathrm{p}_{j}}$. That gives the interaction term in the action as

$$
\int_{t_{1}}^{t_{2}}\left(-\varphi_{\mathrm{p}} q_{\mathrm{p}}+A_{j_{\mathrm{p}}} q_{\mathrm{p}} v_{\mathrm{p}_{j}}\right) \mathrm{d} t
$$

Once again nonphysicists may not be told that the second term in parentheses must be summed over all three values of $j$ since $j$ appears twice.

The integrand above is the interaction term in the electromagnetic Lagrangian,

$$
\mathcal{L}_{\text {int }}=-\varphi_{\mathrm{p}} q_{\mathrm{p}}+A_{j_{\mathrm{p}}} q_{\mathrm{p}} v_{\mathrm{p}_{j}}
$$

For now at least.
The Lagrangian density of the photon field is also needed. Since the photon field is a four-vector rather than a scalar, the self-evident electromagnetic density is

$$
£_{\text {seem }}=-\frac{\epsilon_{0}}{2}\left(-A_{j_{t}}^{2}+c^{2} A_{j_{i}}^{2}+\frac{1}{c^{2}} \varphi_{t}^{2}-\varphi_{i}^{2}\right)
$$

Here the constant $\epsilon_{0}$ is called the "permittivity of space." Note that the second term in parentheses must be summed over both $i$ and $j$. The curious sign pattern for the parenthetical terms arises because it involves two dot products: one from the square four-gradient (derivatives), and one from the square four-potential. Simply put, having electrostatic potentials is worth a minus sign, and having time derivatives is too.

It might be noted that in principle the proper Lagrangian density could be minus the above expression. But a minus sign in a Lagrangian does not change the motion. The convention is to choose the sign so that the corresponding Hamiltonian describes energies that can be increased by arbitrarily large amounts, not lowered by arbitrarily large amounts. Particles can have unlimited amounts of positive kinetic energy, not negative kinetic energy.

Still, it does seem worrisome that the proper sign of the Lagrangian density is not self-evident. But that issue will have to wait until the next subsection.

Collecting things together, the self-evident Lagrangian for electromagnetic field plus proton is

$$
\mathcal{L}_{\text {seem }+\mathrm{p}}=\int £_{\text {seem }} \mathrm{d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} v_{\mathrm{p}_{j}}^{2}-\varphi_{\mathrm{p}} q_{\mathrm{p}}+A_{j_{\mathrm{p}}} q_{\mathrm{p}} v_{\mathrm{p}_{j}}
$$

Here $£_{\text {seem }}$ was given above.
The first thing to check now is the equation of motion for the proton. Following subsection A.22.2, it can be found from

$$
\frac{\mathrm{d}}{\mathrm{~d} t}\left(\frac{\partial \mathcal{L}}{\partial v_{\mathrm{p}_{i}}}\right)=\left(\frac{\partial \mathcal{L}}{\partial r_{\mathrm{p}_{i}}}\right)
$$

Substituting in the Lagrangian above gives

$$
\frac{\mathrm{d}}{\mathrm{~d} t}\left(m_{\mathrm{p}} v_{\mathrm{p}_{i}}+A_{i_{\mathrm{p}}} q_{\mathrm{p}}\right)=-\varphi_{i_{\mathrm{p}}} q_{\mathrm{p}}+A_{j_{i_{\mathrm{p}}}} q_{\mathrm{p}} v_{\mathrm{p}_{j}}
$$

This can be cleaned up, $\{$ D.6\}. In short, first an "electric" field $\overrightarrow{\mathcal{E}}$ and a "magnetic" field $\overrightarrow{\mathcal{B}}$ are defined as, in vector notation,

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=-\nabla \varphi-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A} \tag{A.130}
\end{equation*}
$$

The individual components are

$$
\begin{equation*}
\mathcal{E}_{i}=-\varphi_{i}-A_{i_{t}} \quad \mathcal{B}_{i}=A_{\overline{\bar{v}_{\bar{\imath}}}}-A_{\overline{\bar{v}_{\bar{\imath}}}} \tag{A.131}
\end{equation*}
$$

Here $i=1,2$, or 3 corresponds to the $x, y$, or $z$ components respectively. Also $\bar{\imath}$ follows $i$ in the periodic sequence $\ldots 123123 \ldots$ and $\overline{\bar{\imath}}$ precedes $i$. In these terms, the simplified equation of motion of the proton becomes, in vector notation,

$$
\begin{equation*}
\frac{\mathrm{d} m_{\mathrm{p}} \vec{v}_{\mathrm{p}}}{\mathrm{~d} t}=q_{\mathrm{p}}\left(\overrightarrow{\mathcal{E}}_{\mathrm{p}}+\vec{v}_{\mathrm{p}} \times \overrightarrow{\mathcal{B}}_{\mathrm{p}}\right) \tag{A.132}
\end{equation*}
$$

The left hand side is mass times acceleration. Relativistically speaking, the mass should really be the moving mass here, but OK. The right hand side is known as the "Lorentz force."

Note that there are 4 potentials with 4 derivatives each, for a total of 16 derivatives. But matter does not observe all 16 individually. Only the 3 components of the electric field and the 3 of the magnetic field are actually observed. That suggests that there may be changes to the fields that can be made that are not observable. Such changes are called "gage (or gauge) changes." The name arises from the fact that a gage is a measuring device. You and I would then of course say that these changes should be called nongage changes. They are not measurable. But "gage" is really shorthand for "Take that, you stupid gage."

Consider the most general form of such gage changes. Given potentials $\varphi$ and $\vec{A}$, equivalent potentials can be created as

$$
\varphi^{\prime}=\varphi-\chi_{t} \quad \vec{A}^{\prime}=\vec{A}+\nabla \chi
$$

Here $\chi$ can be any function of space and time that you want.
The potentials $\varphi^{\prime}$ and $\overrightarrow{A^{\prime}}$ give the exact same electric and magnetic fields as $\varphi$ and $\vec{A}$. (These claims are easily checked using a bit of vector calculus. Use Stokes to show that they are the most general changes possible.)

The fact that you can make unmeasurable changes to the potentials like that is called the "gage" (or gauge) property of the electromagnetic field. Nonphysicists probably think it is something you read off from a voltage gage. Hilarious, isn't it?

Observable or not, the evolution equations of the four potentials are also needed. To find them it is convenient to spread the proton charge out a bit. That is the same trick as was used in subsection A.22.2. For the spread-out charge, a "charge density" $\rho_{\mathrm{p}}$ can be defined as the charge per unit volume. It is also convenient to define a "current density" $\vec{\jmath}_{\mathrm{p}}$ as the charge density times its velocity. Then the proton-photons interaction terms in the Lagrangian are:

$$
\begin{equation*}
\int\left(-\varphi \rho_{\mathrm{p}}+A_{j} \jmath_{\mathrm{p}_{j}}\right) \mathrm{d}^{3} \vec{r} \approx-\varphi_{\mathrm{p}} q_{\mathrm{p}}+A_{j_{\mathrm{p}}} q_{\mathrm{p}} v_{\mathrm{p}_{j}} \tag{A.133}
\end{equation*}
$$

Here the right hand side is an approximation if the proton charge is almost concentrated at a single point, or exact for a point charge.

The interaction terms can now be included in the Lagrangian density to give the total Lagrangian

$$
\begin{equation*}
\mathcal{L}_{\text {seem }+\mathrm{p}}=\int\left(£_{\text {seem }}+£_{\text {int }}\right) \mathrm{d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} v_{\mathrm{p}_{j}}^{2} \tag{A.134}
\end{equation*}
$$

$$
£_{\text {seem }}=-\frac{\epsilon_{0}}{2}\left(-A_{j_{t}}^{2}+c^{2} A_{j_{i}}^{2}+\frac{1}{c^{2}} \varphi_{t}^{2}-\varphi_{i}^{2}\right) \quad £_{\mathrm{int}}=-\varphi \rho_{\mathrm{p}}+A_{j} \jmath_{\mathrm{p}}^{j} ~(~
$$

If there are more charged particles than just a proton, their charge and current densities will combine into a net $\rho$ and $\vec{\jmath}$.

The field equations now follow similarly as in subsection A.22.2. For the electrostatic potential:

$$
\frac{\partial}{\partial t}\left(\frac{\partial £}{\partial \varphi_{t}}\right)+\frac{\partial}{\partial r_{i}}\left(\frac{\partial £}{\partial \varphi_{i}}\right)=\frac{\partial £}{\partial \varphi}
$$

where $£$ is the combined Lagrangian density. Worked out and converted to vector notation, that gives

$$
\begin{equation*}
\frac{1}{c^{2}} \frac{\partial^{2} \varphi}{\partial t^{2}}-\nabla^{2} \varphi=\frac{\rho}{\epsilon_{0}} \tag{A.135}
\end{equation*}
$$

This is the same equation as for the Koulomb potential earlier.
Similarly, for the components of the vector potential

$$
\frac{\partial}{\partial t}\left(\frac{\partial £}{\partial A_{j_{t}}}\right)+\frac{\partial}{\partial r_{i}}\left(\frac{\partial £}{\partial A_{j_{i}}}\right)=\frac{\partial £}{\partial \varphi}
$$

That gives

$$
\begin{equation*}
\frac{\partial^{2} \vec{A}}{\partial t^{2}}-c^{2} \nabla^{2} \vec{A}=\frac{\vec{\jmath}}{\epsilon_{0}} \tag{A.136}
\end{equation*}
$$

The above equations are again Klein-Gordon equations, so they respect the speed of light. And since the action is now Lorentz invariant, all observers agree with the evolution. That seems very encouraging.

Consider now the steady case, with no charge motion. The current density $\vec{\jmath}$ is then zero. That leads to zero vector potentials. Then there is no magnetic field either, (A.130).

The steady equation (A.135) for the electrostatic field $\varphi$ is exactly the same as the one for the Koulomb potential. But note that the electric force per unit charge is now minus the gradient of the electrostatic potential, (A.130) and (A.132). And that means that like charges repel, not attract. All protons in the universe no longer clump together into one big ball. And neither do electrons. That sounds great.

But wait a second. How come that apparently protons suddenly manage to create fields that are repulsive to protons? What happened to energy minimization? It seems that all is not yet well in the universe.

## A.22.5 Lorenz saves the universe

The previous subsection derived the self-evident equations of electromagnetics. But there were some worrisome aspects. A look at the Hamiltonian can clarify the problem.

Given the Lagrangian (A.134) of the previous subsection, the Hamiltonian can be found as, $\{$ A.1.5\}:

$$
H_{\text {seem }+\mathrm{p}}=\int\left(\frac{\partial £}{\partial A_{j_{t}}} A_{j_{t}}+\frac{\partial £}{\partial \varphi_{t}} \varphi_{t}\right) \mathrm{d}^{3} \vec{r}+\frac{\partial \mathcal{L}}{\partial v_{\mathrm{p}_{j}}} v_{\mathrm{p}_{j}}-\mathcal{L}
$$

That gives

$$
\begin{equation*}
H_{\text {seem }+\mathrm{p}}=\frac{\epsilon_{0}}{2} \int\left(A_{j_{t}}^{2}+c^{2} A_{j_{i}}^{2}-\frac{1}{c^{2}} \varphi_{t}^{2}-\varphi_{i}^{2}\right) \mathrm{d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} v_{\mathrm{p}_{j}}^{2}+\int \varphi \rho_{\mathrm{p}} \mathrm{~d}^{3} \vec{r} \tag{A.137}
\end{equation*}
$$

(This would normally still need to be rewritten in terms of canonical momenta, but that is not important here.)

Note that the electrostatic potential $\varphi$ produces negative electromagnetic energy. That means that the electromagnetic energy can have arbitrarily large negative values for large enough $\varphi$.

That then answers the question of the previous subsection: "How come a proton produces an electrostatic field that repels it? What happened to energy minimization?" There is no such thing as energy minimization here. If there is no lowest energy, then there is no ground state. Instead the universe should evolve towards larger and larger electrostatic fields. That would release infinite amounts of energy. It should blow life as we know it to smithereens. (The so-called second law of thermodynamics says, simply put, that thermal energy is easier to put into particles than to take out again. See chapter 11.)

In fact, the Koulomb force would also produce repulsion between equal sarges, if its field energy was negative instead of positive. Just change the sign of the constant $\epsilon_{1}$ in classical selectodynamics. Then its universe should blow up too. Unlike what you will read elsewhere, the difference between the Koulomb force, (or its more widely known sibling, the Yukawa force of $\{\mathrm{A} .42\}$ ), and the Coulomb force is not simply that the photon wave function is a fourvector. It is whether negative field energy appears in the most straightforward formulation.

As the previous subsection noted, you might assume that the electrodynamic Lagrangian, and hence the Hamiltonian, would have the opposite sign. But that does not help. In that case the vector potentials $A_{j}$ would produce the negative energies. Reversing the sign of the Hamiltonian is like reversing the direction of time. In either direction, the universe gets blown to smithereens.

To be sure, it is not completely sure that the universe will be blown to smithereens. A negative field energy only says that it is in theory possible to
extract limitless amounts of energy out of the field. But you would still need some actual mechanism to do so. There might not be one. Nature might be carefully constrained so that there is no dynamic mechanism to extract the energy.

In that case, there might then be some mathematical expression for the constraint. As another way to look at that, suppose that you would indeed have a highly unstable system. And suppose that there is still something recognizable left at the end of the first day. Then surely you would expect that whatever is left is special in some way. That it obeys some special mathematical condition.

So presumably, the electromagnetic field that we observe obeys some special condition, some constraint. What could this constraint be? Since this is very basic physics, you would guess it to be relatively simple. Certainly it must be Lorentz invariant. The simplest condition that meets this requirement is that the dot product of the four-gradient $\vec{\nabla}$ with the four-potential $\vec{A}$ is zero. Written out that produces the so-called "Lorenz condition:"

$$
\begin{equation*}
\frac{1}{c} \frac{\partial \varphi / c}{\partial t}+\nabla \cdot \vec{A}=0 \tag{A.138}
\end{equation*}
$$

This condition implies that only a very special subset of possible solutions of the Klein-Gordon equations given in the previous subsection is actually observed in nature.

Please note that the Lorenz condition is named after the Danish physicist Ludvig Lorenz, not the Dutch physicist Hendrik Lorentz. Almost all my sources mislabel it the Lorentz condition. The savior of the universe deserves more respect. Always remember: the Lorenz condition is Lorentz invariant.
(You might wonder why the first term in the Lorenz condition does not have the minus sign of dot products. One way of thinking about it is that the four-gradient in its "natural" condition already has a minus sign on the time derivative. Physicists call it a "covariant" four-vector rather than a "contravariant" one. A better way to see it is to grind it out; you can use the Lorentz transform (1.6) of chapter 1.2.1 to show directly that the above form is the same for different observers. But those familiar with index notation will recognize immediately that the Lorenz condition is Lorentz invariant from the fact that it equals $\partial_{\mu} A^{\mu}=0$, and that has $\mu$ as both subscript and superscript. See chapter 1.2.5 for more.)

To be sure, the Lorenz condition can only be true if the interaction with matter does not produce violations. To check that, the evolution equation for the Lorenz condition quantity can be obtained from the Klein-Gordon equations of the previous subsection. In particular, in vector notation take $\partial / \partial t$ (A.135) plus $\nabla$ (A.136) to get

$$
\begin{equation*}
\left[\frac{\partial^{2}}{\partial t^{2}}-c^{2} \nabla^{2}\right]\left(\frac{1}{c^{2}} \frac{\partial \varphi}{\partial t}+\nabla \cdot \vec{A}\right)=\frac{1}{\epsilon_{0}}\left(\frac{\partial \rho}{\partial t}+\nabla \cdot \vec{\jmath}\right) \tag{A.139}
\end{equation*}
$$

The parenthetical expression in the left hand side should be zero according to the Lorenz condition. But that is only possible if the left hand side is zero too, so

$$
\frac{\partial \rho}{\partial t}=-\nabla \cdot \vec{\jmath}
$$

This important result is known as "Maxwell's continuity equation." It expresses conservation of charge. (To see that, take any arbitrary volume. Integrate both sides of the continuity equation over that volume. The left hand side then becomes the time derivative of the charge inside the volume. The right hand side becomes, using the [divergence] [Gauss] [Ostrogradsky] theorem, the net inflow of charge. And if the charge inside can only change due to inflow or outflow, then no charge can be created out of nothing or destroyed.) So charge conservation can be seen as a consequence of the need to maintain the Lorenz condition.

Note that the Lorenz condition (A.138) looks mathematically just like the continuity equation. It produces conservation of the integrated electrostatic potential. In subsection A. 22.7 it will be verified that it is indeed enough to produce a stable electromagnetic field. One with meaningfully defined energies that do not run off to minus infinity.

Note that charge conservation by itself is not quite enough to ensure that the Lorenz condition is satisfied. However, if in addition the Lorenz quantity and its time derivative are zero at just a single time, it is OK. Then (A.139) ensures that the Lorenz condition remains true for all time.

## A.22.6 Gupta-Bleuler condition

The ideas of the previous subsection provide one way to quantize the electromagnetic field, $\llbracket 17,6 \rrbracket$.

As already seen in subsection A. 22.3 (A.128), in quantum field theory the potentials become quantum fields, i.e. operator fields. For electromagnetics the quantum field four-vector is a bit more messy

$$
\widehat{\widehat{A}}=\binom{\widehat{\varphi} / c}{\vec{A}}=\sum_{\vec{k}} \frac{\varepsilon_{k}}{\sqrt{2} k} \sum_{\nu=0}^{3} \overleftrightarrow{e}_{\vec{k}}^{\nu}\left(e^{\left.i \mathrm{k} \cdot \vec{r} \widehat{a}_{\vec{k} \nu}+e^{-\mathrm{i} \vec{k} \cdot \vec{a}} \widehat{a}_{\vec{k} \nu}^{\dagger}\right) ~}\right.
$$

Since a four-vector has four components, a general four-vector can be written as a linear combination of four chosen basis four-vectors $\vec{e}_{\vec{k}}^{0}, \overleftrightarrow{e}_{\vec{k}}^{1}, \overleftrightarrow{e}_{\vec{k}}^{2}$, and $\vec{e}_{\vec{k}}^{3}$. (That is much like a general vector in three dimensions can be written as a linear combination of $\hat{\imath}, \hat{\jmath}$, and $\hat{k}$.) The four basis vectors physically represent different possible "polarizations" of the electromagnetic field. That is why they are typically aligned with the momentum of the wave rather than with some Cartesian axis system and its time axis. Note that each polarization vector has
its own annihilation operator $\widehat{a}_{\vec{k} \nu}$ and creation operator $\widehat{a}_{\vec{k} \nu}^{\dagger}$. These annihilate respectively create photons with that wave number vector $\vec{k}$ and polarization.
(Electromagnetic waves in empty space are special; for them only two independent polarizations are possible. Or to be precise, even in empty space the Klein-Gordon equations with Lorenz condition allow a third polarization. But these waves produce no electric and magnetic fields and contain no net electromagnetic energy. So they are physically irrelevant. You can call them "gage equivalent to the vacuum." That sounds better than irrelevant.)

The Lorenz condition of the previous subsection is again needed to get rid of negative energy states. The question is now exactly how to phrase the Lorenz condition in quantum terms.
(There is an epidemic among my, highly authorative, sources that come up with negative norm states without Lorenz condition. Now the present author himself is far from an expert on quantum field theories. But he knows one thing: norms cannot be negative. If you come up with negative norms, it tells you nothing about the physics. It tells you that you are doing the mahematics wrong. I believe the correct argument goes something like this: "Suppose that we can do our usual stupid canonical quantization tricks for this system. Blah Blah. That gives negative norm states. Norms cannot be negative. Ergo: we cannot do our usual stupid canonical quantization tricks for this system." If you properly define the creation and annihilation operators to put photons in negative energy states, there is no mathematical problem. The commutator relation for the negative energy states picks up a minus sign and the norms are positive as they should. Now the mathematics is sound and you can start worrying about problems in the physics. Like that there are negative energy states. And maybe lack of Lorentz invariance, although the original system is Lorentz invariant, and I do not see what would not be Lorentz invariant about putting particles in the negative energy states.)

The simplest idea would be to require that the quantum field above satisfies the Lorenz condition. But the quantum field determines the dynamics. Like in the classical case, you do not want to change the dynamics. Instead you want to throw certain solutions away. That means that you want to throw certain wave functions $|\Psi\rangle$ away.

The strict condition would be to require (in the Heisenberg picture \{A.12\})

$$
\left(\frac{1}{c} \frac{\partial \widetilde{\varphi} / c}{\partial t}+\nabla \cdot \widetilde{\vec{A}}\right)|\Psi\rangle=0
$$

for all physically observable states $|\Psi\rangle$. Here the parenthetical expression is the operator of the Lorenz quantity that must be zero. The above requirement makes $|\Psi\rangle$ an eigenvector of the Lorenz quantity with eigenvalue zero. Then according to the rules of quantum mechanics, chapter 3.4, the only measurable value of the Lorenz quantity is zero.

But the above strict condition is too restrictive. Not even the vacuum state with no photons would be physically observable. That is because the creation operators in $\widehat{\varphi}$ and $\widehat{\vec{A}}$ will create nonzero photon states when applied on the vacuum state. That suggests that only the annihilation terms should be included. That then gives the "Gupta-Bleuler condition:"

$$
\left(\frac{1}{c} \frac{\partial \widetilde{\varphi}^{+} / c}{\partial t}+\nabla \cdot \tilde{\vec{A}}^{+}\right)|\Psi\rangle=0
$$

for physically observable states $|\Psi\rangle$. Here the superscript + on the quantum fields means that only the $\widehat{a}_{\vec{k} \nu}$ annihilation operator terms are included.

You might of course wonder why the annihilation terms are indicated by a plus sign, instead of the creation terms. After all, it are the creation operators that create more photons. But the plus sign actually stands for the fact that the annihilation terms are associated with an $e^{-\mathrm{i} \omega t}$ time dependence instead of $e^{\mathrm{i} \omega t}$. Yes true, $e^{-\mathrm{i} \omega t}$ has a minus sign, not a plus sign. But $e^{-\mathrm{i} \omega t}$ has the normal sign, and "normal" is represented by a plus sign. Is not addition more normal than subtraction? Please do not pull at your hair like that, there are less drastic ways to save on professional hair care.

Simply dropping the creation terms may seem completely arbitrary. But it actually has some physical logic to it. Consider the inner product

$$
\left\langle\Psi^{\prime}\right|\left(\frac{1}{c} \frac{\partial \widetilde{\varphi} / c}{\partial t}+\nabla \cdot \widetilde{\vec{A}}\right)|\Psi\rangle=0
$$

This is the amount of state $\left|\Psi^{\prime}\right\rangle$ produced by applying the Lorenz quantity on the physically observable state $|\Psi\rangle$. The strict condition is equivalent to saying that this inner product must always be zero; no amount of any state may be produced. For the Gupta-Bleuler condition, the above inner product remains zero if $\left|\Psi^{\prime}\right\rangle$ is a physically observable state. (The reason is that the creation terms can be taken to the other side of the inner product as annihilation terms. Then they produce zero if $\left|\Psi^{\prime}\right\rangle$ is physically observable.) So the Gupta-Bleuler condition implies that no amount of any physically observable state may be produced by the Lorenz quantity.

There are other ways to do quantization of the electromagnetic field. The quantization following Fermi, as discussed in subsection A.22.8, can be converted into a modern quantum field theory. But that turns out to be a very messy process indeed, $\llbracket 17,6 \rrbracket$. The derivation is essentially to mess around at length until you more or less prove that you can use the Lorenz condition result instead. You might as well start there.

It does turns out that the so-called "path-integral" formulation of quantum mechanics does a very nice job here, [53, pp. 30ff]. It avoids many of the contortions of canonical quantization like the ones above.

In fact, a popular quantum field textbook, [35, p. 79], refuses to do canonical quantization of the electromagnetic field at all, calling it an awkward subject.

This book is typically used during the second year of graduate study in physics, so it is not that its readers are unsophisticated.

## A.22.7 The conventional Lagrangian

Returning to the classical electromagnetic field, it still needs to be examined whether the Lorenz condition has made the universe safe for life as we know it.

The answer depends on the Lagrangian, because the Lagrangian determines the evolution of a system. So far, the Lagrangian has been written in terms of the four potentials $\varphi$ and $A_{j}$ (with $j=1,2$, and 3 ) of the electromagnetic field. But recall that matter does not observe the four potentials directly. It only notices the electric field $\overrightarrow{\mathcal{E}}$ and the magnetic field $\overrightarrow{\mathcal{B}}$. So it may help to reformulate the Lagrangian in terms of the electric and magnetic fields. Concentrating on the observed fields is likely to show up more clearly what is actually observed.

With a bit of mathematical manipulation, $\{$ D. 37.3$\}$, the self-evident electromagnetic Lagrangian density can be written as:

$$
£_{\text {seem }}=\frac{\epsilon_{0}}{2}\left(\mathcal{E}^{2}-c^{2} \mathcal{B}^{2}-c^{2}\left\{\frac{1}{c^{2}} \frac{\partial \varphi}{\partial t}+\nabla \cdot \vec{A}\right\}^{2}\right)+\ldots
$$

Here the dots stand for terms that do not affect the motion. (Since in the action, Lagrangian densities get integrated over space and time, terms that are pure spatial or time derivatives integrate away. The quantities relevant to the action principle vanish at the limits of integration.)

The term inside the curly brackets is zero according to the Lorenz condition (A.138). Therefore, it too does not affect the motion. (To be precise, the term does not affect the motion because it is squared. By itself it would affect the motion. In the formal way in which the Lagrangian is differentiated, one power is lost.)

The conventional Lagrangian density is found by disregarding the terms that do not change the motion:

$$
£_{\text {conem }}=\frac{\epsilon_{0}}{2}\left(\mathcal{E}^{2}-c^{2} \mathcal{B}^{2}\right)
$$

So the conventional Lagrangian density of the electromagnetic field is completely in terms of the observable fields.

As an aside, it might be noted that physicists find the above expression too intuitive. So you will find it in quantum field books in relativistic index notation as:

$$
£_{\text {conem }}=-\frac{\epsilon_{0}}{4} F_{\mu \nu} F^{\mu \nu}
$$

Here the "field strength tensor" is defined by

$$
F_{\mu \nu}=c\left(\partial_{\mu} A_{\nu}-\partial_{\nu} A_{\mu}\right) \quad \mu=0,1,2,3 \quad \nu=0,1,2,3
$$

Note that the indices on each $A$ are subscripts instead of superscripts as they should be. That means that you must add a minus sign whenever the index on an $A$ is 0 . If you do that correctly, you will find that from the $16 F_{\mu \nu}$ values, some are zero, while the rest are components of the electric or magnetic fields. To go from $F_{\mu \nu}$ to $F^{\mu \nu}$, you must raise both indices, so add a minus sign for each index that is zero. If you do all that the same Lagrangian density as before results.

Because the conventional Lagrangian density is different from the self-evident one, the field equations (A.135) and (A.136) for the potentials pick up a few additional terms. To find them, repeat the analysis of subsection A. 22.4 but use the conventional density above in (A.134). Note that you will need to write the electric and magnetic fields in terms of the potentials using (A.131). (Using the field strength tensor is actually somewhat simpler in converting to the potentials. If you can get all the blasted sign changes right, that is.)

Then the conventional field equations become:

$$
\begin{gather*}
\frac{1}{c^{2}} \frac{\partial^{2} \varphi}{\partial t^{2}}-\nabla^{2} \varphi-\frac{1}{c^{2}} \frac{\partial^{2} \varphi}{\partial t^{2}}-\frac{\partial \nabla \cdot \vec{A}}{\partial t}=\frac{\rho}{\epsilon_{0}}  \tag{A.140}\\
\frac{\partial^{2} \vec{A}}{\partial t^{2}}-c^{2} \nabla^{2} \vec{A}+\nabla \frac{\partial \varphi}{\partial t}+c^{2} \nabla(\nabla \cdot \vec{A})=\frac{\vec{\jmath}}{\epsilon_{0}} \tag{A.141}
\end{gather*}
$$

Here $\rho$ is again the charge density and $\vec{\jmath}$ the current density of the charges that are around,

The additional terms in each equation above are the two before the equals signs. Note that these additional terms are zero on account of the Lorenz condition. So they do not change the solution.

The conventional field equations above are obviously more messy than the original ones. Even if you cancel the second order time derivatives in (A.140). However, they do have one advantage. If you use these conventional equations, you do not have to worry about satisfying the Lorenz condition. Any solution to the equations will give you the right electric and magnetic fields and so the right motion of the charged particles.

To be sure, the potentials will be different if you do not satisfy the Lorenz condition. But the potentials have no meaning of their own. At least not in classical electromagnetics.

To verify that the Lorenz condition is no longer needed, first recall the indeterminacy in the potentials. As subsection A.22.4 discussed, more than one set of potentials can produce the same electric and magnetic fields. In particular, given potentials $\varphi$ and $\vec{A}$, you can create equivalent potentials as

$$
\varphi^{\prime}=\varphi-\chi_{t} \quad \vec{A}^{\prime}=\vec{A}+\nabla \chi
$$

Here $\chi$ can be any function of space and time that you want. The potentials $\varphi^{\prime}$ and $\overrightarrow{A^{\prime}}$ give the exact same electric and magnetic fields as $\varphi$ and $\vec{A}$. Such a transformation of potentials is called a "gage transform."

Now suppose that you have a solution $\varphi$ and $\vec{A}$ of the conventional field equations, but it does not satisfy the Lorenz condition. In that case, simply apply a gage transform as above to get new fields $\varphi^{\prime}$ and $\vec{A}^{\prime}$ that do satisfy the Lorenz condition. To do so, write out the Lorenz condition for the new potentials,

$$
\frac{1}{c^{2}} \frac{\partial \varphi^{\prime}}{\partial t}+\nabla \cdot \vec{A}^{\prime}=\frac{1}{c^{2}} \frac{\partial \varphi}{\partial t}-\frac{1}{c^{2}} \frac{\partial^{2} \chi}{\partial t^{2}}+\nabla \cdot \vec{A}+\nabla^{2} \chi
$$

You can always choose the function $\chi$ to make this quantity zero. (Note that that gives an inhomogeneous Klein-Gordon equation for $\chi$.)

Now it turns out that the new potentials $\varphi^{\prime}$ and $\vec{A}^{\prime}$ still satisfy the conventional equations. That can be seen by straight substitution of the expressions for the new potentials in the conventional equations. So the new potentials are perfectly OK: they satisfy both the Lorenz condition and the conventional equations. But the original potentials $\varphi$ and $\vec{A}$ produced the exact same electric and magnetic fields. So the original potentials were OK too.

The evolution equation (A.140) for the electrostatic field is worth a second look. Because of the definition of the electric field (A.130), it can be written as

$$
\begin{equation*}
\nabla \cdot \overrightarrow{\mathcal{E}}=\frac{\rho}{\epsilon_{0}} \tag{A.142}
\end{equation*}
$$

That is called "Maxwell's first equation," chapter 13.2. It ties the charge density to the electric field quite rigidly.

Maxwell's first equation is a consequence of the Lorenz condition. It would not be required for the original Klein-Gordon equations without Lorenz condition. In particular, it is the Lorenz condition that allows the additional two terms in the evolution equation (A.140) for the electrostatic potential. These then eliminate the second order time derivative from the equation. That then turns the equation from a normal evolution equation into a restrictive spatial condition on the electric field.

It may be noted that the other evolution equation (A.141) is Maxwell's fourth equation. Just rewrite it in terms of the electric and magnetic fields. The other two Maxwell equations follow trivially from the definitions (A.130) of the electric and magnetic fields in terms of the potentials.

Since there is no Lorenz condition for the conventional equations, it becomes interesting to find the corresponding Hamiltonian. That should allow the stability of electromagnetics to be examined more easily.

The Hamiltonian for electromagnetic field plus a proton may be found the same way as (A.137) in subsection A.22.5, \{A.1.5\}. Just use the conventional Lagrangian density instead. That gives

$$
H_{\text {conem }+\mathrm{p}}=\int\left(\frac{\epsilon_{0}}{2}\left(\mathcal{E}^{2}+c^{2} \mathcal{B}^{2}+2 \mathcal{E}_{i} \varphi_{i}\right)+\varphi \rho_{\mathrm{p}}\right) \mathrm{d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} v_{\mathrm{p}_{j}}^{2}
$$

But the proton charge density $\rho_{\mathrm{p}}$ may eliminated using Maxwell's first equation above. An additional integration by parts of that term then causes it to drop away against the previous term. That gives the conventional energy as

$$
\begin{equation*}
E_{\text {conem }+\mathrm{p}}=\frac{\epsilon_{0}}{2} \int\left(\mathcal{E}^{2}+c^{2} \mathcal{B}^{2}\right) \mathrm{d}^{3} \vec{r}+\frac{1}{2} m_{\mathrm{p}} \vec{v}_{\mathrm{p}}^{2} \tag{A.143}
\end{equation*}
$$

The first term is the energy in the observable fields and the final term is the kinetic energy of the proton.

The simplified energy above is no longer really a Hamiltonian; you cannot write Hamilton's equations based on it as in \{A.1.5\}. But it does still give the energy that is conserved.

The energy above is always positive. So it can no longer be lowered by arbitrary amounts. The system will not blow up. And that then means that the original Klein-Gordon equations (A.135) and (A.136) for the fields are stable too as long as the Lorenz condition is satisfied. They produce the same evolution. And they satisfy the speed of light restriction and are Lorentz invariant. Lorenz did it!

Note also the remarkable result that the interaction energy between proton charge and field has disappeared. The proton can no longer minimize any energy of interaction between itself and the field it creates. Maxwell's first equation is too restrictive. All the proton can try to do is minimize the energy in the electric and magnetic fields.

## A.22.8 Quantization following Fermi

Quantizing the electromagnetic field is not easy. The previous subsection showed a couple of problems. The gage property implies that the electromagnetic potentials $\varphi$ and $\vec{A}$ are indeterminate. Also, taking the Lorenz condition into account, the second order time derivative is lost in the Klein-Gordon equation for the electrostatic potential $\varphi$. The equation turns into Maxwell's first equation,

$$
\nabla \cdot \overrightarrow{\mathcal{E}}=\frac{\rho}{\epsilon_{0}}
$$

That is not an evolution equation but a spatial constraint for the electric field $\overrightarrow{\mathcal{E}}$ in terms of the charge density $\rho$.

Various ways to deal with that have been developed. The quantization procedure discussed in this subsection is a simplified version of the one found in Bethe's book, [6, pp. 255-271]. It is due to Fermi, based on earlier work by Dirac and Heisenberg \& Pauli. This derivation was a great achievement at the time, and fundamental to more advanced quantum field approaches, [6, p. 266]. Note that all five mentioned physicists received a Nobel Prize in physics at one time or the other.

The starting point in this discussion will be the original potentials $\varphi$ and $\vec{A}$ of subsection A.22.4. The ones that satisfied the Klein-Gordon equations (A.135) and (A.136) as well as the Lorenz condition (A.138).

It was Fermi who recognized that you can make things a lot simpler for yourself if you write the potentials as sums of exponentials of the form $e^{\mathrm{i} \vec{k} \cdot \vec{r}}$ :

$$
\varphi=\sum_{\text {all } \vec{k}} c_{\vec{k}} e^{i \vec{k} \cdot \vec{r}} \quad \vec{A}=\sum_{\text {all } \vec{k}} \vec{d}_{\vec{k}} e^{i \vec{k} \cdot \vec{r}}
$$

That is the same trick as was used in quantizing the Koulomb potential in subsection A.22.3. However, in classical mechanics you do not call these exponentials momentum eigenstates. You call them "Fourier modes." The principle is the same. The constant vector $\vec{k}$ that characterizes each exponential is still called the wave number vector. Since the potentials considered here vary with time, the coefficients $c_{\vec{k}}$ and $\vec{d}_{\vec{k}}$ are functions of time.

Note that the coefficients $\vec{d}_{\vec{k}}$ are vectors. These will have three independent components. So the vector potential can be written more explicitly as

$$
\vec{A}=\sum_{\text {all } \vec{k}} d_{1, \vec{k}} \vec{e}_{1, \vec{k}} e^{\mathrm{i} \cdot \vec{k} \cdot \vec{r}}+d_{2, \vec{k}} \vec{e}_{2, \vec{k}} e^{\mathrm{i} \cdot \vec{k} \cdot \vec{r}}+d_{3, \vec{k}} \vec{e}_{3, \vec{k}} \mathrm{e}^{\mathrm{i} \vec{k} \cdot \vec{r}}
$$

where $\vec{e}_{1, \vec{k}}, \vec{e}_{2, \vec{k}}$, and $\vec{e}_{3, \vec{k}}$ are unit vectors. Fermi proposed that the smart thing to do is to take the first of these unit vectors in the same direction as the wave number vector $\vec{k}$. The corresponding electromagnetic waves are called "longitudinal." The other two unit vectors should be orthogonal to the first component and to each other. That still leaves a bit choice in direction. Fortunately, in practice it does not really make a difference exactly how you take them. The corresponding electromagnetic waves are called "transverse."

In short, the fields can be written as
$\varphi=\sum_{\text {all } \vec{k}} c_{\vec{k}} e^{\mathrm{i} \vec{k} \cdot \vec{r}}$
$\vec{A}_{\|}=\sum_{\text {all } \vec{k}} d_{1, \vec{k}} \vec{e}_{1, \vec{k}} e^{i \vec{k} \cdot \vec{r}}$
$\vec{A}_{\perp}=\sum_{\text {all } \vec{k}} d_{2, \vec{k}} \vec{e}_{2, \vec{k}} e^{\mathrm{i} \vec{k} \cdot \vec{r}}+d_{3, \vec{k}} \vec{e}_{3, \vec{k}} e^{\mathrm{i} \vec{k} \cdot \vec{r}}$
where

$$
\begin{equation*}
\vec{e}_{1, \vec{k}}=\frac{\vec{k}}{k} \quad \vec{e}_{2, \vec{k}} \cdot \vec{k}=\vec{e}_{3, \vec{k}} \cdot \vec{k}=\vec{e}_{2, \vec{k}} \cdot \vec{e}_{3, \vec{k}}=0 \tag{A.144}
\end{equation*}
$$

From those expressions, and the directions of the unit vectors, it can be checked by straight substitution that the "curl" of the longitudinal potential is zero:

$$
\operatorname{curl} \vec{A}_{\|} \equiv \nabla \times \vec{A}_{\|}=0 \quad \text { (irrotational) }
$$

A vector field with zero curl is called "irrotational." (The term can be understood from fluid mechanics; there the curl of the fluid velocity field gives the local average angular velocity of the fluid.)

The same way, it turns out that that the "divergence" of the transverse potential is zero

$$
\operatorname{div} \vec{A}_{\perp} \equiv \nabla \cdot \vec{A}_{\perp}=0 \quad \text { (solenoidal) }
$$

A field with zero divergence is called "solenoidal." (This term can be understood from magnetostatics; a magnetic field, like the one produced by a solenoid, an electromagnet, has zero divergence.)

To be fair, Fermi did not really discover that it can be smart to take vector fields apart into irrotational and solenoidal parts. That is an old trick known as the "Helmholtz decomposition."

Since the transverse potential has no divergence, the longitudinal potential is solely responsible for the Lorenz condition (A.138). The transverse potential can do whatever it wants.

The real problem is therefore with the longitudinal potential $\vec{A}_{\|}$and the electrostatic potential $\varphi$. Bethe [6] deals with these in terms of the Fourier modes. However, that requires some fairly sophisticated analysis. It is actually easier to return to the potentials themselves now.

Reconsider the expressions (A.130) for the electric and magnetic fields in terms of the potentials. They show that the electrostatic potential produces no magnetic field. And neither does the longitudinal potential because it is irrotational.

They do produce a combined electric field $\overrightarrow{\mathcal{E}}_{\varphi \|}$. But this electric field is irrotational, because the longitudinal potential is, and the gradient $\nabla$ of any scalar function is. That helps, because then the Stokes theorem of calculus implies that the electric field $\overrightarrow{\mathcal{E}}_{\varphi| |}$ is minus the gradient of some scalar potential:

$$
\overrightarrow{\mathcal{E}}_{\varphi \|}=-\nabla \varphi_{\mathrm{C}}
$$

Note that normally $\varphi_{\mathrm{C}}$ is not the same as the electrostatic potential $\varphi$, since there is also the longitudinal potential. To keep them apart, $\varphi_{\mathrm{C}}$ will be called the "Coulomb potential."

As far as the divergence of the electric field $\overrightarrow{\mathcal{E}}_{\varphi| |}$ is concerned, it is the same as the divergence of the complete electric field. The reason is that the transverse field has no divergence. And the divergence of the complete electric field is given by Maxwell's first equation. Together these observations give

$$
\overrightarrow{\mathcal{E}}_{\varphi \|}=-\nabla \varphi_{\mathrm{C}} \quad \overrightarrow{\mathcal{B}}_{\varphi \|}=0 \quad \nabla \cdot \overrightarrow{\mathcal{E}}_{\varphi \|}=-\nabla^{2} \varphi_{\mathrm{C}}=\frac{\rho}{\epsilon_{0}}
$$

Note that the final equation is a Poisson equation for the Coulomb potential.
Now suppose that you replaced the electrostatic field $\varphi$ with the Coulomb potential $\varphi_{\mathrm{C}}$ and had no longitudinal field $\vec{A}_{\|}$at all. It would give the same electric and magnetic fields. And they are the only ones that are observable. They give the forces on the particles. The potentials are just mathematical tools in classical electromagnetics.

So why not? To be sure, the combination of the Coulomb potential $\varphi_{\mathrm{C}}$ and remaining vector potential $\vec{A}_{\perp}$ will no longer satisfy the Lorenz condition. But who cares?

Instead of the Lorenz condition, the combination of Coulomb potential plus transverse potential satisfies the so-called "Coulomb condition:"

$$
\begin{equation*}
\nabla \cdot \vec{A}=0 \tag{A.145}
\end{equation*}
$$

The reason is that now $\vec{A}=\vec{A}_{\perp}$ and the transverse vector potential has no divergence. Physicists like to say that the original potentials used the "Lorenz gage," while the new ones use the "Coulomb gage."

Because the potentials $\varphi_{\mathrm{C}}$ and $\vec{A}_{\perp}$ do no longer satisfy the Lorenz condition, the Klein-Gordon equations (A.135) and (A.136) do no longer apply. But the conventional equations (A.140) and (A.141) do still apply; they do not need the Lorenz condition.

Now consider the Coulomb potential somewhat closer. As noted above it satisfies the Poisson equation

$$
-\nabla^{2} \varphi_{\mathrm{C}}=\frac{\rho}{\epsilon_{0}}
$$

The solution to this equation was already found in the first subsection, (A.107). If the charge distribution $\rho$ consists of a total of $I$ point charges, it is

$$
\begin{equation*}
\varphi_{\mathrm{C}}(\vec{r} ; t)=\sum_{i=1}^{I} \frac{q_{i}}{4 \pi \epsilon_{0}\left|\vec{r}-\vec{r}_{i}\right|} \tag{A.146}
\end{equation*}
$$

Here $q_{i}$ is the charge of point charge number $i$, and $\vec{r}_{i}$ its position.
If the charge distribution $\rho$ is smoothly distributed, simply take it apart in small "point charges" $\rho(\underline{r} ; t) \mathrm{d}^{3} \overrightarrow{\underline{r}}$. That gives

$$
\begin{equation*}
\varphi_{\mathrm{C}}(\vec{r} ; t)=\int_{\text {all } \overrightarrow{\underline{r}}} \frac{\rho(\vec{r} ; t)}{4 \pi \epsilon_{0}|\vec{r}-\underline{\vec{r}}|} \mathrm{d}^{3} \underline{\vec{r}} \tag{A.147}
\end{equation*}
$$

The key point to note here is that the Coulomb potential has no life of its own. It is rigidly tied to the positions of the charges. That then provides the most detailed answer to the question: "What happened to energy minimization?" Charged particles have no option of minimizing any energy of interaction with the field. Maxwell's first equation, the Poisson equation above, forces them to create a Coulomb field that is repulsive to them. Whether they like it or not.

Note further that all the mechanics associated with the Coulomb field is quasi-steady. The Poisson equation does not depend on how fast the charged particles evolve. The Coulomb electric field is minus the spatial gradient of the potential, so that does not depend on the speed of evolution either. And the

Coulomb force on the charged particles is merely the electric field times the charge.

It is still not obvious how to quantize the Coulomb potential, even though there is no longer a longitudinal field. But who cares about the Coulomb potential in the first place? The important thing is how the charged particles are affected by it. And the forces on the particles caused by the Coulomb potential can be computed using the electrostatic potential energy, $\{\mathrm{D} .37 .4\}$,

$$
\begin{equation*}
V_{\mathrm{C}}=\frac{1}{2} \sum_{i=1}^{I} \sum_{\substack{i=1 \\ \underline{i} \neq i}}^{I} \frac{q_{i} q_{\underline{i}}}{4 \pi \epsilon_{0}\left|\vec{r}_{i}-\vec{r}_{\underline{i}}\right|} \tag{A.148}
\end{equation*}
$$

For example, this is the Coulomb potential energy that was used to find the energy levels of the hydrogen atom in chapter 4.3. It can still be used in unsteady motion because everything associated with the Coulomb potential is quasi-steady. Sure, it is due to the interaction of the particles with the electromagnetic field. But where in the above mathematical expression does it say electromagnetic field? All it contains are the coordinates of the charged particles. So what difference does it make where the potential energy comes from? Just add the energy above to the Hamiltonian and then pretend that there are no electrostatic and longitudinal fields.

Incidentally, note the required omission of the terms with $\underline{i}=i$ in the potential energy above. Otherwise you would get infinite energy. In fact, a point charge in classical electromagnetics does have infinite Coulomb energy. Just take any of the point charges and mentally chop it up into two equal parts sitting at the same position. The interaction energy between the halves is infinite.

The issue does not exist if the charge is smoothly distributed. In that case the Coulomb potential energy is, $\{D .37 .4\}$,

$$
\begin{equation*}
V_{\mathrm{C}}=\frac{1}{2} \int_{\text {all } \vec{r}} \int_{\text {all }} \frac{\rho(\vec{r} ; t) \rho(\overrightarrow{\underline{r}} ; t)}{4 \pi \epsilon_{0}|\vec{r}-\overrightarrow{\vec{r}}|} \mathrm{d}^{3} \vec{r} \mathrm{~d}^{3} \overrightarrow{\underline{r}} \tag{A.149}
\end{equation*}
$$

While the integrand is infinite at $\overrightarrow{\underline{r}}=\vec{r}$, the integral remains finite.
So the big idea is to throw away the electrostatic and longitudinal potentials and replace them with the Coulomb energy $V_{\mathrm{C}}$, origin unknown. Now it is mainly a matter of working out the details.

First, consider the Fermi Lagrangian. It is found by throwing out the electrostatic and longitudinal potentials from the earlier Lagrangian (A.134) and subtracting $V_{\mathrm{C}}$. That gives, using the point charge approximation (A.133) and in vector notation,

$$
\begin{equation*}
\mathcal{L}_{\mathrm{F}}=\frac{\epsilon_{0}}{2} \int\left[\left|\vec{A}_{\perp_{t}}\right|^{2}-\sum_{\underline{j}=1}^{3} c^{2}\left|\vec{A}_{\perp_{\underline{j}}}\right|^{2}\right] \mathrm{d}^{3} \vec{r}+\sum_{i=1}^{I}\left[q_{i} \vec{v}_{i} \cdot \vec{A}_{\perp_{i}}+\frac{1}{2} m_{i} \vec{v}_{i}^{2}\right]-V_{\mathrm{C}} \tag{A.150}
\end{equation*}
$$

Note that it is now assumed that there are $I$ particles instead of just the single proton in (A.134). Because $i$ is already used to index the particles, $\underline{j}$ is used to index the three directions of spatial differentiation. The Coulomb energy $V_{\mathrm{C}}$ was already given in (A.148). The velocity of particle $i$ is $\vec{v}_{i}$, while $q_{i}$ is its charge and $m_{i}$ its mass. The subscript $i$ on the transverse potential in the interaction term indicates that it is evaluated at the location of particle $i$.

You may wonder how you can achieve that only the transverse potential $\vec{A}_{\perp}$ is left. That would indeed be difficult to do if you work in terms of spatial coordinates. The simplest way to handle it is to work in terms of the transverse waves (A.144). They are transverse by construction.

The unknowns are now no longer the values of the potential at the infinitely many possible positions. Instead the unknowns are now the coefficients $d_{2, \vec{k}}$ and $d_{3, \vec{k}}$ of the transverse waves. Do take into account that since the field is real,

$$
d_{2,-\vec{k}}=d_{2, \vec{k}}^{*} \quad d_{3,-\vec{k}}=d_{3, \vec{k}}^{*}
$$

So the number of independent variables is half of what it seems. The most straightforward way of handling this is to take the unknowns as the real and imaginary parts of the $d_{2, \vec{k}}$ and $d_{3, \vec{k}}$ for half of the $\vec{k}$ values. For example, you could restrict the $\vec{k}$ values to those for which the first nonzero component is positive. The corresponding unknowns must then describe both the $\vec{k}$ and $-\vec{k}$ waves.
(The $\vec{k}=0$ terms are awkward. One way to deal with it is to take an adjacent periodic box and reverse the sign of all the charges and fields in it. Then take the two boxes together to be a new bigger periodic box. The net effect of this is to shift the mesh of $\vec{k}$-values figure 6.17 by half an interval. That means that the $\vec{k}=0$ terms are gone. And other problems that may arise if you sum over all boxes, like to find the total Coulomb potential, are gone too. Since the change in $\vec{k}$ values becomes zero in the limit of infinite box size, all this really amounts to is simply ignoring the $\vec{k}=0$ terms.)

The Hamiltonian can be obtained just like the earlier one (A.137), \{A.1.5\}. (Or make that \{A.1.4\}, since the unknowns, $d_{2, \vec{k}}$ and $d_{3, \vec{k}}$, are now indexed by the discrete values of the wave number $\vec{k}$.) But this time it really needs to be done right, because this Hamiltonian is supposed to be actually used. It is best done in terms of the components of the potential and velocity vectors. Using $j$ to index the components, the Lagrangian becomes
$\mathcal{L}_{\mathrm{F}}=\frac{\epsilon_{0}}{2} \int \sum_{j=1}^{3}\left[\left|A_{\perp j_{t}}\right|^{2}-\sum_{\underline{j}=1}^{3} c^{2}\left|A_{\perp j_{\underline{j}}}\right|^{2}\right] \mathrm{d}^{3} \vec{r}+\sum_{i=1}^{I} \sum_{j=1}^{3}\left[q_{i} v_{i_{j}} A_{\perp j_{i}}+\frac{1}{2} m_{i} v_{i_{j}}^{2}\right]-V_{\mathrm{C}}$
Now Hamiltonians should not be in terms of particle velocities, despite what (A.137) said. Hamiltonians should be in terms of "canonical momenta,"
\{A.1.4\}. The canonical momentum corresponding to the velocity component $v_{i_{j}}$ of a particle $i$ is defined as

$$
p_{i_{j}}^{\mathrm{c}} \equiv \frac{\partial \mathcal{L}}{\partial v_{i_{j}}}
$$

Differentiating the Lagrangian above gives

$$
p_{i_{j}}^{\mathrm{c}}=m_{i} v_{i_{j}}+q_{i} A_{j_{i}}
$$

It is this canonical momentum that in quantum mechanics gets replaced by the operator $\hbar \partial / \mathrm{i} \partial r_{j}$. That is important since, as the above expression shows, canonical momentum is not just linear momentum in the presence of an electromagnetic field.

The time derivatives of the real and imaginary parts of the coefficients $d_{2, \vec{k}}$ and $d_{3, \vec{k}}$ should be replaced by similarly defined canonical momenta. However, that turns out to be a mere rescaling of these time derivatives.

The Hamiltonian then becomes, following \{A.1.4\} and in vector notation,

$$
\begin{align*}
H_{\mathrm{F}}= & \frac{\epsilon_{0}}{2} \int\left[\left|\vec{A}_{\perp_{t}}\right|^{2}+\sum_{\underline{j}=1}^{3} c^{2}\left|\vec{A}_{\perp_{\underline{j}}}\right|^{2}\right] \mathrm{d}^{3} \vec{r} \\
& +\sum_{i=1}^{I} \frac{\left(\vec{p}_{i}^{\mathrm{c}}-q_{i} \vec{A}_{\perp_{i}}\right)^{2}}{2 m_{i}}+\frac{1}{2} \sum_{i=1}^{I} \sum_{\substack{i=1 \\
\underline{i} \neq i}}^{I} \frac{q_{i} q_{\underline{i}}}{4 \pi \epsilon_{0}\left|\vec{r}_{i}-\vec{r}_{\underline{i}}\right|} \tag{A.151}
\end{align*}
$$

Note in particular that the center term is the kinetic energy of the particles, but in terms of their canonical momenta.

In terms of the waves (A.144), the integral falls apart in separate contributions from each $d_{2, \vec{k}}$ and $d_{3, \vec{k}}$ mode. That is a consequence of the orthogonality of the exponentials, compare the Parseval identity in $\{\mathrm{A} .26\}$. (Since the exponentials are complex, the absolute values in the integral are now required.) As a result, the equations for different coefficients are only indirectly coupled by the interaction with the charged particles. In particular, it turns out that each coefficient satisfies its own harmonic oscillator equation with forcing by the charged particles, \{A.1.4\},

$$
\epsilon_{0} \mathcal{V}\left(\ddot{d}_{j, \vec{k}}+k^{2} c^{2} d_{j, \vec{k}}\right)=\sum_{i} q_{i} \vec{v}_{i} \cdot \vec{e}_{j, \vec{k}} e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{i}} \quad \text { for } j=2 \text { and } 3
$$

If the speed of the particle gets comparable to the speed of light, you may want to use the relativistic energy (1.2);

$$
\frac{\left(\vec{p}_{i}^{\mathrm{c}}-q_{i} \vec{A}_{\perp_{i}}\right)^{2}}{2 m_{i}} \Longrightarrow \sqrt{\left(m_{i} c^{2}\right)^{2}+\left(\vec{p}_{i}^{\mathrm{c}}-q_{i} \vec{A}_{\perp_{i}}\right)^{2} c^{2}}
$$

Sometimes, it is convenient to assume that the system under consideration also experiences an external electromagnetic field. For example, you might consider an atom or atomic nucleus in the magnetic field produced by an electromagnet. You probably do not want to include every electron in the wires of the electromagnet in your model. That would be something else. Instead you can simply add the vector potential $\vec{A}_{\text {ext }_{i}}$ that they produce to $\vec{A}_{\perp_{i}}$ in the Hamiltonian. If there is also an external electrostatic potential, add a separate term $q_{i} \varphi_{\text {ext }}$ to the Hamiltonian for each particle $i$. The external fields will be solutions of the homogeneous evolution equations (A.140) and (A.141), (i.e. the equations without charge and current densities). However, the external fields will not vanish at infinity; that is why they can be nonzero without charge and current densities.

Note that the entire external vector potential is needed, not just the transverse part. The longitudinal part is not included in $V_{\mathrm{C}}$. Bethe [6, p. 266] also notes that the external field should satisfy the Lorenz condition. No further details are given. However, at least in various simple cases, a gage transform that kills off the Lorenz condition may be applied. See for example the gage property for a pure external field $\{$ A.19.5\}. In the classical case a gage transform of the external fields does not make a difference either, because it does not change either the Lagrangian equations for the transverse field nor those for the particles. Using the Lorenz condition cannot hurt, anyway.

Particle spin, if any, is not included in the above Hamiltonian. At nonrelativistic speeds, its energy can be described as a dot produce with the local magnetic field, chapter 13.4.

So far all this was classical electrodynamics. But the interaction between the charges and the transverse waves can readily be quantized using essentially the same procedure as used for the Koulomb potential in subsection A.22.3. The details are worked out in addendum $\{\mathrm{A} .23\}$ for the fields. It allows a relativistic description of the emission of electromagnetic radiation by atoms and nuclei, $\{\mathrm{A} .24\}$ and $\{\mathrm{A} .25\}$.

While the transverse field must be quantized, the Coulomb potential can be taken unchanged into quantum mechanics. That was done, for example, for the nonrelativistic hydrogen atom in chapter 4.3 and for the relativistic one in addendum $\{\mathrm{D} .81\}$.

Finally, any external fields are assumed to be given; they are not quantized either.

Note that the Fermi quantization is not fully relativistic. In a fully relativistic theory, the particles too should be described by quantum fields. The Fermi quantization does not do that. So even the relativistic hydrogen atom is not quite exact, even though it is orders of magnitude more accurate than the already very accurate nonrelativistic one. The energy levels are still wrong by the so-called "Lamb shift," \{A.39\} But this is an extremely tiny effect. Little in life is perfect, isn't it?

## A.22.9 The Coulomb potential and the speed of light

The Coulomb potential

$$
\varphi_{\mathrm{C}}(\vec{r} ; t)=\sum_{i=1}^{I} \frac{q_{i}}{4 \pi \epsilon_{0}\left|\vec{r}-\vec{r}_{i}\right|}
$$

does not respect the speed of light $c$. Move a charge, and the Coulomb potential immediately changes everywhere in space. However, special relativity says that an event may not affect events elsewhere unless these events are reachable by the speed of light. Something else must prevent the use of the Coulomb potential to transmit observable effects at a speed greater than that of light.

To understand what is going on, assume that at time zero some charges at the origin are given a well-deserved kick. As mentioned earlier, the KleinGordon equations respect the speed of light. Therefore the original potentials $\varphi$ and $\vec{A}$, the ones that satisfied the Klein-Gordon equations and Lorenz condition, are unaffected by the kick beyond a distance ct from the origin. The original potentials do respect the speed of light.

The Coulomb potential above, however, includes the longitudinal part $\vec{A}_{\|}$ of the vector potential $\vec{A}$. As the Coulomb potential reflects, $\vec{A}_{\|}$does change immediately all the way up to infinity. But the transverse part $\vec{A}_{\perp}$ also changes immediately all the way up to infinity. Beyond the limit dictated by the speed of light, the two parts of the potential exactly cancel each other. As a result, beyond the speed of light limit, the net vector potential $\vec{A}$ does not change.

The bottom line is
The mathematics of the Helmholtz decomposition of $\vec{A}$ into $\vec{A}_{\|}$and $\vec{A}_{\perp}$ hides, but of course does not change, the limitation imposed by the speed of light.

The limitation is still there, it is just much more difficult to see. The change in current density $\vec{\jmath}$ caused by kicking the charges near the origin is restricted to the immediate vicinity of the origin. But both the longitudinal part $\vec{\jmath}_{\|}$and the transverse part $\vec{\jmath}_{\perp}$ extend all the way to infinity. And then so do the longitudinal and transverse potentials. It is only when you add the two that you see that the sum is zero beyond the speed of light limit.

## A. 23 Quantization of radiation

Long ago, the electromagnetic field was described in terms of classical physics by Maxwell, chapter 13. His equations have stood up well to special relativity. However, they need correction for quantum mechanics. According to the PlanckEinstein relation, the electromagnetic field comes in discrete particles of energy
$\hbar \omega$ called photons. A classical electromagnetic field cannot explain that. This addendum will derive the quantum field in empty space. While the description tries to be reasonably self-contained, to really appreciate the details you may have to read some other addenda too. It may also be noted that the discussion here is quite different from what you will find in other sources, $\{\mathrm{N} .12\}$.

First, representing the electromagnetic field using the photons of quantum mechanics is called "second quantization." No, there is no earlier quantization of the electromagnetic field involved. The word "second" is there for historical reasons. Historically, physicists have found it hysterical to confuse students.

In the quantum description, the electromagnetic field is an observable property of photons. And the key assumption of quantum mechanics is that observable properties of particles are the eigenvalues of Hermitian operators, chapter 3. Furthermore, these operators act on wave functions that are associated with the particles.

Therefore, second quantization is basically straightforward. Find the nature of the wave function of photons. Then identify the Hermitian operators that give the observable electromagnetic field.

However, to achieve this in a reasonable manner requires a bit of preparation. To understand photon wave functions, an understanding of a few key concepts of classical electromagnetics is essential. And the Hermitian operators that act on these wave functions are quite different from the typical operators normally used in this book. In particular, they involve operators that create and annihilate photons. Creation and annihilation of particles is a purely relativistic effect, described by so-called quantum field theory.

Also, after the field has been quantized, then of course you want to see what the effects of the quantization really are, in terms of observable quantities.

## A.23.1 Properties of classical electromagnetic fields

Classical electromagnetics is discussed in considerable detail in chapter 13.2 and 13.3. Here only a few selected results are needed.

The classical electromagnetic field is a combination of a so-called electric field $\overrightarrow{\mathcal{E}}$ and a magnetic field $\overrightarrow{\mathcal{B}}$. These are measures for the forces that the field exerts on any charged particles inside the field. The classical expression for the force on a charged particle is the so-called Lorentz force law

$$
q(\overrightarrow{\mathcal{E}}+\vec{v} \times \overrightarrow{\mathcal{B}})
$$

where $q$ is the charge of the particle and $\vec{v}$ its velocity. However, this is not really important here since quantum mechanics uses neither forces nor velocities.

What is important is that electromagnetic fields carry energy. That is how the sun heats up the surface of the earth. The electromagnetic energy in a
volume $\mathcal{V}$ is given by, chapter 13.2 (13.11):

$$
\begin{equation*}
E_{\mathcal{V}}=\frac{1}{2} \epsilon_{0} \int_{\mathcal{V}}\left(\overrightarrow{\mathcal{E}}^{2}+c^{2} \overrightarrow{\mathcal{B}}^{2}\right) \mathrm{d}^{3} \vec{r} \tag{A.152}
\end{equation*}
$$

where $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is called the permittivity of space and $c=310^{8}$ $\mathrm{m} / \mathrm{s}$ the speed of light. As you might guess, the energy per unit volume is proportional to the square fields. After all, no fields, no energy; also the energy should always be positive. The presence of the permittivity of space is needed to get proper units of energy. The additional factor $\frac{1}{2}$ is not so trivial; it is typically derived from examining the energy stored inside condensers and coils. That sort of detail is outside the scope of this book.

Quantum mechanics is in terms of potentials instead of forces. As already noted in chapter 1.3.2, in classical electromagnetics there is both a scalar potential $\varphi$ as well as a vector potential $\vec{A}$. In classical electromagnetics these potentials by themselves are not really important. What is important is that their derivatives give the fields. Specifically:

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=-\nabla \varphi-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A} \tag{A.153}
\end{equation*}
$$

Here the operator

$$
\nabla=\hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

is called nabla or del. As an example, for the $z$ components of the fields:

$$
\mathcal{E}_{z}=-\frac{\partial \varphi}{\partial z}-\frac{\partial A_{z}}{\partial t} \quad \mathcal{B}_{z}=\frac{\partial A_{y}}{\partial x}-\frac{\partial A_{x}}{\partial y}
$$

Quantum mechanics is all about the potentials. But the potentials are not unique. In particular, for any arbitrary function $\chi$ of position and time, you can find two different potentials $\varphi^{\prime}$ and $\vec{A}^{\prime}$ that produce the exact same electric and magnetic fields as $\varphi$ and $\vec{A}$. These potentials are given by

$$
\begin{equation*}
\varphi^{\prime}=\varphi-\frac{\partial \chi}{\partial t} \quad \vec{A}^{\prime}=\vec{A}+\nabla \chi \tag{A.154}
\end{equation*}
$$

(To check that the fields for these potentials are indeed the same, note that $\nabla \times$ $\nabla \chi$ is zero for any function $\chi$.) This indeterminacy in potentials is the famous "gauge property" of the electromagnetic field. The arbitrary function $\chi$ is the "gauge function."

Classical relativistic mechanics likes to combine the four scalar potentials in a four-dimensional vector, or four-vector, chapter 1.3.2:

$$
\overleftrightarrow{A}=\binom{\varphi / c}{\vec{A}}=\left(\begin{array}{c}
\varphi / c \\
A_{x} \\
A_{y} \\
A_{z}
\end{array}\right)
$$

## A.23.2 Photon wave functions

The wave function of photons was discussed in addendum \{A.21\}. A summary of the key results will be given here.

Superficially, the photon wave function $\overleftrightarrow{A}_{\gamma}$ takes the same form as an electromagnetic potential four-vector like in the previous subsection. However, where classical potentials are real, the photon wave function is in general complex. And unlike physical potentials, the derivatives of the photon wave function are not physically observable.

Furthermore, to use the photon wave function in an reasonably efficient manner, it is essential to simplify it. The gauge property of the previous subsection implies that the wave function is not unique. So among all the possible alternatives, it is smart to select the simplest. And in empty space, as discussed here, the simplest photon wave function is of the form:

$$
\vec{A}_{\gamma}=\binom{0}{\vec{A}_{\gamma}} \quad \nabla \cdot \vec{A}_{\gamma}=0
$$

The gauge function corresponding to this wave function is called the CoulombLorenz gauge. Seen from a moving coordinate system, this form of the wave function gets messed up, so do not do that.

The real interest is in quantum states of definite energy. Now for a nonrelativistic particle, wave functions with definite energy must be eigenfunctions of the so-called Hamiltonian eigenvalue problem. That eigenvalue problem is also known as the time-independent Schrödinger equation. However, a relativistic particle of zero rest mass like the photon must satisfy a different eigenvalue problem, \{A.21\}:

$$
\begin{equation*}
-\nabla^{2} \vec{A}_{\gamma}^{e}=k^{2} \vec{A}_{\gamma}^{e} \quad k \equiv \frac{E}{\hbar c}=\frac{p}{\hbar} \quad E=\hbar \omega \quad p=\hbar k \tag{A.155}
\end{equation*}
$$

Here $\vec{A}_{\gamma}^{e}$ is the energy eigenfunction. Further $p$ is the magnitude of the linear momentum of the photon. The second-last equation is the so-called PlanckEinstein relation that gives the photon energy $E$ in terms of its frequency $\omega$, while the last equation is the de Broglie relation that gives the photon momentum $p$ in terms of its wave number $k$. The relation between frequency and wave number is $\omega=k c$ with $c$ the speed of light.

The simplest energy eigenfunctions are those that have definite linear momentum. A typical example of such an energy eigenfunction is

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{e}}=\hat{k} e^{\mathrm{i} k y} \tag{A.156}
\end{equation*}
$$

This wave function has definite linear momentum $\hat{j} \hbar k$, as you can see from applying the components of the linear momentum operator $\hbar \nabla / \mathrm{i}$ on it. And it is an energy eigenfunction, as you can verify by substitution in (A.155). Further,
since the wave function vector is in the $z$-direction, it is called linearly polarized in the $z$-direction.

Now the photon wave function $\overleftrightarrow{A}_{\gamma}$ is not a classical electromagnetic potential. The "electric and magnetic fields" $\overrightarrow{\mathcal{E}}_{\gamma}$ and $\overrightarrow{\mathcal{B}}_{\gamma}$ that you would find by using the classical expressions (A.153) are not physically observable quantities. So they do not have to obey the classical expression (A.152) for the energy in an electromagnetic field.

However, you make life a lot simpler for yourself if you normalize the photon wave functions so that they do satisfy it. That produces a normalized wave function and corresponding unobservable fields of the form, $\{\mathrm{A} .21\}$ :

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \vec{A}_{\gamma}^{\mathrm{e}} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \vec{A}_{\gamma}^{\mathrm{e}} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k} \nabla \times \vec{A}_{\gamma}^{\mathrm{e}} \tag{A.157}
\end{equation*}
$$

where the constant $\varepsilon_{k}$ is found by substitution into the normalization condition:

$$
\begin{equation*}
\frac{1}{2} \epsilon_{0} \int_{\text {all }}\left(\left|\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right|^{2}+c^{2}\left|\overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}\right|^{2}\right) \mathrm{d}^{3} \vec{r}=\hbar \omega \tag{A.158}
\end{equation*}
$$

Consider how this works out for the example eigenfunction of definite linear momentum mentioned above. That eigenfunction cannot be normalized in infinite space since it does not go to zero at large distances. To normalize it, you have to assume that the electromagnetic field is confined to a big periodic box of volume $\mathcal{V}$. In that case the normalized eigenfunction and unobservable fields become:

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \hat{k} e^{\mathrm{i} k y} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \hat{k} e^{\mathrm{i} k y} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \hat{\imath} e^{\mathrm{i} k y} \quad \varepsilon_{k}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}} \tag{A.159}
\end{equation*}
$$

Another interesting example is given in \{A.21.6\}. It is a photon state with definite angular momentum $\hbar$ in the direction of motion. Such a photon state is called right-circularly polarized. In this example the linear momentum is taken to be in the $z$-direction, rather than the $y$-direction. The normalized wave function and unobservable fields are:

$$
\begin{equation*}
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \frac{\hat{\imath}+\mathrm{i} \hat{\jmath}}{\sqrt{2}} e^{\mathrm{i} k z} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \frac{\hat{\imath}+\mathrm{i} \hat{\jmath}}{\sqrt{2}} e^{\mathrm{i} k z} \quad c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \frac{-\mathrm{i} \hat{\imath}+\hat{\jmath}}{\sqrt{2}} e^{\mathrm{i} k z} \quad \varepsilon_{k}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}} \tag{A.160}
\end{equation*}
$$

It will be interesting to see what the observable fields for this photon state look like.

## A.23.3 The electromagnetic operators

The previous subsection has identified the form of the wave function of a photon in an energy eigenstate. The next step is to identify the Hamiltonian operators of the observable electric and magnetic fields.

But first there is a problem. If you have exactly one photon, the wave functions as discussed in the previous subsection would do just fine. If you had exactly two photons, you could readily write a wave function for them too. But a state with an exact number $i$ of photons is an energy eigenstate. It has energy $i \hbar \omega$, taking the zero of energy as the state of no photons. Energy eigenstates are stationary, chapter 7.1.4. They never change. All the interesting mechanics in nature is due to uncertainty in energy. As far as photons are concerned, that requires uncertainty in the number of photons. And there is no way to write a wave function for an uncertain number of particles in classical quantum mechanics. The mathematical machinery is simply not up to it.

The mathematics of quantum field theory is needed, as discussed in addendum \{A.15\}. The key concepts will be briefly summarized here. The mathematics starts with Fock space kets. Consider a single energy eigenfunction for photons, like one of the examples given in the previous subsection. The Fock space ket

$$
|i\rangle
$$

indicates the wave function if there are exactly $i$ photons in the considered energy eigenfunction. The number $i$ is called the occupation number of the state. (If more than one photon state is of interest, an occupation number is added to the ket for each state. However, the discussion here will stay restricted to a single state.)

The Fock space ket formalism allows wave functions to be written for any number of particles in the state. And by taking linear combinations of kets with different occupation numbers, uncertainty in the number of photons can be described. So uncertainty in energy can be described.

Kets are taken to be orthonormal. The inner product $\left\langle i_{1} \mid i_{2}\right\rangle$ of two kets with different occupation numbers $i_{1}$ and $i_{2}$ is zero. The inner product of a ket with itself is taken to be one. That is exactly the same as for energy eigenfunctions in classical quantum mechanics,

Next, it turns out that operators that act on photon wave functions are intrinsically linked to operators that annihilate and create photons. Mathematically, at least. These operators are defined by the relations

$$
\begin{equation*}
\widehat{a}|i\rangle=\sqrt{i}|i-1\rangle \quad \widehat{a}^{\dagger}|i-1\rangle=\sqrt{i}|i\rangle \tag{A.161}
\end{equation*}
$$

for any number of photons $i$. In words, the annihilation operator $\widehat{a}$ takes a state of $i$ photons and turns it into a state with one less photon. The creation operator $\widehat{a}^{\dagger}$ puts the photon back in. The scalar factors $\sqrt{i}$ are a matter of convenience. If you did not put them in here, you would have to do it elsewhere.

At first it may seem just weird that there are physical operators like that. But a bit more thought may make it more plausible. First of all, nature pretty much forces the Fock space kets on us. Classical quantum mechanics would like to number particles such as photons just like classical physics likes to do: photon

1 , photon $2, \ldots$ But nature makes a farce out of that with the symmetrization requirement. It allows absolutely no difference in the way one photon occupies a state compared to another one. Indeed, nature goes to such a length of preventing us to, God forbid, make a distinction between one photon and another that she puts every single photon in the universe partly in every single microscopic photon state on earth. Now Fock space kets are the only way to express how many photons are in a given state without saying which photons. And if the symbols of nature are then apparently Fock space kets, the operators of nature are pretty unavoidably annihilation and creation operators. There is not much else you can do with Fock space kets than change the number of particles.

The annihilation and creation operators are not Hermitian. They cannot be taken unchanged to the other side of an inner product of kets. However, they are Hermitian conjugates: they change into each other when taken to the other side of an inner product:
$\left.\left.\left.\left.\left.\left.\left.\left.\left\langle\mid i_{2}\right\rangle|\widehat{a}| i_{1}\right\rangle\right\rangle=\left\langle\widehat{a}^{\dagger} \mid i_{2}\right\rangle| | i_{1}\right\rangle\right\rangle \equiv\left\langle i_{2}\right| \widehat{a}\left|i_{1}\right\rangle \quad\left\langle\mid i_{1}\right\rangle\left|\widehat{a}^{\dagger}\right| i_{2}\right\rangle\right\rangle=\left\langle\widehat{a} \mid i_{1}\right\rangle| | i_{2}\right\rangle\right\rangle \equiv\left\langle i_{1}\right| \widehat{a}^{\dagger}\left|i_{2}\right\rangle$
To see this, note that the inner products are only nonzero if $i_{2}=i_{1}-1$ because of the orthogonality of kets with different numbers of photons. And if $i_{2}=$ $i_{1}-1$, then (A.161) shows that all four inner products above equal $\sqrt{i_{1}}$.

That is important because it shows that Hermitian operators can be formed from combinations of the two operators. For example, $\widehat{a}+\widehat{a}^{\dagger}$ is a Hermitian operator. Each of the two operators changes into the other when taken to the other side of an inner product. So the sum stays unchanged. More generally, if $c$ is any real or complex number, $\widehat{a} c+\widehat{a}^{\dagger} c^{*}$ is Hermitian.

And that then is the basic recipe for finding the operators of the observable electric and magnetic fields. Take $\widehat{a}$ times the unobservable field of the normalized photon state, (A.157) with (A.158) and (A.155). Add the Hermitian conjugate of that. And put in the usual $1 / \sqrt{2}$ factor of quantum mechanics for averaging states. In total

$$
\begin{equation*}
\widehat{\hat{\mathcal{E}}}=\frac{1}{\sqrt{2}}\left(\widehat{a} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}+\widehat{a}^{\dagger} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n} *}\right) \quad \widehat{\overrightarrow{\mathcal{B}}}=\frac{1}{\sqrt{2}}\left(\widehat{a} \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}+\widehat{a}^{\dagger} \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n} *}\right) \tag{A.162}
\end{equation*}
$$

You might wonder why there are two terms in the operators, one with a complex conjugate wave function. Mathematically that is definitely needed to get Hermitian operators. That in turn is needed to get real observed fields. But what does it mean physically? One way of thinking about it is that the observed field is real because it does not just involve an interaction with an $e^{\mathrm{i}(\vec{k} \cdot \vec{r}-\omega t)}$ photon, but also with an $e^{-\mathrm{i}(\vec{k} \cdot \vec{r}-\omega t)}$ antiphoton.

Of course, just because the above operators are Hermitian does not prove that they are the right ones for the observable electric and magnetic fields. Unfortunately, there is no straightforward way to deduce quantum mechanics
operators from mere knowledge of the classical approximation. Vice-versa is not a problem: given the operators, it is fairly straightforward to deduce the corresponding classical equations for a macroscopic system. It is much like at the start of this book, where it was postulated that the momentum of a particle corresponds to the operator $\hbar \partial / \mathrm{i} \partial x$. That was a leap of faith. However, it was eventually seen that it did produce the correct classical momentum for macroscopic systems, chapter 7.2.1 and 7.10, as well as correct quantum results like the energy levels of the hydrogen atom, chapter 4.3. A similar leap of faith will be needed to quantize the electromagnetic field.

## A.23.4 Properties of the observable electromagnetic field

The previous subsection postulated the operators (A.162) for the observable electric and magnetic fields. This subsection will examine the consequences of these operators, in order to gain confidence in them. And to learn something about the effects of quantization of the electromagnetic field.

Consider first a simple wave function where there are exactly $i$ photons in the considered photon state. In terms of Fock space kets, the wave function is then:

$$
\Psi=c_{i} e^{-\mathrm{i} i \omega t}|i\rangle
$$

where $c_{i}$ is a constant with magnitude 1. This follows the Schrödinger rule that the time dependence in a wave function of definite energy $E$ is given by $e^{-\mathrm{i} E t / \hbar}$, with in this case $E=i \hbar \omega$.

The expectation value of the electric field at a given position and time is then by definition

$$
\left.\langle\overrightarrow{\mathcal{E}}\rangle=\langle\Psi \mid \widehat{\mathcal{E}} \Psi\rangle=\frac{1}{\sqrt{2}}\langle i| e^{\mathrm{i} \omega t} c_{i}^{*}\left|\left(\widehat{a}_{\gamma}^{\mathrm{n}}+\widehat{a}^{\dagger} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n} *}\right) c_{i} e^{-\mathrm{i} i \omega t}\right| i\right\rangle
$$

That is zero because $\widehat{a}$ and $\widehat{a}^{\dagger}$ turn the right hand ket into $|i-1\rangle$ respectively $|i+1\rangle$. These are orthogonal to the left hand $\langle i|$. The same way, the expectation magnetic field will be zero too.

## Oops.

Zero electric and magnetic fields were not exactly expected if there is a nonzero number of photons present.

No panic please. This is an energy eigenstate. Often these do not resemble classical physics at all. Think of a hydrogen atom in its ground state. The expectation value of the linear momentum of the electron is zero in that state. That is just like the electric and magnetic fields are zero here. But the expectation value of the square momentum of the hydrogen electron is not zero. In fact, that gives the nonzero expectation value of the kinetic energy of the electron, 13.6 eV . So maybe the square fields need to be examined here.

Come to think of it, the first thing to check should obviously have been the energy. It better be $i \hbar \omega$ for $i$ photons. Following the Newtonian analogy for the classical energy integral (A.152), the Hamiltonian should be

$$
H=\frac{1}{2} \epsilon_{0} \int_{\text {all }}\left(\widehat{\overrightarrow{\mathcal{E}}}^{2}+c^{2}{\widehat{\mathcal{B}^{2}}}^{2}\right) \mathrm{d}^{3} \vec{r}
$$

This can be greatly simplified by plugging in the given expressions for the operators and identifying the integrals, $\{$ D. 40$\}$ :

$$
\begin{equation*}
H=\frac{1}{2} \hbar \omega\left(\widehat{a}^{\dagger} \widehat{a}+\widehat{a} \widehat{a}^{\dagger}\right) \tag{A.163}
\end{equation*}
$$

Now apply this Hamiltonian on a state with $i$ photons. First, using the definitions (A.161) of the annihilation and creation operators

$$
\widehat{a}^{\dagger} \widehat{a}|i\rangle=\widehat{a}^{\dagger}(\sqrt{i}|i-1\rangle)=i|i\rangle \quad \widehat{a} \widehat{a}^{\dagger}|i\rangle=\widehat{a}(\sqrt{i+1}|i+1\rangle)=(i+1)|i\rangle
$$

This shows that the operators $\widehat{a}$ and $\widehat{a}^{\dagger}$ do not commute; their order makes a difference. In particular, according to the above their commutator equals

$$
\begin{equation*}
\left[\widehat{a}, \widehat{a}^{\dagger}\right] \equiv \widehat{a} \widehat{a}^{\dagger}-\widehat{a}^{\dagger} \widehat{a}=1 \tag{A.164}
\end{equation*}
$$

Anyway, using the above relations the expression for the Hamiltonian applied on a Fock space ket becomes

$$
H|i\rangle=\hbar \omega\left(i+\frac{1}{2}\right)|i\rangle
$$

The factor in front of the final ket is the energy eigenvalue. It is more or less like expected, which was $i \hbar \omega$ for $i$ photons. But there is another one-half photon worth of energy.

That, however, may be correct. It closely resembles what happened for the harmonic oscillator, chapter 4.1. Apparently the energy in the electromagnetic field is never zero, just like a harmonic oscillator is never at rest. The energy increases by $\hbar \omega$ for each additional photon as it should.

Actually, the half photon "vacuum energy" is somewhat of a problem. If you start summing these half photons over all infinitely many frequencies, you end up, of course, with infinity. Now the ground state energy does not affect the dynamics. But if you do "measurements" of the electric or magnetic fields in vacuum, you will get nonzero values. So apparently there is real energy there. Presumably that should affect gravity. Maybe the effect would not be infinite, if you cut off the sum at frequencies at which quantum mechanics might fail, but it should certainly be extremely dramatic. So why is it not observed? The answer is unknown. See chapter 8.7 for one suggestion.

The vacuum energy also has consequences if you place two conducting plates extremely closely together. The conducting plates restrict the vacuum field
between the plates. (Or at least the relatively low energy part of it. Beyond say the X-ray range photons will not notice the plates.) Because of the restriction of the plates, you would expect the vacuum energy to be less than expected. Because of energy conservation, that must mean that there is an attractive force between the plates. That is the so-called "Casimir force." This weird force has actually been measured experimentally. Once again it is seen that the half photon of vacuum energy in each state is not just a mathematical artifact.

Because of the infinite energy, some authors describe the vacuum as a "seething cauldron" of electromagnetic waves. These authors may not be aware that the vacuum state, being a ground state, is stationary. Or they may not have access to a dictionary of the English language.

The next test of the field operators is to reconsider the expectation electric field when there is uncertainty in energy. Also remember to add another half photon of energy now. Then the general wave function takes the form:

$$
\Psi=\sum_{i} c_{i} e^{-\mathrm{i}\left(i+\frac{1}{2}\right) \omega t}|i\rangle
$$

The expectation value of the electric field follows as

$$
\left.\langle\overrightarrow{\mathcal{E}}\rangle=\sum_{i} \sum_{j} \frac{1}{\sqrt{2}}\langle i| \mathrm{e}^{\mathrm{i}\left(i+\frac{1}{2}\right) \omega t} c_{i}^{*}\left|\left(\widehat{a} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}+\widehat{a} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n} *}\right) c_{j} e^{-\mathrm{i}\left(j+\frac{1}{2}\right) \omega t}\right| j\right\rangle
$$

Using the definitions of the annihilation and creation operators and the orthonormality of the kets, this can be worked out further to

$$
\begin{equation*}
\langle\overrightarrow{\mathcal{E}}\rangle=C e^{-\mathrm{i} \omega t} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}+C^{*} e^{\mathrm{i} \omega t} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n} *} \quad C \equiv \frac{1}{\sqrt{2}} \sum_{i} c_{i-1}^{*} c_{i} \sqrt{i} \tag{A.165}
\end{equation*}
$$

Well, the field is no longer zero. Note that the first term in the electric field is more or less what you would expect from the unobservable field of a single photon. But the observable field adds the complex conjugate. That makes the observable field real.

The properties of the observable fields can now be determined. For example, consider the photon wave function (A.159) given earlier. This wave function had its linear momentum in the $y$-direction. It was "linearly polarized" in the $z$ direction. According to the above expression, the observable electric field is:

$$
\langle\overrightarrow{\mathcal{E}}\rangle=\hat{k} \varepsilon_{k}\left(C e^{\mathrm{i}(k y-\omega t)}+C^{*} e^{-\mathrm{i}(k y-\omega t)}\right)
$$

The first term is roughly what you would want to write down for the unobservable electric field of a single photon. The second term, however, is the complex conjugate of that. It makes the observable field real. Writing $C$ in the form $|C| e^{\mathrm{i} \alpha}$ and using the Euler formula 2.5 to clean up gives:

$$
\langle\overrightarrow{\mathcal{E}}\rangle=\hat{k} 2 \varepsilon_{k}|C| \cos (k y-\omega t+\alpha)
$$

That is a real electromagnetic wave. It is still polarized in the $z$-direction, and it travels in the $y$-direction.

The corresponding magnetic field goes exactly the same way. The only difference in (A.159) is that $\hat{k}$ gets replaced by $\hat{\imath}$. Therefore

$$
\langle c \overrightarrow{\mathcal{B}}\rangle=\hat{\imath} 2 \varepsilon_{k}|C| \cos (k y-\omega t+\alpha)
$$

Note that like for the photon wave function, the observable fields are normal to the direction of wave propagation, and to each other.

As another example, consider the "circularly polarized" photon wave function (A.160). This wave function had its linear momentum in the $z$-direction, and it had definite angular momentum $\hbar$ around the $z$-axis. Here the observable fields are found to be

$$
\begin{aligned}
& \langle\overrightarrow{\mathcal{E}}\rangle=\sqrt{2} \varepsilon_{k}|C|[\hat{\imath} \cos (k z-\omega t+\alpha)-\hat{\jmath} \sin (k z-\omega t+\alpha)] \\
& \langle c \overrightarrow{\mathcal{B}}\rangle=\sqrt{2} \varepsilon_{k}|C|[\hat{\imath} \sin (k z-\omega t+\alpha)+\hat{\jmath} \cos (k z-\omega t+\alpha)]
\end{aligned}
$$

Like for linearly polarized light, the electric and magnetic fields are normal to the direction of wave propagation and to each other. But here the electric and magnetic field vectors rotate around in a circle when seen at a fixed position $z$. Seen at a fixed time, the end points of the electric vectors that start from the $z$-axis form a helix. And so do the magnetic ones.

The final question is under what conditions you would get a classical electromagnetic field with relatively little quantum uncertainty. To answer that, first note that the square quantum uncertainty is given by

$$
\sigma_{\overline{\mathcal{E}}}{ }^{2}=\left\langle\overrightarrow{\mathcal{E}}^{2}\right\rangle-\langle\overrightarrow{\mathcal{E}}\rangle^{2}
$$

(This is the square of chapter 4.4.3 (4.44) multiplied out and identified.)
To evaluate this uncertainty requires the expectation value of the square electric field. That can be found much like the expectation value (A.165) of the electric field itself. The answer is

$$
\left\langle\overrightarrow{\mathcal{E}}^{2}\right\rangle=2 D_{0}\left|\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right|^{2}+D_{1} e^{-2 i \omega t}\left(\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right)^{2}+D_{1}^{*} e^{2 \mathrm{i} \omega t}\left(\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n} *}\right)^{2}
$$

where

$$
D_{0} \equiv \frac{1}{2} \sum_{i}\left|c_{i}\right|^{2}\left(i+\frac{1}{2}\right) \quad D_{1} \equiv \frac{1}{2} \sum_{i} c_{i-1}^{*} c_{i+1} \sqrt{i} \sqrt{i+1}
$$

Note that when this is substituted into the integral (A.152) for the energy, the $D_{0}$ term gives half the expectation value of the energy. In particular, the coefficient $D_{0}$ itself is half the expectation value of the $i+\frac{1}{2}$ number of photons of energy. The other half comes from the corresponding term in the magnetic field. The $D_{1}$ terms above integrate away against the corresponding terms in the magnetic field, $\{\mathrm{D} .40\}$.

To determine the uncertainty in the electric field, it is convenient to write the expectation square electric field above in real form. To do so, the coefficient $D_{1}$ is written in the form $\left|D_{1}\right| e^{2 i \beta}$. Also, the square unobservable electric field $\left(\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right)^{2}$ is written in the form $\left|\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right|^{2} e^{2 \mathrm{i} \gamma}$. Here $\gamma$ will normally depend on position; for example $\gamma=k y$ for the given example of linearly polarized light.

Then the expectation square electric field becomes, using the Euler formula (2.5) and some trig,

$$
\left\langle\overrightarrow{\mathcal{E}}^{2}\right\rangle=2\left(D_{0}-\left|D_{1}\right|\right)\left|\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right|^{2}+4\left|D_{1}\right|\left|\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right|^{2} \cos ^{2}(\gamma-\omega t+\beta)
$$

with $D_{0}$ and $D_{1}=\left|D_{1}\right| e^{2 i \beta}$ as given above. Similarly the square of the expectation electric field, as given earlier in (A.165), can be written as

$$
\langle\overrightarrow{\mathcal{E}}\rangle^{2}=4|C|^{2}\left|\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right|^{2} \cos ^{2}(\gamma-\omega t+\alpha) \quad C=|C| e^{\mathrm{i} \alpha}=\frac{1}{\sqrt{2}} \sum_{i} c_{i-1}^{*} c_{i} \sqrt{i}
$$

For a field without quantum uncertainty, $\left\langle\overrightarrow{\mathcal{E}}^{2}\right\rangle$ and $\langle\overrightarrow{\mathcal{E}}\rangle^{2}$ as given above must be equal. Note that first of all this requires that $\left|D_{1}\right|=D_{0}$, because otherwise $\left\langle\overrightarrow{\mathcal{E}}^{2}\right\rangle$ does not become zero periodically like $\langle\overrightarrow{\mathcal{E}}\rangle^{2}$ does. Also $\beta$ will have to be $\alpha$, up to a whole multiple of $\pi$, otherwise the zeros are not at the same times. Finally, $|C|$ will have to be equal to $D_{0}$ too, or the amplitudes will not be the same.

However, regardless of uncertainty, the coefficients must always satisfy

$$
\left|D_{1}\right| \leqslant D_{0} \quad|C|^{2} \leqslant \frac{1}{2}\left(D_{0}+\left|D_{1}\right|\right)
$$

The first inequality applies because otherwise $\left\langle\overrightarrow{\mathcal{E}}^{2}\right\rangle$ would become negative whenever the cosine is zero. The second applies because $\langle\overrightarrow{\mathcal{E}}\rangle^{2}$ cannot be larger than $\left\langle\overrightarrow{\mathcal{E}}^{2}\right\rangle$; the square uncertainty cannot be negative. For quantum certainty then, the above relations must become equalities. However, a careful analysis shows that they cannot become equalities, $\{\mathrm{D} .40\}$.

So there is always some quantum uncertainty left. Maximum uncertainty occurs when the number of photons has a definite value. Then $D_{1}=C=0$.

If there is always at least some uncertainty, the real question is under what conditions it is relatively small. Analysis shows that the uncertainty in the fields is small under the following conditions, $\{\mathrm{D} .40\}$ :

- The expectation value of the number of photons $\langle i\rangle$ is large enough.
- Nonnegligible coefficients $c_{i}$ are limited to a relatively small range around $i=\langle i\rangle$. However, that range must still contain a relatively large number of coefficients.
- The coefficients for successive values of $i$ are different by a factor that is approximately equal to $e^{\mathrm{i} \alpha}$.

In that case classical electric and magnetic field result with little quantum uncertainty. Note that the above conditions apply for photons restricted to a single quantum state. In a real electromagnetic field, many quantum states would be occupied and things would be much messier still.

It may also be noted that the above conditions bear a striking resemblance to the conditions that produce a particle with a fairly coherent position and momentum in classical quantum mechanics, chapter 7.10.

## A. 24 Quantum spontaneous emission

Chapter 7.8 explained the general interaction between atoms and electromagnetic fields. However, spontaneous emission of radiation was found using a dirty trick due to Einstein. He peeked at the solution for blackbody radiation. This addendum will give a proper quantum description. Warning: while this addendum tries to be reasonably self-contained, to really appreciate the details you may have to read some other addenda too.

The problem with the descriptions of emission and absorption of radiation in chapter 7.7 and 7.8 is that they assume that the electromagnetic field is given. The electromagnetic field is not given; it changes by one photon. That is rather important for spontaneous emission, where it changes from no photons to one photon. To account for that correctly requires that the electromagnetic field is properly quantized. That is done in this note.

To keep it simple, it will be assumed that the atom is a hydrogen one. Then there is just one electron to worry about. (The general analysis can be found in $\{\mathrm{A} .25\})$. The hydrogen atom is initially in some high energy state $\psi_{\mathrm{H}}$. Then it emits a photon and transitions to a lower energy state $\psi_{\mathrm{L}}$. The emitted photon comes out in a state with energy

$$
E_{\gamma}=\hbar \omega \approx E_{\mathrm{H}}-E_{\mathrm{L}}
$$

Recall that the photon energy is given in terms of its frequency $\omega$ by the PlanckEinstein relation. This photon energy is approximately the difference between the atomic energies. It does not have to be exact; there can be some energy slop, chapter 7.6.1.

Only a single photon energy state needs to be considered at a time. At the end of the story, the results can be summed over all possible photon states. To allow for stimulated emission, it will be assumed that initially there may already be $i$ preexisting photons present. For spontaneous emission, $i=0$. The initial system state will be indicated as:

$$
\psi_{1}=\psi_{\mathrm{H}}|i\rangle
$$

Here the so-called Fock space ket $|i\rangle$ is simply a concise way of indicating that there are $i$ photons in the considered photon quantum state.

In the final state the atom has decayed to a lower energy state $\psi_{\mathrm{L}}$. In doing so it has released 1 more photon into the considered photon state. So the final wave function is

$$
\psi_{2}=\psi_{\mathrm{L}}|i+1\rangle
$$

The key to the emission process is now the set of Hamiltonian coefficients, chapter 7.6,

$$
\left\langle E_{1}\right\rangle=\left\langle\psi_{1} \mid H \psi_{1}\right\rangle \quad H_{21}=\left\langle\psi_{2} \mid H \psi_{1}\right\rangle \quad\left\langle E_{2}\right\rangle=\left\langle\psi_{2} \mid H \psi_{2}\right\rangle
$$

Here $H$ is the Hamiltonian. All that really needs to be done in this note is to identify these coefficients, and in particular the so-called matrix element $H_{21}$. With the matrix element known, Fermi's golden rule can be used to find the precise transition rate, chapter 7.6.1.

To identify the Hamiltonian coefficients, first the Hamiltonian must be identified. Recall that the Hamiltonian is the operator of the total energy of the system. It will take the form

$$
H=H_{\mathrm{atom}}+H_{\gamma}+H_{\mathrm{atom}, \gamma}
$$

The first term in the right hand side is the inherent energy of the hydrogen atom. This Hamiltonian was written down way back in chapter 4.3. However, its precise form is of no interest here. The second term in the right hand side is the energy in the electromagnetic field. Electromagnetic fields too have inherent energy, about $\hbar \omega$ per photon in fact. The third term is the energy of the interaction between the atomic electron and the electromagnetic field.

Unlike the first term in the Hamiltonian, the other two are inherently relativistic: the number of photons is hardly a conserved quantity. Photons are readily created or absorbed by a charged particle, like the electron here. And it turns out that Hamiltonians for photons are intrinsically linked to operators that annihilate and create photons. Mathematically, at least. These operators are defined by the relations

$$
\begin{equation*}
\widehat{a}|i\rangle=\sqrt{i}|i-1\rangle \quad \widehat{a}^{\dagger}|i-1\rangle=\sqrt{i}|i\rangle \tag{A.166}
\end{equation*}
$$

for any number of photons $i$. In words, the annihilation operator $\widehat{a}$ takes a state of $i$ photons and turns it into a state with one less photon. The creation operator $\widehat{a}^{\dagger}$ puts the photon back in. The scalar factors $\sqrt{i}$ are a matter of convenience. If you did not put them in here, you would have to do it elsewhere.

The Hamiltonian that describes the inherent energy in the electromagnetic field turns out to be, $\{\mathrm{A} .23\}$,

$$
H_{\gamma}=\frac{1}{2} \hbar \omega\left(\widehat{a}^{\dagger} \widehat{a}+\widehat{a} \widehat{a}^{\dagger}\right)
$$

As a sanity check, this Hamiltonian can be applied on a state of $i$ photons. Using the definitions of the annihilation and creation operators given above,
$H_{\gamma}|i\rangle=\frac{1}{2} \hbar \omega\left(\widehat{a}^{\dagger} \sqrt{i}|i-1\rangle+\widehat{a} \sqrt{i+1}|i+1\rangle\right)=\frac{1}{2} \hbar \omega(i|i\rangle+(i+1)|i\rangle)=\hbar \omega\left(i+\frac{1}{2}\right)|i\rangle$

The factor in front of the final ket is the energy eigenvalue. So the energy in the field increases by one unit $\hbar \omega$ for each photon added, exactly as it should. The additional half photon is the ground state energy of the electromagnetic field. Even in its ground state, the electromagnetic field has some energy left. That is much like a one-dimensional harmonic oscillator still has $\frac{1}{2} \hbar \omega$ of energy left in its ground state, chapter 4.1.

Finally the energy of the interaction between the electron and electromagnetic field is needed. This third part of the total Hamiltonian is the messiest. To keep it as simple as possible, it will assumed that the transition is of the normal electric dipole type. In such transitions the electron interacts only with the electric part of the electromagnetic field. In addition, just like in the analysis of chapter 7.7.1 using a classical electromagnetic field, it will be assumed that the electric field is in the $z$-direction and propagates in the $y$-direction. (The general multipole analysis can be found in $\{\mathrm{A} .25\}$ ).

Now recall that in quantum mechanics, observable properties of particles are the eigenvalues of Hermitian operators, chapter 3.3. For example, the observable values of linear momentum of an electron in the $y$-direction are the eigenvalues of the linear momentum operator $\widehat{p}_{y}=\hbar \partial / \mathrm{i} \partial y$. This operator acts on the electron wave function.

Similarly, the electric field $\mathcal{E}_{z}$ that the electron interacts with is an observable property of the corresponding photons. So the observable values of the electric field must be the eigenvalues of a Hermitian electric field operator $\widehat{\mathcal{E}}_{z}$. And this operator acts on photon wave functions.

In the analysis using a classical electromagnetic field, the energy of interaction between the electron and the electromagnetic field was taken to be approximately $e \mathcal{E}_{z} z$. That is similar to the $m g h$ potential of a particle due to gravity. The electron electric charge $-e$ takes the place of the mass $m$, the electric field $\mathcal{E}_{z}$ that of the acceleration of gravity $g$, and $z$ that of the height $h$. Using the quantized electric field, there is no given classical field $\mathcal{E}_{z}$, and instead the operator $\widehat{\mathcal{E}}_{z}$ must be used:

$$
H_{\text {atom }, \gamma}=e \widehat{\mathcal{E}}_{z} z
$$

The operator $\widehat{\mathcal{E}}_{z}$ acts on the ket part of the combined atom-photon wave function. (And, although you may not think of it that way, the factor $z$ is really an operator that acts on the electron wave function part. That is true even in the analysis using the classical field.)

The electric field operator $\widehat{\mathcal{E}}_{z}$ can be identified from the appropriate photon wave function. The photon wave function here is assumed to have its linear momentum in the $y$-direction and its unobservable electric field in the $z$-direction. The corresponding normalized wave function and unobservable electric field were given in $\{\mathrm{A} .21 .6\}$ (A.95):

$$
\vec{A}_{\gamma}^{\mathrm{n}}=\frac{\varepsilon_{k}}{\mathrm{i} k c} \hat{k} e^{\mathrm{i} k y} \quad \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}=\varepsilon_{k} \hat{k} e^{\mathrm{i} k y} \quad \varepsilon_{k}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}}
$$

Here $\epsilon_{0}$ is the permittivity of space. Also $\mathcal{V}$ is the volume of the large periodic box in which the entire system will be assumed to be located. In truly infinite space the analysis would be extremely messy, littered with ugly delta functions.

The rules to get the operator of the observable electric field were discussed in addendum $\{\mathrm{A} .23\}$. First the unobservable electric field above is multiplied by the annihilation operator, then the Hermitian conjugate of that product is added, and the sum is divided by $\sqrt{2}$ :

$$
\widehat{\mathcal{E}}_{z}=\frac{\varepsilon_{k}}{\sqrt{2}}\left(\widehat{a} e^{\mathrm{i} k y}+\widehat{a}^{\dagger} e^{-\mathrm{i} k y}\right)
$$

(Note that for the usual Schrödinger approach followed here, time dependence is described by the wave function. Most sources switch here to a Heisenberg approach where the time-dependence is pushed into the operators. There is however no particular need to do so.)

In the electric dipole approximation, it is assumed that the atom is so small compared to the wave length of the photon that $k y$ can be assumed to be zero. Therefore

$$
\widehat{\mathcal{E}}_{z}=\frac{\varepsilon_{k}}{\sqrt{2}}\left(\widehat{a}+\widehat{a}^{\dagger}\right)
$$

The combined Hamiltonian is then

$$
H=H_{\mathrm{atom}}+H_{\gamma}+e \frac{\varepsilon_{k}}{\sqrt{2}}\left(\widehat{a}+\widehat{a}^{\dagger}\right) z
$$

with the first two terms as described earlier.
Next the Hamiltonian matrix coefficients are needed. The first one is

$$
\left.\left\langle E_{1}\right\rangle=\left\langle\psi_{1} \mid H \psi_{1}\right\rangle=\langle i| \psi_{\mathrm{H}}\left|\left(H_{\mathrm{atom}}+H_{\gamma}+e \frac{\varepsilon_{k}}{\sqrt{2}}\left(\widehat{a}+\widehat{a}^{\dagger}\right) z\right) \psi_{\mathrm{H}}\right| i\right\rangle
$$

Now the atomic part of the Hamiltonian produces a mere factor $E_{\mathrm{H}}$ when it acts on the atomic part of the right hand wave function. Further, as discussed above, the electromagnetic Hamiltonian produces a factor $\left(i+\frac{1}{2}\right) \hbar \omega$ when it acts on the right hand ket. Finally the interaction part of the Hamiltonian does not produce a contribution. One way to see that is from the atomic inner product. The atomic inner product is zero because negative values of $z$ integrate away against positive ones. Another way to see it is from the electromagnetic inner product. The operators $\widehat{a}$ and $\widehat{a}^{\dagger}$ produce states $|i-1\rangle$ respectively $|i+1\rangle$ when they act on the right hand ket. And those are orthogonal to the left hand ket; inner products between kets with different numbers of photons are zero. Kets are by definition orthonormal.

All together then

$$
\left\langle E_{1}\right\rangle=E_{\mathrm{H}}+\left(i+\frac{1}{2}\right) \hbar \omega
$$

The same way

$$
\left\langle E_{2}\right\rangle=E_{\mathrm{L}}+\left(i+1+\frac{1}{2}\right) \hbar \omega
$$

Finally the matrix element:

$$
\left.H_{21}=\left\langle\psi_{2} \mid H \psi_{1}\right\rangle=\langle i+1| \psi_{\mathrm{L}}\left|\left(H_{\text {atom }}+H_{\gamma}+e \frac{\varepsilon_{k}}{\sqrt{2}}\left(\widehat{a}+\widehat{a}^{\dagger}\right) z\right) \psi_{\mathrm{H}}\right| i\right\rangle
$$

In this case the atomic part of the Hamiltonian produces zero. The reason is that this Hamiltonian produces a simple scalar factor $E_{\mathrm{H}}$ when it acts on the right hand state. It leaves the state $\psi_{\mathrm{H}}$ itself unchanged. And this state produces zero in an inner product with the atomic state $\psi_{\mathrm{L}}$; energy eigenstates are orthonormal. Similarly, the electromagnetic Hamiltonian produces zero. It leaves the ket $|i\rangle$ in the right hand wave wave function unchanged, and that is orthogonal to the left hand $\langle i+1|$. However, in this case the interaction Hamiltonian produces a nonzero contribution:

$$
H_{21}=\frac{\varepsilon_{k} \sqrt{i+1}}{\sqrt{2}}\left\langle\psi_{\mathrm{L}} \mid e z \psi_{\mathrm{H}}\right\rangle
$$

The reason is that the creation operator $\widehat{a}^{\dagger}$ acting on the right hand ket produces a multiple $\sqrt{i+1}$ times the left hand ket. The remaining inner product $\left\langle\psi_{\mathrm{L}} \mid e z \psi_{\mathrm{H}}\right\rangle$ is called the "atomic matrix element," as it only depends on what the atomic states are.

The task laid out in chapter 7.6.1 has been accomplished: the relativistic matrix element has been found. A final expression for the spontaneous emission rate can now be determined.

Before doing so, however, it is good to first compare the obtained result with that of chapter 7.7.1. That section used a classical given electromagnetic field, not a quantized one. So the comparison will show up the effect of the quantization of the electromagnetic field. The section defined a modified matrix element

$$
\bar{H}_{21}=H_{21} e^{\mathrm{i}\left(\left\langle E_{2}\right\rangle-\left\langle E_{1}\right\rangle\right) t / \hbar}
$$

This matrix element determined the entire evolution of the system. For the quantized electric field discussed here, this coefficient works out to be

$$
\begin{equation*}
\bar{H}_{21}=\frac{\varepsilon_{k} \sqrt{i+1}}{\sqrt{2}}\left\langle\psi_{\mathrm{L}} \mid e z \psi_{\mathrm{H}}\right\rangle e^{\mathrm{i}\left(\omega-\omega_{0}\right) t} \quad \varepsilon_{k}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}} \tag{A.167}
\end{equation*}
$$

where $\omega_{0}=\left(E_{\mathrm{H}}-E_{\mathrm{L}}\right) / \hbar$.
That is essentially the same form as for the classical field. Recall that the second term in (7.44) for the classical field can be ignored. The first term is the same as above, within a constant. To see the real difference in the constants, note that the transition probability is proportional to the square magnitude of the matrix element. The square magnitudes are:
quantized: $\left|\bar{H}_{21}^{2}\right|=\frac{(i+1) \hbar \omega}{2 \epsilon_{0} \mathcal{V}}\left|\left\langle\psi_{\mathrm{L}} \mid e z \psi_{\mathrm{H}}\right\rangle\right|^{2} \quad$ classical: $\left|\bar{H}_{21}^{2}\right|=\frac{\mathcal{E}_{\mathrm{f}}^{2}}{4}\left|\left\langle\psi_{\mathrm{L}} \mid e z \psi_{\mathrm{H}}\right\rangle\right|^{2}$

Now if there is a large number $i$ of photons in the state, the two expressions are approximately the same. The electromagnetic energy of the wave according to classical physics, $\epsilon_{0} \mathcal{E}_{\mathrm{f}}^{2} \mathcal{V} / 2,\{\mathrm{~A} .23\}$, is then approximately the number of photons $i \approx i+1$ times $\hbar \omega$.

But for spontaneous emission there is a big difference. In that case, classical physics would take the initial electromagnetic field $\mathcal{E}_{\mathrm{f}}$ to be zero. And that then implies that the atom stays in the excited state $\psi_{\mathrm{H}}$ for always. There is no electromagnetic field to move it out of the state. So there is no spontaneous emission.

Instead quantum mechanics takes the initial field to have $i=0$ photons. But note the square matrix element above. It is not zero! The matrix element is as if there is still a full photon left in the electromagnetic field. So spontaneous emission can and does occur in the quantized electromagnetic field. Also, as noted in chapter 7.8, one full photon is exactly what is needed to explain spontaneous emission. Einstein's $A$ coefficient has been found using pure quantum analysis. Without peeking at the black body spectrum.

That can also be seen without detouring through the messy analysis of chapter 7.7 and 7.8. To find the spontaneous emission rate directly, the matrix element above can be plugged into Fermi's Golden Rule (7.38) of chapter 7.6.1. The density of states needed in it was given earlier in chapter 6.3 (6.7) and 6.19. Do note that these modes include all directions of the electric field, not just the $z$-direction. To account for that, you need to average the square atomic matrix element over all three Cartesian directions. That produces the spontaneous transition rate

$$
\frac{\omega^{3}}{\pi \hbar c^{3} \epsilon_{0}} \frac{\left|\left\langle\psi_{\mathrm{L}} \mid e x \psi_{\mathrm{H}}\right\rangle\right|^{2}+\left|\left\langle\psi_{\mathrm{L}} \mid e y \psi_{\mathrm{H}}\right\rangle\right|^{2}+\left|\left\langle\psi_{\mathrm{L}} \mid e z \psi_{\mathrm{H}}\right\rangle\right|^{2}}{3}
$$

The above result is the same as Einstein's, (7.47) and (7.48). (To see why a simple average works in the final term, first note that it is obviously the right average for photons with axial linear momenta and fields. Then note that the average is independent of the angular orientation of the axis system in which the photons are described. So it also works for photons that are axial in any rotated coordinate system. To verify that the average is independent of angular orientation does not really require linear algebra; it suffices to show that it is true for rotation about one axis, say the $z$-axis.)

Some additional observations may be interesting. You might think of the spontaneous emission as caused by excitation from the ground state electromagnetic field. But as seen earlier, the actual energy of the ground state is half a photon, not one photon. And the zero level of energy should not affect the dynamics anyway. According to the analysis here, spontaneous emission is a twilight effect, chapter 5.3. The Hamiltonian coefficient $H_{21}$ is the energy if the atom is not excited and there is a photon if the atom is excited and there is no
photon. In quantum mechanics, the twilight term allows the excited atom to interact with the photon that would be there if it was not excited. Sic.

## A. 25 Multipole transitions

This addendum gives a description of the multipole interaction between atoms or nuclei and electromagnetic fields. In particular, the spontaneous emission of a photon of electromagnetic radiation in an atomic or nuclear transition will be examined. But stimulated emission and absorption are only trivially different.

The basic ideas were already worked out in earlier addenda, especially in $\{\mathrm{A} .21\}$ on photon wave functions and $\{\mathrm{A} .24\}$ on spontaneous emission. However, these addenda left the actual interaction between the atom or nucleus and the field largely unspecified. Only a very simple form of the interaction, called the electric dipole approximation, was worked out there.

Many transitions are not possible by the electric dipole mechanism. This addendum will describe the more general multipole interaction mechanisms. That will allow rough estimates of how fast various possible transitions occur. These will include the Weisskopf and Moszkowski estimates for the gamma decay of nuclei. It will also allow a general description exactly how the selection rules of chapter 7.4.4 relate to nuclear and photon wave functions.

The overall picture is that before the transition, the atom or nucleus is in a high energy state $\psi_{\mathrm{H}}$. Then it transitions to a lower energy state $\psi_{\mathrm{L}}$. During the transition it emits a photon that carries away the excess energy. The energy of that photon is related to its frequency $\omega$ by the Planck-Einstein relation:

$$
E_{\mathrm{H}}-E_{\mathrm{L}}=\hbar \omega_{0} \approx \hbar \omega
$$

Here $\omega_{0}$ is the nominal frequency of the photon. The actual photon frequency $\omega$ might be slightly different; there can be some slop in energy conservation. However, that will be taken care of by using Fermi's golden rule, chapter 7.6.1.

It is often useful to express the photon frequency in terms of the so-called wave number $k$ :

$$
\omega=k c
$$

Here $c$ is the speed of light. The wave number is a physically important quantity since it is inversely proportional to the wave length of the photon. If the typical size of the atom or nucleus is $R$, then $k R$ is an nondimensional quantity. It describes the ratio of atom or nucleus size to photon wave length. Normally this ratio is very small, which allows helpful simplifications.

It will be assumed that only the electrons need to be considered for atomic transitions. The nucleus is too heavy to move much in such transitions. For nuclear transitions, (inside the nuclei), it is usually necessary to consider both types of nucleons, protons and neutrons. Protons and neutrons will be treated as point particles, though each is really a combination of three quarks.

As noted in chapter 7.5.3 and 7.6.1, the "driving force" in a transition is the so-called Hamiltonian matrix element:

$$
H_{21}=\left\langle\psi_{\mathrm{L}}\right| H\left|\psi_{\mathrm{H}}\right\rangle
$$

Here $H$ is the Hamiltonian, which will depend on the type of transition. In particular, it depends on the properties of the emitted photon.

If the matrix element $H_{21}$ is zero, transitions of that type are not possible. The transition is "forbidden." If the matrix element is very small, they will be very slow. (If the term "forbidden" is used without qualification, it indicates that the electric-dipole type of transition cannot occur,)

## A.25.1 Approximate Hamiltonian

The big ideas in multipole transitions are most clearly seen using a simple model. That model will be explained in this subsection. However, the results in this subsection will not be quantitatively correct for multipole transitions of higher order. Later subsections will correct these deficiencies. This two-step approach is followed because otherwise it can be easy to get lost in all the mathematics of multipole transitions. Also, the terminology used in multipole transitions really arises from the simple model discussed here. And in any case, the needed corrections will turn out to be very simple.

An electromagnetic wave consists of an electric field $\overrightarrow{\mathcal{E}}$ and a magnetic field $\overrightarrow{\mathcal{B}}$. A basic plane wave takes the form, (13.10):

$$
\overrightarrow{\mathcal{E}}=\hat{\imath} \sqrt{2} \mathcal{E}_{0} \cos \left(k z-\omega t-\alpha_{0}\right) \quad \overrightarrow{\mathcal{B}}=\hat{\jmath} \frac{\sqrt{2} \mathcal{E}_{0}}{c} \cos \left(k z-\omega t-\alpha_{0}\right)
$$

For convenience the $z$-axis was taken in the direction of propagation of the wave. Also the $x$-axis was taken in the direction of the electric field. The constant $c$ is the speed of light and the constant $\mathcal{E}_{0}$ is the root-mean-square value of the electric field. (The amplitude of the electric field is then $\sqrt{2} \mathcal{E}_{0}$, but the root mean square value is more closely related to what you end up with when the electromagnetic field is properly quantized.) Finally $\alpha_{0}$ is some unimportant phase angle.

The above waves need to be written as complex exponentials using the Euler formula (2.5):
$\overrightarrow{\mathcal{E}}=\hat{\imath} \frac{\mathcal{E}_{0}}{\sqrt{2}}\left(e^{\mathrm{i}\left(k z-\omega t-\alpha_{0}\right)}+e^{-\mathrm{i}\left(k z-\omega t-\alpha_{0}\right)}\right) \quad \overrightarrow{\mathcal{B}}=\hat{\jmath} \frac{\mathcal{E}_{0}}{\sqrt{2} c}\left(e^{\mathrm{i}\left(k z-\omega t-\alpha_{0}\right)}+e^{-\mathrm{i}\left(k z-\omega t-\alpha_{0}\right)}\right)$
Only one of the two exponentials will turn out to be relevant to the transition process. For absorption that is the first exponential. But for emission, the case discussed here, the second exponential applies.

There are different ways to see why only one exponential is relevant. Chapter 7.7 follows a classical approach in which the field is given. In that case, the evolution equation that gives the transition probability is, $\{\mathrm{D} .38\}$,

$$
\mathrm{i} \hbar \dot{\bar{c}}_{2} \approx H_{21} e^{\mathrm{i}\left(E_{2}-E_{1}\right) t / \hbar}
$$

Here $\left|c_{2}\right|^{2}$ is the transition probability. For emission, the final state is the low energy state. Then the Planck-Einstein relation gives the exponential above as $e^{-\mathrm{i} \omega_{0} t}$. (By convention, frequencies are taken to be positive.) Now the Hamiltonian matrix element $H_{21}$ will involve the electric and magnetic fields, with their exponentials. The first exponentials, combined with the exponential above, produce a time-dependent factor $e^{-\mathrm{i}\left(\omega_{0}+\omega\right) t}$. Since normal photon frequencies are large, this factor oscillates extremely rapidly in time. Because of these oscillations, the corresponding terms never produce a significant contribution to the transition probability. Opposite contributions average away against each other. So the first exponentials can be ignored. But the second exponentials produce a time dependent factor $e^{-\mathrm{i}\left(\omega_{0}-\omega\right) t}$. That does not oscillate rapidly provided that the emitted photon has frequency $\omega \approx \omega_{0}$. So such photons can achieve a significant probability of being emitted.

For absorption, the low energy state is the first one, instead of the second. That makes the exponential above $e^{+\mathrm{i} \omega_{0} t}$, and the entire story inverts.

The better way to see that the first exponentials in the fields drop out is to quantize the electromagnetic field. This book covers that only in the addenda. In particular, addendum \{A. 24$\}$ described the process. Fortunately, quantization of the electromagnetic field is mainly important to figure out the right value of the constant $\mathcal{E}_{0}$ to use, especially for spontaneous emission. It does not directly affect the actual analysis in this addendum. In particular the conclusion remains that only the second exponentials survive.

The bottom line is that for emission

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=\hat{\imath} \frac{\mathcal{E}_{0}}{\sqrt{2}} e^{-\mathrm{i}\left(k z-\omega t-\alpha_{0}\right)} \quad \overrightarrow{\mathcal{B}}=\hat{\jmath} \frac{\mathcal{E}_{0}}{\sqrt{2} c} e^{-\mathrm{i}\left(k z-\omega t-\alpha_{0}\right)} \tag{A.168}
\end{equation*}
$$

Also, as far as this addendum is concerned, the difference between spontaneous and stimulated emission is only in the value of the constant $\mathcal{E}_{0}$.

Next the Hamiltonian is needed. For the matrix element, only the part of the Hamiltonian that describes the interaction between the atom or nucleus and the electromagnetic fields is relevant, $\{\mathrm{A} .24\}$. (Recall that the matrix element drives the transition process; no interaction means no transition.) Assume that the electrons in the atom, or the protons and neutrons in the nucleus, are numbered using an index $i$. Then by approximation the interaction Hamiltonian of a single particle $i$ with the electromagnetic field is

$$
H_{i} \approx-q_{i} \overrightarrow{\mathcal{E}}_{i} \cdot \vec{r}_{i}-\frac{q_{i}}{2 m_{i}} \overrightarrow{\mathcal{B}}_{i} \cdot \widehat{\vec{L}}_{i}-\frac{q_{i}}{2 m_{i}} g_{i} \overrightarrow{\mathcal{B}}_{i} \cdot \hat{\vec{S}}_{i}
$$

In general, you will need to sum this over all particles $i$. But the discussion here will usually look at one particle at a time.

The first term in the Hamiltonian above is like the $m g h$ potential of gravity, with the particle charge $q_{i}$ taking the place of the mass $m$, the electric field that of the acceleration of gravity $g$, and the particle position $\vec{r}_{i}$ that of the height $h$.

The second and third terms in the Hamiltonian are due to the fact that a charged particle that is going around in circles acts as a little electromagnet. An electromagnet wants to align itself with an ambient magnetic field. That is just like a compass needle aligns itself with the magnetic field of earth.

This effect shows up as soon as there is angular momentum. Indeed, the operator $\widehat{\vec{L}}_{i}$ above is the orbital angular momentum of the particle and $\widehat{\vec{S}}_{i}$ is the spin. The factor $g_{i}$ is a nondimensional number that describes the relative efficiency of the particle spin in creating an electromagnetic response. For an electron in an atom, $g_{i}$ is very close to 2 . That is a theoretical value expected for fundamental particles, chapter 13.4. However, for a proton in a nucleus the value is about 5.6, assuming that the effect of the surrounding protons and neutrons can be ignored. (Actually, it is quite well established that normally the surrounding particles cannot be ignored. But it is difficult to say what value for $g_{i}$ to use instead, except that it will surely be smaller than 5.6, and greater than 2.)

A special case needs to be made for the neutrons in a nucleus. Since the neutron has no charge, $q_{i}=0$, you would expect that its contribution to the Hamiltonian is zero. However, the final term in the Hamiltonian is not zero. A neutron has a magnetic response. (A neutron consists of three charged quarks. The combined charge of the three is zero, but the combined magnetic response is not.) To account for that, in the final term, you need to use the charge $e$ and mass $m_{\mathrm{p}}$ of the proton, and take $g_{i}$ about -3.8 . This value of $g_{i}$ ignores again the effects of surrounding protons and neutrons.

There are additional issues that are important. Often it is assumed that in a transition only a single particle changes states. If that particle is a neutron, it might then seem that the first two terms in the Hamiltonian can be ignored. But actually, the neutron and the rest of the nucleus move around their common center of gravity. And the rest of the nucleus is charged. So normally the first two terms cannot be ignored. This is mainly important for the so-called electric dipole transitions; for higher multipole orders, the electromagnetic field is very small near the origin, and the motion of the rest of the nucleus does not produce much effect. In a transition of a single proton, you may also want to correct the first term for the motion of the rest of the nucleus. But also note that the rest of the nucleus is not really a point particle. That may make a significant difference for higher multipole orders. Therefore simple corrections remain problematic. See [33] and [11] for further discussion of these nontrivial issues.

The given Hamiltonian ignores the fact that the electric and magnetic fields are unsteady and not uniform. That is the reason why the higher multipoles found in the next subsection will not be quite right. They will be good enough to show the basic ideas however. And the quantitative problems will be corrected in later subsections.

## A.25.2 Approximate multipole matrix elements

The last step is to write down the matrix element. Substituting the approximate Hamiltonian and fields of the previous subsection into the matrix element of the introduction gives:

$$
H_{21, i}=\left\langle\psi_{\mathrm{L}}\right| H\left|\psi_{\mathrm{H}}\right\rangle \approx-\frac{\mathcal{E}_{0}}{\sqrt{2}}\left\langle\psi_{\mathrm{L}}\right| e^{-\mathrm{i} k z_{i}}\left[q_{i} x_{i}+\left(q_{i} / 2 m_{i} c\right)\left(\widehat{L}_{i, y}+g_{i} \widehat{S}_{i, y}\right)\right]\left|\psi_{\mathrm{H}}\right\rangle
$$

This will normally need to be summed over all electrons $i$ in the atom, or all nucleons $i$ in the nucleus. Note that the time dependent part of the exponential is of no interest. It will in fact not even appear when the electromagnetic field is properly quantized, $\{\mathrm{A} .24\}$. In a classical treatment, it drops out versus the $e^{\mathrm{i}\left(E_{2}-E_{1}\right) t / \hbar}$ exponential mentioned in the previous subsection.

To split the above matrix element into different multipole orders, write the exponential as a Taylor series:

$$
e^{-\mathrm{i} k z_{i}}=\sum_{n=0}^{\infty} \frac{\left(-\mathrm{i} k z_{i}\right)^{n}}{n!}=\sum_{\ell=1}^{\infty} \frac{\left(-\mathrm{i} k z_{i}\right)^{\ell-1}}{(\ell-1)!}
$$

In the second equality, the summation index was renotated as $n=\ell-1$. The reason is that $\ell$ turns out to be what is conventionally defined as the multipole order.

Using this Taylor series, the matrix element gets split into separate electric and magnetic multipole contributions:

$$
\begin{gathered}
H_{21, i}=\sum_{\ell=1}^{\infty} H_{21, i}^{\mathrm{E} \ell}+H_{21, i}^{\mathrm{M} \ell}=H_{21, i}^{\mathrm{E} 1}+H_{21, i}^{\mathrm{M} 1}+H_{21, i}^{\mathrm{E} 2}+H_{21, i}^{\mathrm{M} 2}+\ldots \\
H_{21, i}^{\mathrm{E} \ell} \approx-\frac{q_{i} \mathcal{E}_{0}}{\sqrt{2}} \frac{(-\mathrm{i} k)^{\ell-1}}{(\ell-1)!}\left\langle\psi_{\mathrm{L}}\right| z_{i}^{\ell-1} x_{i}\left|\psi_{\mathrm{H}}\right\rangle \\
H_{21, i}^{\mathrm{M} \ell} \approx-\frac{q_{i} \mathcal{E}_{0}}{2 \sqrt{2} m_{i} c} \frac{(-\mathrm{i} k)^{\ell-1}}{(\ell-1)!}\left\langle\psi_{\mathrm{L}}\right| z_{i}^{\ell-1}\left(\widehat{L}_{i, y}+g_{i} \widehat{S}_{i . y}\right)\left|\psi_{\mathrm{H}}\right\rangle
\end{gathered}
$$

The terms with $\ell=1$ are the dipole ones, $\ell=2$ the quadrupole ones, 3 the octupole ones, 4 the hexadecapole ones, etcetera. Superscript E indicates an electric contribution, M a magnetic one. The first contribution that is nonzero gives the lowest multipole order that is allowed.

## A.25.3 Corrected multipole matrix elements

The multipole matrix elements of the previous subsection were rough approximations. The reason was the approximate Hamiltonian that was used. This subsection will describe the corrections needed to fix them up. It will still be assumed that the atomic or nuclear particles involved are nonrelativistic. They usually are.

The corrected Hamiltonian is

$$
\begin{equation*}
H=\sum_{i}\left[\frac{1}{2 m_{i}}\left(\hat{\vec{p}}_{i}-q_{i} \vec{A}_{i}\right)^{2}+q_{i} \varphi_{i}-g_{i} \frac{q_{i}}{2 m_{i}} \overrightarrow{\mathcal{B}}_{i} \cdot \hat{\vec{S}}_{i}\right]+V \tag{A.169}
\end{equation*}
$$

where the sum is over the individual electrons in the atom or the protons and neutrons in the nucleus. In the sum, $m_{i}$ is the mass of the particle, $\widehat{\vec{p}}_{i}$ its momentum, and $q_{i}$ its charge. The potential $V$ is the usual potential that keeps the particle inside the atom or nucleus. The remaining parts in the Hamiltonian express the effect of the additional external electromagnetic field. In particular, $\varphi_{i}$ is the electrostatic potential of the field and $\vec{A}_{i}$ the so-called vector potential, each evaluated at the particle position. Finally

$$
\overrightarrow{\mathcal{B}}=\nabla \times \vec{A}
$$

is the magnetic part of the field. The spin $\widehat{\vec{S}}_{i}$ of the particle interacts with this field at the location of the particle, with a relative strength given by the nondimensional constant $g_{i}$. See chapter 1.3.2 for a classical justification of this Hamiltonian, or chapter 13 for a quantum one.

Nonrelativistically, the spin does not interact with the electric field. That is particularly limiting for the neutron, which has no net charge to interact with the electric field. In reality, a rapidly moving particle with spin will also interact with the electric field, \{A.39\}. See the Dirac equation and in particular \{D.74\} for a relativistic description of the interaction of spin with an electromagnetic field. That would be too messy to include here, but it can be found in [44]. Note also that since in reality the neutron consists of three quarks, that should allow it to interact directly with a nonuniform electric field.

If the field is quantized, you will also want to include the Hamiltonian of the field in the total Hamiltonian above. And the field quantities become operators. That goes the same way as in $\{$ A. 24$\}$. It makes no real difference for the analysis in this addendum.

It is always possible, and a very good idea, to take the unperturbed electromagnetic potentials so that

$$
\varphi=0 \quad \nabla \cdot \vec{A}=0
$$

See for example the addendum on photon wave functions $\{$ A. 21$\}$ for more on that. That addendum also gives the potentials that correspond to photons
of definite linear, respectively angular momentum. These will be used in this addendum.

The square in the above Hamiltonian may be multiplied out to give

$$
H=H_{0}+\sum_{i}\left[-\frac{q_{i}}{m_{i}} \vec{A}_{i} \cdot \widehat{\vec{p}}_{i}+\frac{q_{i}^{2}}{2 m_{i}} \vec{A}_{i}^{2}-g_{i} \frac{q_{i}}{2 m_{i}} \overrightarrow{\mathcal{B}}_{i} \cdot \hat{\vec{S}}_{i}\right]
$$

The term $H_{0}$ is the Hamiltonian of the atom or nucleus in the absence of interaction with the external electromagnetic field. Like in the previous subsection, it is not directly relevant to the interaction with the electromagnetic field. Note further that $\hat{\vec{p}}$ and $\vec{A}$ commute because $\nabla \cdot \vec{A}$ is zero. The term proportional to $\vec{A}^{2}$ will be ignored as it is normally very small. (It gives rise to two-photon emission, [33].)

That makes the interaction Hamiltonian of a single particle $i$ equal to

$$
\begin{equation*}
H_{i}=-\frac{q_{i}}{m_{i}} \vec{A}_{i} \cdot \widehat{\vec{p}}_{i}-g_{i} \frac{q_{i}}{2 m_{i}} \overrightarrow{\mathcal{B}}_{i} \cdot \hat{\vec{S}}_{i} \tag{A.170}
\end{equation*}
$$

Note that the final spin term has not changed from the approximate Hamiltonian written down earlier. However, the first term appears completely different from before. Still, there must obviously be a connection.

To find that connection requires considerable manipulation. First the vector potential $\vec{A}$ must be identified in terms of the simple electromagnetic wave as written down earlier in (A.168). To do so, note that the vector potential must be related to the fields as

$$
\overrightarrow{\mathcal{E}}=-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A}
$$

See, for example, $\{\mathrm{A} .21\}$ for a discussion. That allows the vector potential corresponding to the simple wave (A.168) to be identified as:

$$
\vec{A}=-\hat{\imath} \frac{\mathcal{E}_{0}}{\sqrt{2} \mathrm{i} \omega} e^{-\mathrm{i}\left(k z-\omega t-\alpha_{0}\right)}
$$

This wave can be generalized to allow general directions of wave propagation and fields. That gives:
$\vec{A}=-\hat{\imath}_{\mathcal{E}} \frac{\mathcal{E}_{0}}{\sqrt{2} \mathrm{i} \omega} e^{-\mathrm{i}\left(\vec{k} \cdot \vec{r}-\omega t-\alpha_{0}\right)} \quad \overrightarrow{\mathcal{E}}=\hat{\imath}_{\mathcal{E}} \frac{\mathcal{E}_{0}}{\sqrt{2}} e^{\left.-\mathrm{i} \mathrm{k} \cdot \vec{k} \cdot \vec{r}-\omega t-\alpha_{0}\right)} \quad \overrightarrow{\mathcal{B}}=\hat{\imath}_{\mathcal{B}} \frac{\mathcal{E}_{0}}{\sqrt{2} c} e^{-\mathrm{i}\left(\vec{k} \cdot \vec{r}-\omega t-\alpha_{0}\right)}$
Here the unit vector $\hat{\imath}_{\mathcal{E}}$ is in the direction of the electric field and $\hat{\imath}_{\mathcal{B}}$ in the direction of the magnetic field. A unit vector $\hat{\imath}_{k}$ in the direction of wave propagation can be defined as their cross product. This defines the wave number vector as

$$
\vec{k} \equiv \hat{\imath}_{k} k \quad \hat{\imath}_{k}=\hat{\imath}_{\mathcal{E}} \times \hat{\imath}_{\mathcal{B}} \quad \hat{\imath}_{\mathcal{E}} \cdot \hat{\imath}_{\mathcal{B}}=0
$$

The three unit vectors are orthonormal. Note that for a given direction of wave propagation $\hat{\imath}_{k}$, there will be two independent waves. They differ in the direction of the electric field $\hat{\imath}_{\mathcal{E}}$. The choice for the direction of the electric field for first wave is not unique; the field must merely be orthogonal to the direction of wave propagation. An arbitrary choice must be made. The electric field of the second wave needs to be orthogonal to that of the first wave. The example in the previous subsections took the wave propagation in the $z$-direction, $\hat{\imath}_{k}=$ $\hat{k}$, and the electric field in the $x$-direction, $\hat{\imath}_{\mathcal{E}}=\hat{\imath}$, to give the magnetic field in the $y$-direction, $\hat{\imath}_{\mathcal{B}}=\hat{\jmath}$. In that case the second independent wave will have its electric field in the $y$-direction, $\hat{\imath}_{\mathcal{E}}=\hat{\jmath}$, and its magnetic field in the negative $x$ direction, $\hat{\imath}_{\mathcal{B}}=-\hat{\imath}$.

The single-particle matrix element is now, dropping again the time-dependent factors,

$$
\begin{aligned}
H_{21, i} & =\left\langle\psi_{\mathrm{L}}\right| H_{i}\left|\psi_{\mathrm{H}}\right\rangle \\
& =\frac{q_{i}}{m_{i}} \frac{\mathcal{E}_{0}}{\sqrt{2} \mathrm{i} \omega}\left\langle\psi_{\mathrm{L}}\right| e^{-\mathrm{i} \vec{k} \cdot \vec{r}} \hat{\imath}_{\mathcal{E}} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle-g_{i} \frac{q_{i}}{2 m_{i}} \frac{\mathcal{E}_{0}}{\sqrt{2} c}\left\langle\psi_{\mathrm{L}}\right| e^{-\mathrm{i} \vec{k} \cdot \overrightarrow{\imath_{\imath}^{\mathcal{B}}}} \hat{\mathcal{B}} \cdot \widehat{\vec{S}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
\end{aligned}
$$

The first term needs to be cleaned up to make sense out of it. That is an extremely messy exercise, banned to $\{\mathrm{D} .43\}$.

However, the result is much like before:

$$
H_{21, i}=\sum_{\ell=1}^{\infty} H_{21, i}^{\mathrm{E} \ell}+H_{21, i}^{\mathrm{M} \ell}=H_{21, i}^{\mathrm{E} 1}+H_{21, i}^{\mathrm{M} 1}+H_{21, i}^{\mathrm{E} 2}+H_{21, i}^{\mathrm{M} 2}+\ldots
$$

where

$$
\begin{array}{r}
H_{21, i}^{\mathrm{E} \ell}=-\frac{q_{i} \mathcal{E}_{0}}{\sqrt{2}} \frac{(-\mathrm{i} k)^{\ell-1}}{(\ell-1)!}\left\langle\psi_{\mathrm{L}}\right| \frac{1}{\ell} r_{i, k}^{\ell-1} r_{i, \mathcal{E}}\left|\psi_{\mathrm{H}}\right\rangle \\
H_{21, i}^{\mathrm{M} \ell} \approx-\frac{q^{\mathcal{E}} \mathcal{E}_{0}}{2 \sqrt{2} m_{i} c} \frac{(-\mathrm{i} k)^{\ell-1}}{(\ell-1)!}\left\langle\psi_{\mathrm{L}}\right| r_{i, k}^{\ell-1}\left(\frac{2}{\ell+1} \widehat{L}_{i, \mathcal{B}}+g_{i} \widehat{S}_{i, \mathcal{B}}\right)\left|\psi_{\mathrm{H}}\right\rangle \tag{A.172}
\end{array}
$$

Here $r_{i, k}$ is the component of the position of the particle in the direction of motion. Similarly, $r_{i, \mathcal{E}}$ is the component of position in the direction of the electric field, while the angular momentum components are in the direction of the magnetic field.

This can now be compared to the earlier results using the approximate Hamiltonian. Those earlier results assumed the special case that the wave propagation was in the $z$-direction and had its electric field in the $x$-direction. In that case,

$$
\begin{equation*}
\text { example: } \quad r_{i, k}=z_{i} \quad r_{i, \mathcal{E}}=x_{i} \quad \widehat{L}_{i, \mathcal{B}}=\widehat{L}_{i . y} \quad \widehat{S}_{i, \mathcal{B}}=\widehat{S}_{i, y} \tag{A.173}
\end{equation*}
$$

Noting that, it is seen that the correct electric contributions only differ from the approximate ones by a simple factor $1 / \ell$. This factor is 1 for electric dipole contributions, so these were correct already. Similarly, the magnetic contribution
differs only by the additional factor $2 /(\ell+1)$ for the orbital angular momentum from the approximate result. This factor is 1 for magnetic dipole contributions. So these too were already correct.

However, there is a problem with the electric contribution in the case of nuclei. A nuclear potential does not just depend on the position of the nuclear particles, but also on their momentum. That introduces an additional term in the electric contribution, $\{\mathrm{D} .43\}$. A ballpark for that term shows that this may well make the listed electric contribution quantitatively invalid, $\{\mathrm{N} .14\}$. Unfortunately, nuclear potentials are not known to sufficient accuracy to give a solid prediction for the contribution. In the following, this problem will usually simply be ignored, like other textbooks do.

## A.25.4 Matrix element ballparks

Recall that electromagnetic transitions are driven by the matrix element. The previous subsection managed to split the matrix element into separate electric and magnetic multipole contributions. The intent in this subsection is now to show that normally, the first nonzero multipole contribution is the important one. Subsequent multipole contributions are normally small compared to the first nonzero one.

To do so, this subsection will ballpark the multipole contributions. The ballparks will show that the magnitude of the contributions decreases rapidly with increasing multipole order $\ell$.

But of course ballparks are only that. If a contribution is exactly zero for some special reason, (usually a symmetry), then the ballpark is going to be wrong. That is why it is the first nonzero multipole contribution that is important, rather than simply the first one. The next subsection will discuss the so-called selection rules that determine when contributions are zero.

The ballparks are formulated in terms a typical size $R$ of the atom or nucleus. For the present purposes, this size will be taken to be the average radial position of the particles away from the center of atom or nucleus. Then the magnitudes of the electric multipole contributions can be written as

$$
\left.\left|H_{21, i}^{\mathrm{E} \ell}\right|=\frac{\left|q_{i}\right| \mathcal{E}_{0} R}{\sqrt{2}} \frac{(k R)^{\ell-1}}{\ell(\ell-1)!}\left|\left\langle\psi_{\mathrm{L}}\right|\left(r_{i, k} / R\right)^{\ell-1}\left(r_{i, \mathcal{E}} / R\right)\right| \psi_{\mathrm{H}}\right\rangle \mid
$$

There is no easy way to say exactly what the inner product above will be. However, since the positions inside it have been scaled with the mean radius $R$, its value is supposedly some normal finite number. Unless the inner product happens to be zero for some special reason of course. Assuming that this does not happen, the inner product can be ignored for the ballpark. And that then shows that each higher nonzero electric multipole contribution is smaller than the previous one by a factor $k R$. Now $k$ is inversely proportional to the wave length of the photon that is emitted or absorbed. This wave length is normally
very much larger than the size of the atom or nucleus $R$. That means that $k R$ is very small. And that then implies that a nonzero multipole contribution at a higher value of $\ell$ will be very much less than one at a lower value. So contributions for values of $\ell$ higher than the first nonzero one can normally be ignored.

The magnitudes of the magnetic contributions can be written as
$\left.\left|H_{21, i}^{\mathrm{M} \ell}\right| \approx-\frac{\left|q_{i}\right| \mathcal{E}_{0} R}{\sqrt{2}} \frac{(k R)^{\ell-1}}{\ell(\ell-1)!}\left|\left\langle\psi_{\mathrm{L}}\right|\left(r_{i, k} / R\right)^{\ell-1} \frac{1}{\hbar}\left(\frac{2}{\ell+1} \widehat{L}_{i, \mathcal{B}}+g_{i} \widehat{S}_{i, \mathcal{B}}\right)\right| \psi_{\mathrm{H}}\right\rangle \left\lvert\, \ell \frac{\hbar}{2 m_{i} c R}\right.$
Recall that angular momentum values are multiples of $\hbar$. Therefore the matrix element can again be ballparked as some finite number, if nonzero. So once again, the multipole contributions get smaller by a factor $k R$ for each increase in order. That means that the nonzero magnetic contributions too decrease rapidly with $\ell$.

That leaves the question how magnetic contributions compare to electric ones. First compare a magnetic multipole term to the electric one of the same multipole order $\ell$. The above estimates show that the magnetic term is mainly different from the electric one by the factor

$$
\frac{\hbar}{2 m_{i} c R} \approx \begin{cases}\text { atoms: } & \frac{1 \AA}{500 R} \\ \text { nuclei: } & \frac{1 \mathrm{fm}}{10 R}\end{cases}
$$

Atomic sizes are in the order of an $\AA$ Angstrom, and nuclear ones in the order of a few femtometers. So ballpark magnetic contributions are small compared to electric ones of the same order $\ell$. And more so for atoms than for nuclei. (Transition rates are proportional to the square of the first nonzero contribution. So the ballpark transition rate for a magnetic transition is smaller than an electric one of the same order by the square of the above factor.)

A somewhat more physical interpretation of the above factor can be given:

$$
\frac{\hbar}{2 m_{i} c R}=\sqrt{\frac{T_{\mathrm{bp}}}{2 m_{i} c^{2}}} \quad T_{\mathrm{bp}} \equiv \frac{\hbar^{2}}{2 m_{i} R^{2}}
$$

Here $T_{\mathrm{bp}}$ is a ballpark for the kinetic energy $-\hbar^{2} \nabla^{2} / 2 m_{i}$ of the particle. Note that this ballpark is exact for the hydrogen atom ground state if you take the Bohr radius as the average radius $R$ of the atom. However, for heavier atoms and nuclei, this ballpark may be low: it ignores the exclusion effects of the other particles. Further $m_{i} c^{2}$ is the rest mass energy of the particle. Now protons and neutrons in nuclei, and at least the outer electrons in atoms are nonrelativistic; their kinetic energy is much less than their rest mass energy. It follows again that magnetic contributions are normally much smaller than electric ones of the same multipole order.

Compare the magnetic multipole term also to the electric one of the next multipole order. The trailing factor in the magnetic element can for this case be written as

$$
\frac{\hbar}{2 m_{i} c R}=k R \frac{T_{\mathrm{bp}}}{\hbar \omega}
$$

The denominator in the final ratio is the energy of the emitted or absorbed photon. Typically, it is significantly less than the ballpark kinetic energy of the particle. That then makes magnetic matrix elements significantly larger than electric ones of the next-higher multipole order. Though smaller than the electric ones of the same order.

## A.25.5 Selection rules

Based on the ballparks given in the previous subsection, the E1 electric dipole contribution should dominate transitions. It should be followed in size by the M1 magnetic dipole one, followed by the E2 electric quadrupole one, etcetera.

But this order gets modified because matrix elements are very often zero for special reasons. This was explained physically in chapter 7.4.4 based on the angular momentum properties of the emitted photon. This subsection will instead relate it directly to the matrix element contributions as identified in subsection A.25.3. To simplify the reasoning, it will again be assumed that the $z$-axis is chosen in the direction of wave motion and the $y$-axis in the direction of the electric field. So (A.173) applies for the multipole contributions (A.171) and (A.172).

Consider first the electric dipole contribution $H_{21, i}^{\mathrm{E} 1}$. According to (A.171) and (A.173) this contribution contains the inner product

$$
\left\langle\psi_{\mathrm{L}}\right| x_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

Why would this be zero? Basically because in the inner product integrals, positive values of $x_{i}$ might exactly integrate away against corresponding negative values. That can happen because of symmetries in the nuclear wave functions.

One such symmetry is parity. For all practical purposes, atomic and nuclear states have definite parity. If the positive directions of the Cartesian axes are inverted, atomic and nuclear states either stay the same (parity 1 or positive), or change sign (parity -1 or negative). Assume, for example, that $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ have both positive parity. That means that they do not change under an inversion of the axes. But the factor $x_{i}$ in the inner product above has odd parity: axes inversion replaces $x_{i}$ by $-x_{i}$. So the complete inner product above changes sign under axes inversion. But inner products are defined in a way that they do not change under axes inversion. (In terms of chapter 2.3, the effect of the axes inversion can be undone by a further inversion of the integration variables.) Something can only change sign and still stay the same if it is zero, ( -0 is 0 but say -5 is not 5 ).

So if both $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ have positive parity, the electric dipole contribution is zero. The only way to get a nonzero inner product is if exactly one of $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ has negative parity. Then the factor -1 that this state picks up under axes inversion cancels the -1 from $x_{i}$, leaving the inner product unchanged as it should. So the conclusion is that in electric dipole transitions $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ must have opposite parities. In other words, the atomic or nuclear parity must "flip over" in the transition. This condition is called the parity "selection rule" for an electric dipole transition. If it is not satisfied, the electric dipole contribution is zero and a different contribution will dominate. That contribution will be much smaller than a typical nonzero electric dipole one, so the transition will be much slower.

The $H_{21, i}^{\mathrm{M} 1}$ magnetic dipole contribution contains the inner product

$$
\left\langle\psi_{\mathrm{L}}\right| \widehat{L}_{i, y}+g_{i} \widehat{S}_{i . y}\left|\psi_{\mathrm{H}}\right\rangle
$$

The angular momentum operators do nothing under axes inversion. One way to see that is to think of $\psi_{\mathrm{H}}$ as written in terms of states of definite $y$-momentum. Then the angular momentum operators merely add scalar factors $m \hbar$ to those states. These do not affect what happens to the remainder of the inner product under axes inversion. Alternatively, note that $\widehat{L}_{y}=\hbar(z \partial / \partial x-x \partial / \partial z) / \mathrm{i}$ and each term has two position coordinates that change sign. And surely spin should behave the same as orbital angular momentum.

If the angular momentum operators do nothing under axes inversion, the parities of the initial and final atomic or nuclear states will have to be equal. So the parity selection rule for magnetic dipole transitions is the opposite from the one for electric dipole transitions. The parity has to stay the same in the transition.

Assuming again that the wave motion is in the $z$-direction, each higher multipole order $\ell$ adds a factor $z_{i}$ to the electric or magnetic inner product. This factor changes sign under axes inversion. So for increasing $\ell$, alternatingly the atomic or nuclear parity must flip over or stay the same.

If the parity selection rule is violated for a multipole term, the term is zero. However, if it is not violated, the term may still be zero for some other reason. The most important other reason is angular momentum. Atomic and nuclear states have definite angular momentum. Consider again the electric dipole inner product

$$
\left\langle\psi_{\mathrm{L}}\right| x_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

States of different angular momentum are orthogonal. That is a consequence of the fact that the momentum operators are Hermitian. What it means is that the inner product above is zero unless $x_{i} \psi_{\mathrm{H}}$ has at least some probability of having the same angular momentum as state $\psi_{\mathrm{L}}$. Now the factor $x_{i}$ can be written in
terms of spherical harmonics using chapter 4.2.3, table 4.3:

$$
x_{i}=\sqrt{\frac{8 \pi}{3}} r_{i}\left(Y_{1}^{-1}-Y_{1}^{1}\right)
$$

So it is a sum of two states, both with square angular momentum quantum number $l_{x}=1$, but with $z$ angular momentum quantum number $m_{x}=-1$, respectively 1 .

Now recall the rules from chapter 7.4.2 for combining angular momenta:

$$
Y_{1}^{-1} \psi_{\mathrm{H}} \quad \Longrightarrow \quad j_{\mathrm{net}}=j_{\mathrm{H}}-1, j_{\mathrm{H}}, \text { or } j_{\mathrm{H}}+1 \quad m_{\mathrm{net}}=m_{\mathrm{H}}-1
$$

Here $j_{\mathrm{H}}$ is the quantum number of the square angular momentum of the atomic or nuclear state $\psi_{\mathrm{H}}$. And $m_{\mathrm{H}}$ is the quantum number of the $z$ angular momentum of the state. Similarly $j_{\text {net }}$ and $m_{\text {net }}$ are the possible values for the quantum numbers of the combined state $Y_{1}^{-1} \psi_{\mathrm{H}}$. Note again that $m_{x}$ and $m_{\mathrm{H}}$ values simply add together. However, the $j_{\mathrm{H}^{-}}$-value changes by up to $l_{x}=1$ unit in either direction. (But if $j_{\mathrm{H}}=0$, the combined state cannot have zero angular momentum.)
(It should be noted that you should be careful in combining these angular momenta. The normal rules for combining angular momenta apply to different sources of angular momentum. Here the factor $x_{i}$ does not describe an additional source of angular momentum, but a particle that already has been given an angular momentum within the wave function $\psi_{\mathrm{H}}$. That means in particular that you should not try to write out $Y_{1}^{-1} \psi_{\mathrm{H}}$ using the Clebsch-Gordan coefficients of chapter $12.7,\{\mathrm{~N} .13\}$. If you do not know what Clebsch-Gordan coefficients are, you have nothing to worry about.)

To get a nonzero inner product, one of the possible states of net angular momentum above will need to match the quantum numbers $j_{\mathrm{L}}$ and $m_{\mathrm{L}}$ of state $\psi_{\mathrm{L}}$. So

$$
j_{\mathrm{L}}=j_{\mathrm{H}}-1, j_{\mathrm{H}}, \text { or } j_{\mathrm{H}}+1 \quad m_{\mathrm{L}}=m_{\mathrm{H}}-1
$$

(And if $j_{\mathrm{H}}=0, j_{\mathrm{L}}$ cannot be zero.) But recall that $x_{i}$ also contained a $Y_{1}^{1}$ state. That state will allow $m_{\mathrm{L}}=m_{\mathrm{H}}+1$. And if you take a wave that has its electric field in the $z$-direction instead of the $x$-direction, you also get a $Y_{1}^{0}$ state that gives the possibility $m_{\mathrm{L}}=m_{\mathrm{H}}$.

So the complete selection rules for electric dipole transitions are

$$
j_{\mathrm{L}}=j_{\mathrm{H}}-1, j_{\mathrm{H}}, \text { or } j_{\mathrm{H}}+1 \quad m_{\mathrm{L}}=m_{\mathrm{H}}-1, m_{\mathrm{H}}, \text { or } m_{\mathrm{H}}+1 \quad \pi_{\mathrm{L}} \pi_{\mathrm{H}}=-1
$$

where $\pi$ means the parity. In addition, at least one of $j_{\mathrm{L}}$ or $j_{\mathrm{H}}$ must be nonzero. And as always for these quantum numbers, $j_{\mathrm{L}} \geqslant 0$ and $\left|m_{\mathrm{L}}\right| \leqslant j_{\mathrm{L}}$. Equivalent selection rules were written down for the hydrogen atom with spin-orbit interaction in chapter 7.4.4.

For magnetic dipole transitions, the relevant inner product is

$$
\left\langle\psi_{\mathrm{L}}\right| \widehat{L}_{i, y}+g_{i} \widehat{S}_{i . y}\left|\psi_{\mathrm{H}}\right\rangle
$$

Note that it is either $\widehat{L}_{y}$ or $\widehat{S}_{y}$ that is applied on $\psi_{\mathbf{H}}$, not both at the same time. It will be assumed that $\psi_{\mathrm{H}}$ is written in terms of states with definite angular momentum in the $z$-direction. In those terms, the effect of $\widehat{L}_{y}$ or $\widehat{S}_{y}$ is known to raise or lower the corresponding magnetic quantum number $m$ by one unit, chapter 12.11. Which means that the net angular momentum can change by one unit. (Like when opposite orbital angular momentum and spin change into parallel ones. Note also that for the hydrogen atom in the nonrelativistic approximation of chapter 4.3, there is no interaction between the electron spin and the orbital motion. In that case, the magnetic dipole term can only change the value of $m_{l}$ or $m_{s}$ by one unit. Simply put, only the direction of the angular momentum changes. That is normally a trivial change as empty space has no preferred direction.)

One big limitation is that in either an electric or a magnetic dipole transition, the net atomic or nuclear angular momentum $j$ can change by no more than one unit. Larger changes in angular momentum require higher multipole orders $\ell$. These add a factor $z_{i}^{\ell-1}$ to the inner products. Now it turns out that:

$$
z_{i}^{\ell-1} \sim \frac{(\ell-1)!\sqrt{4 \pi(2 \ell-1)}}{(2 \ell-1)!!} r_{i}^{\ell-1} Y_{\ell-1}^{0}+\ldots \quad(2 \ell-1)!!\equiv \frac{(2 \ell-1)!}{2^{\ell-1}(\ell-1)!}(\text { A.174 })
$$

Here the dots stand for spherical harmonics with lower square angular momentum. (To verify the above relation, use the Rayleigh formula of $\{A .6\}$, and expand the Bessel function and the exponential in it in Taylor series.) So the factor $z_{i}^{\ell-1}$ has a maximum azimuthal quantum number $l$ equal to $\ell-1$. That means that the maximum achievable change in atomic or nuclear angular momentum increases by one unit for each unit increase in multipole order $\ell$.

It follows that the first multipole term that can be nonzero has $\ell=\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right|$, or $\ell=1$ if the angular momenta are equal. At that multipole level, either the electric or the magnetic term can be nonzero, depending on parity. Normally this term will then dominate the transition process, as the terms of still higher multipole levels are ballparked to be much smaller.

A further limitation applies to orbital angular momentum. The angular momentum operators will not change the orbital angular momentum values. And the factors $z_{i}^{\ell-1}$ and $x_{i}$ can only change it by up to $\ell-1$, respectively 1 units. So the minimum difference in possible orbital angular momentum values will have to be no larger than that:

$$
\begin{equation*}
\text { electric: } \quad\left|l_{\mathrm{H}}-l_{\mathrm{L}}\right|_{\min } \leqslant \ell \quad \text { magnetic: } \quad\left|l_{\mathrm{H}}-l_{\mathrm{L}}\right|_{\min } \leqslant \ell-1 \tag{A.175}
\end{equation*}
$$

This is mainly important for single-particle states of definite orbital angular momentum. That includes the hydrogen atom, even with the relativistic spin-
orbit interaction. (But it does assume the nonrelativistic Hamiltonian in the actual transition process.)

The final limitation is that $j_{\mathrm{H}}$ and $j_{\mathrm{L}}$ cannot both be zero. The reason is that if $j_{\mathrm{H}}$ is zero, the possible angular momentum values of $z_{i}^{\ell-1} x_{i} j_{\mathrm{H}}$ are those of $z_{i}^{\ell-1} x_{i}$. And those values do not include zero to match $j_{\mathrm{L}}=0$. (According to the rules of quantum mechanics, the probability of zero angular momentum is given by the inner product with the spherical harmonic $Y_{0}^{0}$ of zero angular momentum. Since $Y_{0}^{0}$ is just a constant, the inner product is proportional to the average of $z_{i}^{\ell-1} x_{i}$ on a spherical surface around the origin. That average will be zero because by symmetry positive values of $x_{i}$ will average away against corresponding negative ones.)

## A.25.6 Ballpark decay rates

It may be interesting to find some actual ballpark values for the spontaneous decay rates. More sophisticated values, called the Weisskopf and Moszkowski estimates, will be derived in a later subsection. However, they are ballparks one way or the other.

It will be assumed that only a single particle, electron or proton, changes states. It will also be assumed that the first multipole contribution allowed by angular momentum and parity is indeed nonzero and dominant. In fact, it will be assumed that this contribution is as big as it can reasonably be.

To get the spontaneous emission rate, first the proper amplitude $\mathcal{E}_{0}$ of the electric field to use needs to be identified. The same relativistic procedure as in \{A.24\} may be followed to show it should be taken as

$$
\text { spontaneous emission: } \quad \mathcal{E}_{0}=\sqrt{\frac{\hbar \omega}{\epsilon_{0} \mathcal{V}}}
$$

That assumes that the entire system is contained in a very large periodic box of volume $\mathcal{V}$. Also, $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is the permittivity of space

Next, Fermi's golden rule of chapter 7.6 .1 says that the transition rate is

$$
\lambda_{\mathrm{H} \rightarrow \mathrm{~L}}=\overline{\left|H_{21}\right|^{2}} \frac{2 \pi}{\hbar} \frac{\mathrm{~d} N}{\mathrm{~d} E}
$$

Here $H_{21}$ is approximated as the first allowed (nonzero) multipole contribution $H_{21, i}^{\mathrm{E} \ell}$ or $H_{21, i}^{\mathrm{M} \ell}$. So the additional higher order nonzero contributions are ignored, The overline means that this contribution needs to be suitably averaged over all directions of the electromagnetic wave. Further $\mathrm{d} N / \mathrm{d} E$ is the number of photon states in the periodic box per unit energy range. This is the density of states as given in chapter 6.3 (6.7). Using the Planck-Einstein relation it is:

$$
\frac{\mathrm{d} N}{\mathrm{~d} E}=\frac{\omega^{2}}{\hbar \pi^{2} c^{3}} \mathcal{V}
$$

Ballpark matrix coefficients were given in subsection A.25.4. However, a more accurate estimate is desirable. The main problem is the factor $r_{i, k}^{\ell-1}$ in the matrix elements (A.171) and (A.172). This factor equals $z_{i}^{\ell-1}$ if the $z$ axis is taken to be in the direction of wave motion. According to the previous subsection

$$
z_{i}^{\ell-1} \sim \frac{(\ell-1)!\sqrt{4 \pi(2 \ell-1)}}{(2 \ell-1)!!} r_{i}^{\ell-1} Y_{\ell-1}^{0}+\ldots
$$

The dots indicate spherical harmonics of lower angular momentum that do not do anything. Only the shown term is relevant for the contribution of lowest multipole order. So only the shown term should be ballparked. That can be done by estimating $r_{i}$ as $R$, and $Y_{\ell-1}^{0}$ as $1 / \sqrt{4 \pi}$, (which is exact for $\ell=1$ ).

The electric inner product contains a further factor $x_{i}$, taking the $x$-axis in the direction of the electric field. That will be accounted for by upping the value of $\ell$ one unit in the expression above. The magnetic inner product contains angular momentum operators. Since not much can be said about these easily, they will simply be estimated as $\hbar$.

Putting it all together, the estimated decay rates become

$$
\lambda^{\mathrm{E} \ell} \sim \alpha \omega(k R)^{2 \ell} \frac{4(2 \ell+1)}{(2 \ell+1)!!^{2}} f^{\mathrm{E} \ell} \quad \lambda^{\mathrm{M} \ell} \sim \alpha \omega(k R)^{2 \ell} \frac{4(2 \ell-1)}{(2 \ell-1)!!^{2}}\left(\frac{\hbar}{2 m_{i} c R}\right)^{2} f^{\mathrm{M} \ell}
$$

Here

$$
\alpha=\frac{e^{2}}{4 \pi \epsilon_{0} \hbar c} \approx \frac{1}{137}
$$

is the so-called fine structure constant. with $e=1.610^{-19} \mathrm{C}$ the proton or electron charge, $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ the permittivity of space, and $c=$ $310^{8} \mathrm{~m} / \mathrm{s}$ the speed of light. This nondimensional constant gives the strength of the coupling between charged particles and photons, so it should obviously be there. The factor $\omega$ is expected for dimensional reasons; it gives the decay rate units of inverse time. The nondimensional factor $k R$ reflects the fact that the atom or nucleus has difficulty interacting with the photon because its size is so small compared to the photon wave length. That is worse for higher multipole orders $\ell$, as their photons produce less of a field near the origin. The factors $f^{\mathrm{E} \ell}$ and $f^{\mathrm{M} \ell}$ represent unknown corrections for the errors in the ballparks. These factors are hoped to be 1. (Fat chance.) As far as the remaining numerical factors are concerned,

The final parenthetical factor in the magnetic decay rate was already discussed in subsection A.25.4. It normally makes magnetic decays slower than electric ones of the same multipole order, but faster than electric ones of the next order.

These estimates are roughly similar to the Weisskopf ones. While they tend to be larger, that is largely compensated for by the fact that in the above
estimates $R$ is the mean radius. In the Weisskopf estimates it is the edge of the nucleus.

In any case, actual decay rates can vary wildly from either pair of estimates. For example, nuclei satisfy an approximate conservation law for a quantity called isospin. If the transition violates an approximate conservation law like that, the transition rate will be unusually small. Also, it may happen that the initial and final wave functions have little overlap. That means that the regions where they both have significant magnitude are small. (These regions should really be visualized in the high-dimensional space of all the particle coordinates.) In that case, the transition rate can again be unexpectedly small.

Conversely, if a lot of particles change state in a transition, their individual contributions to the matrix element can add up to an unexpectedly large transition rate.

## A.25.7 Wave functions of definite angular momentum

The analysis so far has represented the electromagnetic field in terms of photon states of definite linear momentum. But it is usually much more convenient to use states of definite angular momentum. That allows full use of the conservation laws of angular momentum and parity.

The states of definite angular momentum have vector potentials given by the photon wave functions of addendum \{A.21.7\}. For electric $\mathrm{E} \ell$ and magnetic $\mathrm{M} \ell$ multipole transitions respectively:

$$
\overrightarrow{A_{\gamma}^{\mathrm{E}}}=\frac{A_{0}}{k} \nabla \times \vec{r} \times \nabla j_{\ell}(k r) Y_{\ell}^{m}(\theta, \phi) \quad \vec{A}_{\gamma}^{\mathrm{M}}=A_{0} \vec{r} \times \nabla j_{\ell}(k r) Y_{\ell}^{m}(\theta, \phi)
$$

Here $j_{\ell}$ is a spherical Bessel function, $\{$ A. 6$\}$ and $Y_{\ell}^{m}$ a spherical harmonic, chapter 4.2.3. The azimuthal angular momentum quantum number of the photon is $\ell$. Its quantum number of angular momentum in the chosen $z$-direction is $m$. The electric state has parity $(-1)^{\ell}$ and the magnetic one $(-1)^{\ell-1}$. (That includes the intrinsic parity, unlike in some other sources). Further $A_{0}$ is a constant.

The contribution of a particle $i$ to the matrix element is as before

$$
H_{21, i}=-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| \vec{A}_{i} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle-\frac{q_{i}}{2 m_{i}} g_{i}\left\langle\psi_{\mathrm{L}}\right| \overrightarrow{\mathcal{B}}_{i} \cdot \widehat{\vec{S}}_{i}\left|\psi_{\mathrm{H}}\right\rangle \quad \overrightarrow{\mathcal{B}}_{i}=\nabla_{i} \times \vec{A}_{i}
$$

But now, for electric transitions $\vec{A}_{i}$ needs to be taken as the complex conjugate of the photon wave function $\vec{A}_{\gamma}^{\text {E }}$ above, evaluated at the position of particle i. For magnetic transitions $\vec{A}_{i}$ needs to be taken as the complex conjugate of $\vec{A}_{\gamma}^{\mathrm{M}}$. The complex conjugates are a result of the quantization of radiation, $\{\mathrm{A} .24\}$. And they would not be there for absorption. (The classical reasons are much like the story for plane electromagnetic waves given earlier. But here
the nonquantized waves are too messy to even bother about, in this author's opinion.)

The matrix elements can be approximated assuming that the wave length of the photon is large compared to the size $R$ of the atom or nucleus. The approximate contribution of the particle to the $\mathrm{E} \ell$ electric matrix element is then, $\{\mathrm{D} .43 .2\}$,

$$
H_{21, i}^{\mathrm{E} \ell} \approx-\mathrm{i} q_{i} c A_{0} \frac{(\ell+1) k^{\ell}}{(2 \ell+1)!!}\left\langle\psi_{\mathrm{L}}\right| r_{i}^{\ell} Y_{\ell i}^{m *}\left|\psi_{\mathrm{H}}\right\rangle
$$

The subscript $i$ on the spherical harmonic means that its arguments are the coordinates of particle $i$. For nuclei, the above result is again suspect for the reasons discussed in $\{\mathrm{N} .14\}$.

The approximate contribution of the particle to the $\mathrm{M} \ell$ magnetic matrix element is $\{\mathrm{D} .43 .2\}$,

$$
H_{21, i}^{\mathrm{M} \ell} \approx \frac{q_{i}}{2 m_{i}} A_{0} \frac{(\ell+1) k^{\ell}}{(2 \ell+1)!!}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} r_{i}^{\ell} Y_{\ell i}^{m *}\right) \cdot\left(\frac{2}{\ell+1} \widehat{\vec{L}}_{i}+g_{i} \widehat{\vec{S}}_{i}\right)\left|\psi_{\mathrm{H}}\right\rangle
$$

In general these matrix elements will need to be summed over all particles.
The above matrix elements can be analyzed similar to the earlier linear momentum ones. However, the above matrix elements allow you to keep the atom or nucleus in a fixed orientation. For the linear momentum ones, the nuclear orientation must be changed if the direction of the wave is to be held fixed. And in any cases, linear momentum matrix elements must be averaged over all directions of wave propagation. That makes the above matrix elements much more convenient in most cases.

Finally the matrix elements can be converted into spontaneous decay rates using Fermi's golden rule of chapter 7.6.1. In doing so, the needed value of the constant $A_{0}$ and corresponding density of states are, following $\{\mathrm{A} .21 .7\}$ and \{A.24\},

$$
A_{0}=-\frac{1}{\mathrm{i} c} \sqrt{\frac{\hbar \omega}{\ell(\ell+1) \epsilon_{0} r_{\max }}} \quad \frac{\mathrm{d} N}{\mathrm{~d} E} \approx \frac{1}{\hbar \pi c} r_{\max }
$$

This assumes that the entire system is contained inside a very big sphere of radius $r_{\text {max }}$. This radius $r_{\text {max }}$ disappear in the final answer, and the final decay rates will be the ones in infinite space. (Despite the absence of $r_{\text {max }}$ they do not apply to a finite sphere, because the density of states above is an approximation for large $r_{\text {max }}$.)

It is again convenient to nondimensionalize the matrix elements using some suitably defined typical atomic or nuclear radius $R$. Recent authorative sources, like [33] and $\llbracket 4 \rrbracket$, take the nuclear radius equal to

$$
\begin{equation*}
R=1.2 A^{1 / 3} \mathrm{fm} \tag{A.177}
\end{equation*}
$$

Here $A$ is the number of protons and neutrons in the nucleus and a fm is $10^{-15}$ m.

The final decay rates are much like the ones (A.176) found earlier for linear momentum modes. In fact, linear momentum modes should give the same answer as the angular ones, if correctly averaged over all directions of the linear momentum. The decay rates in terms of angular momentum modes are:

$$
\begin{gather*}
\lambda^{\mathrm{E} \ell}=\alpha \omega(k R)^{2 \ell} \frac{2(l+1)}{l(2 l+1)!!^{2}}\left|h_{21}^{\mathrm{E} \ell}\right|^{2}  \tag{A.178}\\
\lambda^{\mathrm{M} \ell}=\alpha \omega(k R)^{2 \ell} \frac{2(l+1)}{l(2 l+1)!!^{2}}\left(\frac{\hbar}{2 m c R}\right)^{2}\left|h_{21}^{\mathrm{M} \ell}\right|^{2} \tag{A.179}
\end{gather*}
$$

where $\alpha \approx 1 / 137$ is again the fine structure constant. The nondimensional matrix elements in these expressions are

$$
\begin{equation*}
\left|h_{21}^{\mathrm{E} \ell}\right|=\sum_{i} \sqrt{4 \pi} \frac{q_{i}}{e}\left\langle\psi_{\mathrm{L}}\right| r_{i}^{\ell} Y_{\ell i}^{m *} / R^{\ell}\left|\psi_{\mathrm{H}}\right\rangle \tag{A.180}
\end{equation*}
$$

$$
\begin{equation*}
\left|h_{21}^{\mathrm{M} \ell}\right|=\sum_{i} \sqrt{4 \pi} \frac{q_{i}}{e} \frac{m}{m_{i}}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} r_{i}^{\ell} Y_{\ell i}^{m *} / R^{\ell-1}\right) \cdot\left(\frac{2 \widehat{\vec{L}}_{i}}{(\ell+1) \hbar}+\frac{g_{i} \widehat{\vec{S}}_{i}}{\hbar}\right)\left|\psi_{\mathrm{H}}\right\rangle \tag{A.181}
\end{equation*}
$$

The sum is over the electrons or protons and neutrons, with $q_{i}$ their charge and $m_{i}$ their mass. The reference mass $m$ would normally be taken to be the mass of an electron for atoms and of a proton for nuclei. That means that for the electron or proton the charge and mass ratios can be set equal to 1 . For an electron $g_{i}$ is about 2, while for a proton, $g_{i}$ would be about 5.6 if the effect of the neighboring protons and neutrons is ignored. For the neutron, the (net) charge $q_{i}$ is zero. Therefore the electric matrix element is zero, and so is the first term in the magnetic one. In the second term, however, the charge and mass of the proton need to be used, along with $g_{i}=-3.8$, assuming again that the effect of the neighboring protons and neutrons is ignored.

## A.25.8 Weisskopf and Moszkowski estimates

The Weisskopf and Moszkowski estimates are ballpark spontaneous decay rates. They are found by ballparking the nondimensional matrix elements (A.180) and (A.181) given in the previous subsection. The estimates are primarily intended for nuclei. However, they can easily be adopted to the hydrogen atom with a few straightforward changes.

It is assumed that a single proton numbered $i$ makes the transition. The rest of the nucleus stays unchanged and can therefore be ignored in the analysis. Note that this does not take into account that the proton and the rest of the
nucleus should move around their common center of gravity. Correction factors for that can be applied, see [33] and [11] for more. In a similar way, the case that a single neutron makes the transition can be accounted for.

It is further assumed that the initial and final wave functions of the proton are of a relatively simple form, In spherical coordinates:

$$
\psi_{\mathrm{H}}=R_{\mathrm{H}}\left(r_{i}\right) \Theta_{l_{\mathrm{H}} j_{\mathrm{H}}}^{m_{j \mathrm{H}}}\left(\theta_{i}, \phi_{i}\right) \quad \Longrightarrow \quad \psi_{\mathrm{L}}=R_{\mathrm{L}}\left(r_{i}\right) \Theta_{l_{\mathrm{L}} j_{\mathrm{L}}}^{m_{j \mathrm{~L}}}\left(\theta_{i}, \phi_{i}\right)
$$

These wave functions are very much like the $R_{n l}\left(r_{i}\right) Y_{l}^{m_{l}}\left(\theta_{i}, \phi_{i}\right) \uparrow$ wave functions for the electron in the hydrogen atom, chapter 4.3. However, for nuclei, it turns out that you want to combine the orbital and spin states into states with definite net angular momentum $j$ and definite net angular momentum $m_{j}$ in the chosen $z$-direction. Such combinations take the form

$$
\Theta_{l j}^{m_{j}}\left(\theta_{i}, \phi_{i}\right)=c_{1} Y_{l}^{m_{j}-\frac{1}{2}}\left(\theta_{i}, \phi_{i}\right) \uparrow+c_{2} Y_{l}^{m_{j}+\frac{1}{2}}\left(\theta_{i}, \phi_{i}\right) \downarrow
$$

The coefficients $c_{1}$ and $c_{2}$ are of no interest here, but you can find them in chapter 12.82 if needed.

In fact even for the hydrogen atom you really want to take the initial and final states of the electron of the above form. That is due to a small relativistic effect called "spin-orbit interaction," \{A.39\}. It just so happens that for nuclei, the spin-orbit effect is much larger. Note however that the electric matrix element ignores the spin-orbit effect. That is a significant problem, $\{\mathrm{N} .14\}$. It will make the ballparked electric decay rate for nuclei suspect. But there is no obvious way to fix it.

The nondimensional electric matrix element (A.180) can be written as an integral over the spherical coordinates of the proton. It then falls apart into a radial integral and an angular one:

$$
\left|h_{21}^{\mathrm{E} \ell}\right| \approx \int R_{\mathrm{L}}\left(r_{i}\right)^{*}\left(r_{i} / R\right)^{\ell} R_{\mathrm{H}}\left(r_{i}\right) r_{i}^{2} \mathrm{~d} r_{i} \quad \sqrt{4 \pi} \int \Theta_{l_{\mathrm{L}} \mathrm{~L}_{\mathrm{L}} i}^{m_{j \mathrm{~L}}^{*}} Y_{\ell i}^{m *} \Theta_{l_{\mathrm{H} j} i}^{m_{j \mathrm{H}}} \sin ^{2} \theta_{i} \mathrm{~d} \theta_{i} \mathrm{~d} \phi_{i}
$$

Note that in the angular integral the product of the angular wave functions implicitly involves inner products between the spin states. Spin states are orthonormal, so their product is 0 if the spins are different and 1 if they are the same.

The bottom line is that the square electric matrix element can be written as a product of a radial factor,

$$
\begin{equation*}
f_{\mathrm{LH}}^{\mathrm{rad}, \ell} \equiv\left[\int R_{\mathrm{L}}^{*}\left(r_{i}\right)\left(r_{i} / R\right)^{\ell} R_{\mathrm{H}}\left(r_{i}\right) r_{i}^{2} \mathrm{~d} r_{i}\right]^{2} \tag{A.182}
\end{equation*}
$$

and an angular one,

$$
\begin{equation*}
f_{\mathrm{LH}}^{\mathrm{ang}, \ell} \equiv\left[\sqrt{4 \pi} \int \Theta_{l_{\mathrm{L}} j_{\mathrm{L} i} i}^{m_{j \mathrm{~L}}{ }^{2}} Y_{\ell i}^{m *} \Theta_{l_{\mathrm{H} j \mathrm{H} i}}^{m_{j \mathrm{H}}} \sin ^{2} \theta_{i} \mathrm{~d} \theta_{i} \mathrm{~d} \phi_{i}\right]^{2} \tag{A.183}
\end{equation*}
$$

As a result, the electric multipole decay rate (A.180) becomes

$$
\begin{equation*}
\lambda^{\mathrm{E} \ell}=\alpha \omega(k R)^{2 \ell} \frac{2(l+1)}{l(2 l+1)!!^{2}} f_{\mathrm{LH}}^{\mathrm{rad}, \ell} f_{\mathrm{LH}}^{\mathrm{ang}, \ell} \tag{A.184}
\end{equation*}
$$

Here the trailing factors represent the square matrix element.
A similar expression can be written for the nondimensional magnetic matrix element, $\{\mathrm{D} .43 .3\}$ : It gives the decay rate (A.181) as

$$
\begin{equation*}
\lambda^{\mathrm{M} \ell}=\alpha \omega(k R)^{2 \ell} \frac{2(l+1)}{l(2 l+1)!!^{2}}\left(\frac{\hbar}{2 m c R}\right)^{2} f_{\mathrm{LH}}^{\mathrm{rad}, \ell-1} f_{\mathrm{LH}}^{\mathrm{ang}, \ell} f_{\mathrm{LH}}^{\mathrm{mom}}, \ell \tag{A.185}
\end{equation*}
$$

In this case, there is an third factor related to the spin and orbital angular momentum operators that appear in the magnetic matrix element. Also, the integrand in the radial factor is one order of $r$ lower than in the electric element. That is due to the nabla operator $\nabla$ in the magnetic element. It means that in terms of the radial electric factor as defined above, the value of $\ell$ to use is one unit below the actual multipole order.

Consider now the values of these factors. The radial factor (A.182) is the simplest one. The Weisskopf and Moszkowski estimates use a very crude approximation for this factor. They assume that the radial wave functions are equal to some constant up to the nuclear radius $R$ and zero beyond it. (This assumption is not completely illogical for nuclei, as nuclear densities are fairly constant until the nuclear edge.) That gives, $\{\mathrm{D} .43 .3\}$,

$$
f_{\mathrm{LH}}^{\mathrm{rad}, \ell}=\left(\frac{3}{\ell+3}\right)^{2}
$$

Note that the magnetic decay rate uses $\ell+2$ in the denominator instead of $\ell+3$ because of the lower power of $r_{i}$.

More reasonable assumptions for the radial wave functions are possible. For a hydrogen atom instead of a nucleus, the obvious thing to do is to use the actual radial wave functions $R_{n l}$ from chapter 4.3. That gives the radial factors listed in table A.1. These take $R$ equal to the Bohr radius. That explains why some values are so large: the average radial position of the electron can be much larger than the Bohr radius in various excited states. In the table, $n$ is the principal quantum number that gives the energy of the state. Further $l$ is the azimuthal quantum number of orbital angular momentum. The two pairs of $n l$ values correspond to those of the initial and final states; in what order does not make a difference. There are two radial factors listed for each pair of states. The first value applies to electric and multipole transitions at the lowest possible multipole order. That is usually the important one, because normally transition rates decrease rapidly with multipole order.

| $n l$ | $n l$ | $f_{\mathrm{LH}}^{\mathrm{rad},\|\Delta l\|}$ | $f_{\mathrm{LH}}^{\mathrm{rad},\|\Delta l\|+2}$ | $n l$ | $n l$ | $f_{\mathrm{LH}}^{\mathrm{rad},\|\Delta l\|}$ | $f_{\mathrm{LH}}^{\mathrm{rad},\|\Delta l\|+2}$ |

Table A.1: Radial integral correction factors for hydrogen atom wave functions.

To understand the given values more clearly, first consider the relation between multipole order and orbital angular momentum. The derived matrix elements implicitly assume that the potential of the proton or electron only depends on its position, not its spin. So spin does not really affect the orbital motion. That means that the multipole order for nontrivial transitions is constrained by orbital angular momentum conservation, [33]:

$$
\begin{equation*}
\left|l_{\mathrm{H}}-l_{\mathrm{L}}\right| \leqslant \ell \leqslant l_{\mathrm{H}}+l_{\mathrm{L}} \tag{A.186}
\end{equation*}
$$

Note that this is a consequence of (A.175) within the single-particle model. It is just like for the nonrelativistic hydrogen atom, (7.17). (M1 transitions that merely change the direction of the spin, like a $Y_{0}^{0} \uparrow$ to $Y_{0}^{0} \downarrow$ one, are irrelevant since they do not change the energy. Fermi's golden rule makes the transition rate for transitions with no energy change theoretically zero, chapter 7.6.1.)

The minimum multipole order implied by the left-hand constraint above corresponds to an electric transition because of parity. However, this transition may be impossible because of net angular momentum conservation or because $\ell$ must be at least 1. That will make the transition of lowest multipole order a magnetic one. The magnetic transition still uses the same value for the radial factor though. The second radial factor in the table is provided since the nexthigher electric multipole order might reasonably compete with the magnetic one.

More realistic radial factors for nuclei can be formulated along similar lines. The simplest physically reasonable assumption is that the protons and neutrons are contained within an impenetrable sphere of radius $R$. A hydrogen-like numbering system of the quantum states can again be used, figure 14.14, with one difference. For hydrogen, a given energy level $n$ allows all orbital momentum quantum numbers $l$ up to $n-1$. For nuclei, $l$ must be even if $n$ is odd and vice-versa, chapter 14.12.1. Also, while for the (nonrelativistic) hydrogen atom the energy does not depend on $l$, for nuclei that is only a rough approximation. (It assumes that the nuclear potential is like an harmonic oscillator one, and that is really crude.)

Radial factors for the impenetrable-sphere model using this numbering system are given in table A.2.

These results illustrate the limitations of M1 transitions in the single-particle model. Because of the condition (A.186) above and parity, the orbital quantum number $l$ cannot change in M1 transitions. A glance at the table then shows that the radial factor is zero unless the initial and final radial states are identical. (That is a consequence of the orthonormality of the energy states.) So M1 transitions cannot change the radial state. All they can do is change the direction of the orbital angular momentum or spin of a given state. Obviously that is ho-hum, though with a spin-orbit term it may still do something. Without a spin-orbit term, there would be no energy change, and Fermi's golden rule would make the theoretical transition rate then zero. That is similar to the

Table A.2: More realistic radial integral correction factors for nuclei.
limitation of M1 transitions for the nonrelativistic hydrogen atom in chapter 7.4.4.

It may be instructive to use the more realistic radial factors of table A. 2 to get a rough idea of the errors in the Weisskopf ones. The initial comparison will be restricted to changes in the principal quantum number of no more than one unit. That means that transitions between widely separated shells will be ignored. Also, only the lowest possible multipole level will be considered. That corresponds to the first of each pair of values in the table. Assuming an electric transition, $\ell$ is the difference between the $l$ values in the table. Consider now the following two simple approximations of the radial factor:

$$
\text { Weisskopf: } f_{\mathrm{LH}}^{\mathrm{rad}, \ell}=\left(\frac{3}{\ell+3}\right)^{2} \quad \text { Empirical: } f_{\mathrm{LH}}^{\mathrm{rad}, \ell}=\left(\frac{1.5}{\ell+3}\right)^{2} \text { or } 1
$$

(A.187)

The coefficient 1.5 comes from a least square approximation of the data. For M1 transitions, the exact value 1 should be used.

For the given data, it turns out that the Weisskopf estimate is on average too large by a factor 5 . In the worst case, the Weisskopf estimate is too large by a factor 18 . The empirical formula is on average off by a factor 2 , and in the worst case by a factor 4 .

If any arbitrary change in principal quantum number is allowed, the possible errors are much larger. In that case the Weisskopf estimates are off by average factor of 20 , and a maximum factor of 4000 . The empirical estimates are off by an average factor of 8 , and a maximum one of 1000 . Including the next number in table A. 2 does not make much of a difference here.

These errors do depend on the change in principal quantum numbers. For changes in principal quantum number no larger than 2 units, the empirical estimate is off by a factor no greater that 10 . For 3 or 4 unit changes, the estimate is off by a factor no greater than about 100. The absolute maximum error factor of 1000 occurs for a 5 unit change in the principal quantum number. For the Weiskopf estimate, multiply these maximum factors by 4.

These data exclude the M1 transitions mentioned earlier, for which the radial factor is either 0 or 1 exactly. The value 0 implies an infinite error factor for a Weisskopf-type estimate of the radial factor. But that requires an M1 transition with at least a two unit change in the principal quantum number. In other words, it requires an M1 transition with a huge energy change.

Consider now the angular factor in the decay rates (A.184) and (A.185). It arises from integrating the spherical harmonics, (A.183). But the actual angular factor really used in the transition rates (A.184) and (A.185) also involves an averaging over the possible angular orientations of the initial atom. (This orientation is reflected in its magnetic quantum number $m_{j \mathrm{H}}$.) And it involves a summation over the different angular orientations of the final nucleus that can be decayed to. The reason is that experimentally, there is usually no control
over the orientation of the initial and final nuclei. An average initial nucleus will have an average orientation. But each final orientation that can be decayed to is a separate decay process, and the decay rates add up. (The averaging over the initial orientations does not really make a difference; all orientations decay at the same rate, since space has no preferred direction. The summation over the final orientations is critical.)

| $j_{\text {L }}$ | $j_{\text {H }}$ : | $1 / 2$ | $3 / 2$ | 5/2 | 7/2 | 9/2 | 11/2 | 13/2 |

Table A.3: Angular integral correction factors $f_{\mathrm{LH}}^{\text {ang },|\Delta j|}$ and $f_{\mathrm{LH}}^{\text {ang, }|\Delta j|+1}$ for the Weisskopf electric unit and the Moszkowski magnetic one. The correction for the Weisskopf magnetic unit is to cross it out and write in the Moszkowski unit.

Values for the angular factor are in table A.3. For the first and second number of each pair respectively:

$$
\ell=\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right| \quad \ell=\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right|+1
$$

More generally, the angular factor is given by, [33, p. 878],

$$
\begin{equation*}
f_{\mathrm{LH}}^{\text {ang }, \ell}=\left(2 j_{\mathrm{L}}+1\right)\left[\langle\ell 0|\left|j_{\mathrm{H}} 1 / 2\right\rangle\left|j_{\mathrm{L}}-1 / 2\right\rangle\right]^{2} \tag{A.188}
\end{equation*}
$$

Here the quantity in square brackets is called a Clebsch-Gordan coefficient. For small angular momenta, values can be found in figure 12.5. For larger values, refer to $\{\mathrm{N} .13\}$. The leading factor is the reason that the values in the table are not the same if you swap the initial and final states. When the final state has the higher angular momentum, there are more nuclear orientations that an atom can decay to.

It may be noted that [11, p. 9-178] gives the above factor for electric transitions as

$$
f_{\mathrm{LH}}^{\text {ang }, \ell}=\left(2 j_{\mathrm{L}}+1\right)(2 \ell+1)\left(2 l_{\mathrm{L}}+1\right)\left(2 l_{\mathrm{H}}+1\right)\left(\begin{array}{ccc}
l_{\mathrm{L}} & l_{\mathrm{H}} & l \\
0 & 0 & 0
\end{array}\right)^{2}\left\{\begin{array}{ccc}
l_{\mathrm{L}} & j_{\mathrm{L}} & \frac{1}{2} \\
j_{\mathrm{H}} & l_{\mathrm{H}} & \ell
\end{array}\right\}^{2}
$$

Here the array in parentheses is the so-called Wigner 3 j symbol and the one in curly brackets is the Wigner 6 j symbol, $\{\mathrm{N} .13\}$. The idea is that this expression will take care of the selection rules automatically. And so it does, if you assume that the multiply-defined $l$ is $\ell$, as the author seems to say. Of course, selection rules might be a lot easier to evaluate than 3 j and 6 j symbols.

For magnetic multipole transitions, with $\ell=\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right|=\left|l_{\mathrm{H}}-l_{\mathrm{L}}\right|+1$, the same source comes up with

$$
\begin{aligned}
f_{\mathrm{LH}}^{\text {ang }, \ell}= & \left(2 j_{\mathrm{L}}+1\right) \frac{3(2 \ell+1)^{2}(2 \ell-1)}{2 \ell}\left(2 l_{\mathrm{L}}+1\right)\left(2 l_{\mathrm{H}}+1\right) \\
& \times\left(\begin{array}{ccc}
l_{\mathrm{L}} & l_{\mathrm{H}} & \ell-1 \\
0 & 0 & 0
\end{array}\right)^{2}\left\{\begin{array}{ccc}
l_{\mathrm{L}} & j_{\mathrm{L}} & \frac{1}{2} \\
j_{\mathrm{H}} & l_{\mathrm{H}} & \ell-1
\end{array}\right\}^{2}\left\{\begin{array}{ccc}
l_{\mathrm{H}} & l_{\mathrm{L}} & \ell-1 \\
\frac{1}{2} & \frac{1}{2} & 1 \\
j_{\mathrm{H}} & j_{\mathrm{L}} & \ell
\end{array}\right\}^{2}
\end{aligned}
$$

Here the final array in curly brackets is the Wigner 9j symbol. The bad news is that the 6 j symbol does not allow any transitions of lowest multipole order to occur! Someone familiar with 6 j symbols can immediately see that from the so-called triangle inequalities that the coefficients of 6 j symbols must satisfy, $\{\mathrm{N} .13\}$. Fortunately, it turns out that if you simply leave out the 6 j symbol, you do seem to get the right values and selection rules.

The magnetic multipole matrix element also involves an angular momentum factor. This factor turns out to be relatively simple, $\{\mathrm{D} .43 .3\}$ :

$$
\begin{aligned}
& f_{\mathrm{LH}}^{\mathrm{mom},|\Delta j|}=\left(g_{i}-\frac{2}{1+\ell}\right)^{2} \ell^{2} \quad \begin{array}{l}
l_{\min }=j_{\min }+\frac{1}{2} \\
l_{\max }=j_{\max }-\frac{1}{2}
\end{array} \\
& f_{\mathrm{LH}}^{\operatorname{mom},|\Delta j|+1}=\left\{\begin{array}{ll}
\left(g_{i}-\frac{2-4 j_{\min }}{1+\ell}\right)^{2}\left(j_{\max }+1\right)^{2} & l_{\min }=j_{\min }-\frac{1}{2} \neq 0 \\
l_{\max }=j_{\max }-\frac{1}{2}
\end{array}\right] \begin{array}{ll}
\left(g_{i}-\frac{2+4\left(\ell+j_{\min }\right)}{1+\ell}\right)^{2} j_{\min }^{2} & l_{\min }+\frac{1}{2} \\
l_{\max }=j_{\max }+\frac{1}{2}
\end{array}
\end{aligned}
$$

(A.189)

Here "min" and "max" refer to whatever is the smaller, respectively larger, one of the initial and final values.

The stated values of the orbital angular momentum $l$ are the only ones allowed by parity and the orbital angular momentum conservation condition (A.186). In particular, consider the first expression above, for the minimum multipole order $\ell=|\Delta j|$. According to this expression, the change in orbital angular momentum cannot exceed the change in net angular momentum. That forbids a lot of magnetic transitions in a shell model setting, transitions that seem perfectly fine if you only look at net angular momentum and parity. Add to that the earlier observation that M1 transitions cannot change the radial state at all. Magnetic transitions are quite handicapped according to the single-particle model used here.

Of course, a single-particle model is not exact for multiple-particle systems. In a more general setting, transitions that in the ideal model would violate the orbital angular momentum condition can occur. For example, consider the possibility that the true state picks up some uncertainty in orbital angular momentum.

Presumably such transitions would be unexpectedly slow compared to transitions that do not violate any approximate orbital angular momentum conditions. That makes estimating the magnetic transition rates much more tricky. After all, for nuclei the net angular momentum is usually known with some confidence, but the orbital angular momentum of individual nucleons is not.

Fortunately, for electric transitions orbital angular momentum conservation does not provide additional limitations. Here the orbital requirements are already satisfied if net angular momentum and parity are conserved.

The derived decay estimates are now used to define standard decay rates. It is assumed that the multipole order is minimal, $\ell=|\Delta j|$, and that the final angular momentum is $\frac{1}{2}$. As table A. 3 shows, that makes the angular factor equal to 1 . The standard electric decay rate is then

$$
\begin{equation*}
\lambda_{\text {Weisskopf }}^{\mathrm{E} \ell}=\alpha \omega(k R)^{2 \ell} \frac{2(\ell+1)}{\ell(2 \ell+1)!!^{2}} \frac{9}{(\ell+3)^{2}} \tag{A.190}
\end{equation*}
$$

This decay rate is called the "Weisskopf unit" for electric multipole transitions. It is commonly indicated by W.u. Measured actual decay rates are compared to this unit to get an idea whether they are unusually high or low.

Note that the decay rates are typically orders of magnitude off the mark. That is due to effects that cannot be accounted for. Nucleons are not independent particles by far. And even if they were, their radial wave functions would not be constant. The used expression for the electric matrix element is probably no good, $\{\mathrm{N} .14\}$. And especially higher multipole orders depend very sensitively on the nuclear radius, which is imprecisely defined.

The standard magnetic multipole decay rate becomes under the same assumptions:

$$
\lambda_{\text {Moszkowski }}^{\mathrm{M} \ell}=\alpha \omega(k R)^{2 \ell} \frac{2(\ell+1)}{\ell(2 \ell+1)!!^{2}}\left(\frac{\hbar}{2 m c R}\right)^{2} \frac{9}{(\ell+2)^{2}}\left(g_{i}-\frac{2}{\ell+1}\right)^{2} \ell^{2}
$$

(A.191)

This decay rate is called the "Moszkowski unit" for magnetic multipole transitions.

Finally, it should be mentioned that it is customary to ballpark the final momentum factor in the Moszkowski unit by 40. That is because Jesus spent 40 days in the desert. Also, the factor $(\ell+2)^{2}$ is customarily replaced by $(\ell+3)^{2}$, [10, p. 9-49], [36, p. 676], [5, p. 242], because, hey, anything for a laugh. Other sources keep the $(\ell+2)^{2}$ factor just like it is, [11, p. 9-178], [31, p. 332], because,
hey, why not? Note that the Handbook of Physics does both, depending on the author you look at. Taking the most recent of the cited sources, as well as $\llbracket 4 \rrbracket$, as reference the new and improved magnetic transition rate may be:

$$
\begin{equation*}
\lambda_{\text {Weisskopf }}^{\mathrm{M} \ell}=\alpha \omega(k R)^{2 \ell} \frac{2(\ell+1)}{\ell(2 \ell+1)!!^{2}}\left(\frac{\hbar}{m c R}\right)^{2} \frac{90}{(\ell+3)^{2}} \tag{A.192}
\end{equation*}
$$

This is called the Weisskopf magnetic unit. Note that the humor factor has been greatly increased. Whether there is a 2 or 3 in the final fraction does not make a difference. All analysis is relative to the perception of the observer. Where one perceives a 2 another sees a 3. Everthing is relative, as Einstein supposedly said, and otherwise quantum mechanics definitely did.

Note that the Weisskopf magnetic unit looks exactly like the electric one, except for the addition of a zero and the additional fraction between parentheses. That makes it easier to remember, especially for those who can remember the electric unit. For them the savings in time is tremendous, because they do not have to look up the correct expression. That can save a lot of time because many standard references have the formulae wrong or in some weird system of units. All that time is much better spend trying to guess whether your source, or your editor, uses a 2 or a 3 .

## A.25.9 Errors in other sources

There is a notable amount of errors in descriptions of the Weisskopf and Moszkowski estimates found elsewhere. That does not even include not mentioning that the electric multipole rate is likely no good, $\{\mathrm{N} .14\}$. Or randomly using $\ell+2$ or $\ell+3$ in the Weisskopf magnetic unit.

These errors are more basic. The first edition of the Handbook of Physics, [10, p. 9-49], gives both Weisskopf units wrong. Squares are missing on the $\ell+3$, and so is the fine structure constant. The other numerical factors are consistent between the two units, but not right. Probably a strangely normalized matrix element is given, rather than the stated decay rates $\lambda$, and in addition the square was forgotten.

The same Handbook, [10, p. 9-110], but a different author, uses $g_{i} / 2$ instead of $g_{i}$ in the Moszkowski estimate. (Even physicists themselves can get confused if sometimes you define $g_{\mathrm{p}}$ to be 5.6 and sometimes 2.8 , which also happens to be the magnetic moment $\mu_{\mathrm{p}}$ in nuclear magnetons, which is often used as a "nondimensional" unit where $g_{\mathrm{p}}$ is really needed, etcetera.) More seriously, this error is carried over to the given plot of the Moszkowski unit, which is therefore wrong. Which is in addition to the fact that the nuclear radius used in it is too large by modern standards, using 1.4 rather than 1.2 in (A.177).

The error is corrected in the second edition, [11, p. 9-178], but the Moszkowski plot has disappeared. In favor of the Weisskopf magnetic unit, of course.

Think of the scientific way in which the Weisskopf unit has been deduced! This same reference also gives the erroneous angular factor for magnetic transitions mentioned in the previous subsection. Of course an additional 6 j symbol that sneaks in is easily overlooked.

No serious errors were observed in [33]. (There is a readily-fixed error in the conversion formula for when the initial and final states are swapped.) This source does not list the Weisskopf magnetic unit. (Which is certainly defensible in view of its nonsensical assumptions.) Unfortunately non-SI units are used.

The electric dipole matrix element in [36, p. 676] is missing a factor $1 / 2 c$. The claim that this element can be found by "straightforward calculation" is ludicrous. Not only is the mathematics convoluted, it also involves the major assumption that the potentials depend only on position. A square is missing in the Moszkowski unit, and the table of corresponding widths are in eV instead of the stated $1 / \mathrm{s}$.

All three units are given incorrectly in [31, p. 332]. There is a factor $4 \pi$ in them that should not be there. And the magnetic rate is missing a factor $\ell^{2}$. The constant in the numerical expression for M3 transitions should be 15, not 16 . Of course, the difference is negligible compared to replacing the parenthetical expression by 40 , or compared to the orders of magnitude that the estimate is commonly off anyway.

The Weisskopf units are listed correctly in [5, p. 242]. Unfortunately non-SI units are used. The Moszkowski unit is not mentioned. The nonsensical nature of the Weisskopf magnetic unit is not pointed out. Instead it is claimed that it is found by a similar calculation as the electric unit.

## A. 26 Fourier inversion theorem and Parseval

This note discusses Fourier series, Fourier integrals, and Parseval's identity.
Consider first one-dimensional Fourier series. They apply to functions $f(x)$ that are periodic with some given period $\ell$ :

$$
f(x+\ell)=f(x) \quad \text { for all } x
$$

Such functions can be written as a "Fourier series:"

$$
\begin{equation*}
f(x)=\sum_{\text {all } k} f_{k} \frac{e^{\mathrm{i} k x}}{\sqrt{\ell}} \quad f_{k}=\int_{0}^{\ell} f(x) \frac{e^{-\mathrm{i} k x}}{\sqrt{\ell}} \mathrm{~d} x \tag{A.193}
\end{equation*}
$$

Here the $k$ values are those for which the exponentials are periodic of period $\ell$. According to the Euler formula (2.5), that means that $k \ell$ must be a whole multiple $n$ of $2 \pi$, so

$$
\begin{equation*}
k=n \frac{2 \pi}{\ell} \quad n=\ldots,-3,-2,-1,0,1,2,3, \ldots \tag{A.194}
\end{equation*}
$$

Note that notations for Fourier series can vary from one author to the next. The above form of the Fourier series is the prefered one for quantum mechanics. The reason is that the functions $e^{i k x} / \sqrt{\ell}$ form an orthonormal set:

$$
\int_{0}^{\ell} \frac{e^{-\mathrm{i} k x}}{\sqrt{\ell}} \frac{e^{\mathrm{i} \underline{\underline{z}}}}{\sqrt{\ell}} \mathrm{~d} x=\left\{\begin{array}{l}
1 \text { if } k=\underline{k}  \tag{A.195}\\
0 \text { if } k \neq \underline{k}
\end{array}\right.
$$

Quantum mechanics just loves orthonormal sets of functions. In particular, note that the above functions are momentum eigenfunctions. Just apply the linear momentum operator $\widehat{p}=\hbar \mathrm{d} / \mathrm{id} x$ on them. That shows that their linear momentum is given by the de Broglie relation $p=\hbar k$. Here these momentum eigenfunctions are properly normalized. They would not be using different conventions.

That any (reasonable) periodic function $f(x)$ can be written as a Fourier series was already shown in $\{$ D. 8$\}$. That derivation took $\ell$ be the half-period. The formula for the coefficients $f_{k}$ can also be derived directly: simply multiply the expression (A.193) for $f(x)$ with $e^{\mathrm{i} \underline{\underline{k}}} / \sqrt{\ell}$ for any arbitrary value of $\underline{k}$ and integrate over $x$. Because of the orthonormality (A.195), the integration produces zero for all $k$ except if $k=\underline{k}$, and then it produces $f_{\underline{k}}$ as required.

Note from (A.193) that if you known $f(x)$ you can find all the $f_{k}$. Conversely, if you know all the $f_{k}$, you can find $f(x)$ at every position $x$. The formulae work both ways.

But the symmetry goes even deeper than that. Consider the inner product of a pair of functions $f(x)$ and $g(x)$ :

$$
\int_{0}^{\ell} f^{*}(x) g(x) \mathrm{d} x=\int_{0}^{\ell} \sum_{\text {all } k} f_{k}^{*} \frac{e^{-\mathrm{i} k x}}{\sqrt{\ell}} \sum_{\text {all } \underline{k}} g_{\underline{k}} \frac{e^{\mathrm{i} \underline{\underline{k}} x}}{\sqrt{\ell}} \mathrm{~d} x
$$

Using the orthonormality property (A.195) that becomes

$$
\begin{equation*}
\int_{0}^{\ell} f^{*}(x) g(x) \mathrm{d} x=\sum_{\text {all } k} f_{k}^{*} g_{k} \tag{A.196}
\end{equation*}
$$

Now note that if you look at the coefficients $f_{k}$ and $g_{k}$ as the coefficients of infinite-dimensional vectors, then the right hand side is just the inner product of these vectors. In short, Fourier series preserve inner products.

Therefore the equation above may be written more concisely as

$$
\begin{equation*}
\langle f(x) \mid g(x)\rangle=\left\langle f_{k} \mid g_{k}\right\rangle \tag{A.197}
\end{equation*}
$$

This is the so-called "Parseval identity." Now transformations that preserve inner products are called "unitary" in mathematics. So the Parseval identity shows that the transformation from periodic functions to their Fourier coefficients is unitary.

That is quite important for quantum mechanics. For example, assume that $f(x)$ is a wave function of a particle stuck on a ring of circumference $\ell$. Wave functions should be normalized, so:

$$
\int_{0}^{\ell} f^{*}(x) f(x) \mathrm{d} x=1=\sum_{\text {all } k} f_{k}^{*} f_{k}
$$

According to the Born interpretation, the left hand side says that the probability of finding the particle is 1 , certainty, if you look at every position on the ring. But according to the orthodox interpretation of quantum mechanics, $f_{k}^{*} f_{k}$ in the right hand side gives the probability of finding the particle with momentum $p=\hbar k$. The fact that the total sum is 1 means physically that it is certain that the particle will be found with some momentum.

So far, only periodic functions have been covered. But functions in infinite space can be handled by taking the period $\ell$ infinite. To do that, note from (A.194) that the $k$ values of the Fourier series are spaced apart over a distance

$$
\Delta k=\frac{2 \pi}{\ell}
$$

In the limit $\ell \rightarrow \infty, \Delta k$ becomes an infinitesimal increment $\mathrm{d} k$, and the sums become integrals. Now in quantum mechanics it is convenient to replace the coefficients $f_{k}$ by a new function $f(k)$ that is defined so that

$$
f_{k}=\sqrt{\Delta k} f(k) \quad \Longrightarrow \quad\left|f_{k}\right|^{2}=|f(k)|^{2} \Delta k
$$

The reason that this is convenient is that $\left|f_{k}\right|^{2}$ gives the probability for wave number $k$. Then for a function $f(k)$ that is defined as above, $|f(k)|^{2}$ gives the probability per unit $k$-range.

If the above definition and $\sqrt{\ell}=\sqrt{2 \pi} / \Delta k$ are substituted into the Fourier series expressions (A.193), in the limit $\ell \rightarrow \infty$ it gives the "Fourier integral" formulae:

$$
\begin{equation*}
f(x)=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{\infty} f(k) e^{\mathrm{i} k x} \mathrm{~d} k \quad f(k)=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{\infty} f(x) e^{-\mathrm{i} k x} \mathrm{~d} x \tag{A.198}
\end{equation*}
$$

In books on mathematics you will usually find function $f(k)$ indicated as $\widehat{f}(k)$, to clarify that it is a completely different function than $f(x)$. Unfortunately, the hat is already used for something much more important in quantum mechanics. So in quantum mechanics you will have to look at the argument, $x$ or $k$, to know which function it really is.

Of course, in quantum mechanics you are often more interested in the momentum than in the wave number. So it is often convenient to define a new function $f(p)$ so that $|f(p)|^{2}$ gives the probability per unit momentum range
rather than unit wave number range. Because $p=\hbar k$, the needed rescaling of $f(k)$ is by a factor $\sqrt{\hbar}$. That gives

$$
\begin{equation*}
f(x)=\frac{1}{\sqrt{2 \pi \hbar}} \int_{-\infty}^{\infty} f(p) e^{\mathrm{i} p x / \hbar} \mathrm{d} p \quad f(p)=\frac{1}{\sqrt{2 \pi \hbar}} \int_{-\infty}^{\infty} f(x) e^{-\mathrm{i} p x / \hbar} \mathrm{d} x \tag{A.199}
\end{equation*}
$$

Using similar substitutions as for the Fourier series, the Parseval identity (A.197) becomes

$$
\int_{-\infty}^{\infty} f^{*}(x) g(x) \mathrm{d} x=\int_{-\infty}^{\infty} f^{*}(k) g(k) \mathrm{d} k=\int_{-\infty}^{\infty} f^{*}(p) g(p) \mathrm{d} p
$$

or in short

$$
\begin{equation*}
\langle f(x) \mid g(x)\rangle=\langle f(k) \mid g(k)\rangle=\langle f(p) \mid g(p)\rangle \tag{A.200}
\end{equation*}
$$

This identity is sometimes called the "Plancherel theorem," after a later mathematician who generalized its applicability. The bottom line is that Fourier integral transforms too conserve inner products.

So far, this was all one-dimensional. However, the extension to three dimensions is straightforward. The first case to be considered is that there is periodicity in each Cartesian direction:
$f\left(x+\ell_{x}, y, z\right)=f(x, y, z) \quad f\left(x, y+\ell_{y}, z\right)=f(x, y, z) \quad f\left(x, y, z+\ell_{z}\right)=f(x, y, z)$
In quantum mechanics, this would typically correspond to the wave function of a particle stuck in a periodic box of dimensions $\ell_{x} \times \ell_{y} \times \ell_{z}$. When the particle leaves such a box through one side, it reenters it at the same time through the opposite side.

There are now wave numbers for each direction,

$$
k_{x}=n_{x} \frac{2 \pi}{\ell_{x}} \quad k_{y}=n_{y} \frac{2 \pi}{\ell_{y}} \quad k_{z}=n_{z} \frac{2 \pi}{\ell_{z}}
$$

where $n_{x}, n_{y}$, and $n_{z}$ are whole numbers. For brevity, vector notations may be used:

$$
\vec{r} \equiv x \hat{\imath}+y \hat{\jmath}+z \hat{k} \quad \vec{k} \equiv k_{x} \hat{\imath}+k_{y} \hat{\jmath}+k_{z} \hat{k} \quad e^{\mathrm{i} k_{x} x} e^{\mathrm{i} k_{y} y} e^{\mathrm{i} k_{z} z}=e^{\mathrm{i} \vec{k} \cdot \vec{r}}
$$

Here $\vec{k}$ is the "wave number vector."
The Fourier series for a three-dimensional periodic function is

$$
\begin{equation*}
f(\vec{r})=\sum_{\text {all } \vec{k}} f_{\vec{k}} \frac{e^{\mathrm{i} \vec{k} \cdot \vec{r}}}{\sqrt{\mathcal{V}}} \quad f_{\vec{k}}=\int_{\mathcal{V}} f(\vec{r}) \frac{e^{-\mathrm{i} \vec{k} \cdot \vec{r}}}{\sqrt{\mathcal{V}}} \mathrm{~d}^{3} \vec{r} \tag{A.201}
\end{equation*}
$$

Here $f(\vec{r})$ is shorthand for $f(x, y, z)$ and $\mathcal{V}=\ell_{x} \ell_{y} \ell_{z}$ is the volume of the periodic box.

The above expression for $f$ may be derived by applying the one-dimensional transform in each direction in turn:

$$
\begin{aligned}
f(x, y, z) & =\sum_{\text {all } k_{x}} f_{k_{x}}(y, z) \frac{e^{\mathrm{i} k_{x} x}}{\sqrt{\ell_{x}}} \\
& =\sum_{\text {all } k_{x} \text { all } k_{y}} f_{k_{x} k_{y}}(z) \frac{e^{\mathrm{i} k_{x} x}}{\sqrt{\ell_{x}}} \frac{e^{\mathrm{i} k_{y} y}}{\sqrt{\ell_{y}}} \\
& =\sum_{\text {all } k_{x}} \sum_{\text {all } k_{y} \text { all } k_{z}} f_{k_{x} k_{y} k_{z}} \frac{e^{\mathrm{i} k_{x} x}}{\sqrt{\ell_{x}}} \frac{e^{\mathrm{i} k_{y} y}}{\sqrt{\ell_{y}}} \frac{e^{\mathrm{i} k_{z} z}}{\sqrt{\ell_{z}}}
\end{aligned}
$$

This is equivalent to what is given above, except for trivial changes in notation. The expression for the Fourier coefficients can be derived analogous to the onedimensional case, integrating now over the entire periodic box.

The Parseval equality still applies

$$
\begin{equation*}
\langle f(\vec{r}) \mid g(\vec{r})\rangle=\left\langle f_{\vec{k}} \mid g_{\vec{k}}\right\rangle \tag{A.202}
\end{equation*}
$$

where the left inner product integration is over the periodic box.
For infinite space

$$
f(\vec{r})=\frac{1}{\sqrt{2 \pi}^{3}} \int_{\text {all } \vec{k}} f(\vec{k}) e^{\mathrm{i} \vec{k} \cdot \vec{r}} \mathrm{~d}^{3} \vec{k} \quad f(\vec{k})=\frac{1}{{\sqrt{2 \pi^{3}}}^{3}} \int_{\text {all } \vec{r}} f(\vec{r}) e^{-\mathrm{i} \vec{k} \cdot \vec{r}} \mathrm{~d}^{3} \vec{r}
$$

(A.203)

$$
\begin{equation*}
f(\vec{r})=\frac{1}{{\sqrt{2 \pi \hbar^{3}}}^{3}} \int_{\text {all } \vec{p}} f(\vec{p}) e^{\mathrm{i} \cdot \vec{r} / \hbar} \mathrm{d}^{3} \vec{p} \quad f(\vec{p})=\frac{1}{{\sqrt{2 \pi \hbar^{3}}}^{3}} \int_{\text {all } \vec{r}} f(\vec{r}) e^{-\mathrm{i} \vec{p} \cdot \vec{r} / \hbar} \mathrm{d}^{3} \vec{r} \tag{A.204}
\end{equation*}
$$

$$
\begin{equation*}
\langle f(\vec{r}) \mid g(\vec{r})\rangle=\langle f(\vec{k}) \mid g(\vec{k})\rangle=\langle f(\vec{p}) \mid g(\vec{p})\rangle \tag{A.205}
\end{equation*}
$$

These expressions are all obtained completely analogously to the one-dimensional case.

Often, the function is a vector rather than a scalar. That does not make a real difference since each component transforms the same way. Just put a vector symbol over $f$ and $g$ in the above formulae. The inner products are now defined as

$$
\begin{gathered}
\langle\vec{f}(\vec{r}) \mid \vec{g}(\vec{r})\rangle \equiv\left\langle f_{x}(\vec{r}) \mid g_{x}(\vec{r})\right\rangle+\left\langle f_{y}(\vec{r}) \mid g_{y}(\vec{r})\right\rangle+\left\langle f_{z}(\vec{r}) \mid g_{z}(\vec{r})\right\rangle \\
\left\langle\vec{f}_{\vec{k}} \mid \vec{g}_{\vec{k}}\right\rangle \equiv\left\langle f_{\overrightarrow{\vec{k}_{x}}} \mid g_{\vec{k}_{x}}\right\rangle+\left\langle f_{\vec{k} y} \mid g_{\overrightarrow{k_{y}} y}\right\rangle+\left\langle f_{\vec{k}_{z}} \mid g_{\vec{k}_{z}}\right\rangle
\end{gathered}
$$

For the picky, converting Fourier series into Fourier integrals only works for well-behaved functions. But to show that it also works for nasty wave functions, you can set up a limiting process in which you approximate the nasty functions increasingly accurately using well-behaved ones. Now if the wellbehaved functions are converging, then their Fourier transforms are too. The inner products of the differences in functions are the same according to Parseval. And according to the abstract Lebesgue variant of the theory of integration, that is enough to ensure that the transform of the nasty function exists. This works as long as the nasty wave function is square integrable. And wave functions need to be in quantum mechanics.

But being square integrable is not a strict requirement, as you may have been told elsewhere. A lot of functions that are not square integrable have meaningful, invertible Fourier transforms. For example, functions whose square magnitude integrals are infinite, but absolute value integrals are finite can still be meaningfully transformed. That is more or less the classical version of the inversion theorem, in fact. (See D.C. Champeney, A Handbook of Fourier Theorems, for more.)

## A. 27 Details of the animations

This note explains how the wave packet animations of chapter 7.11 and 7.12 were obtained. If you want a better understanding of unsteady solutions of the Schrödinger equation and their boundary conditions, this is a good place to start. In fact, deriving such solutions is a popular item in quantum mechanics books for physicists.

First consider the wave packet of the particle in free space, as shown in chapter 7.11.1. An energy eigenfunction with energy $E$ in free space takes the general form

$$
\psi_{E}=C_{\mathrm{f}} \mathrm{e}^{\mathrm{i} p x / \hbar}+C_{\mathrm{b}} e^{-\mathrm{i} p x / \hbar} \quad p=\sqrt{2 m E}
$$

where $p$ is the momentum of the particle and $C_{\mathrm{f}}$ and $C_{\mathrm{b}}$ are constants.
To study a single wave packet coming in from the far left, the coefficient $C_{\mathrm{b}}$ has to be set to zero. The reason was worked out in chapter 7.10: combinations of exponentials of the form $C_{\mathrm{b}} \mathrm{e}^{-\mathrm{i} p x / \hbar}$ produce wave packets that propagate backwards in $x$, from right to left. Therefore, a nonzero value for $C_{\mathrm{b}}$ would add an unwanted second wave packet coming in from the far right.

Figure A.9: Example energy eigenfunction for the particle in free space.

With only the coefficient $C_{\mathrm{f}}$ of the forward moving part left, you may as well scale the eigenfunction so that $C_{\mathrm{f}}=1$, simplifying it to

$$
\psi_{E}=e^{\mathrm{i} p x / \hbar}
$$

A typical example is shown in figure A.9. Plus and minus the magnitude of the eigenfunction are shown in black, and the real part is shown in red. This wave function is an eigenfunction of linear momentum, with $p$ the linear momentum.

To produce a coherent wave packet, eigenfunctions with somewhat different energies $E$ have to be combined together. Since the momentum is given by $p$ $=\sqrt{2 m E}$, different energy means different momentum $p$; therefore the wave packet can be written as

$$
\begin{equation*}
\Psi(x, t)=\int_{\text {all } p} c(p) e^{-\mathrm{i} E t / \hbar} \psi_{E}(x) \mathrm{d} p \tag{A.206}
\end{equation*}
$$

where $c(p)$ is some function that is only nonzero in a relatively narrow range of momenta $p$ around the nominal momentum. Except for that basic requirement, the choice of the function $c(p)$ is quite arbitrary. Choose some suitable function $c(p)$, then use a computer to numerically integrate the above integral at a large number of plot points and times. Dump the results into your favorite animation software and bingo, out comes the movie.

Figure A.10: Example energy eigenfunction for a particle entering a constant accelerating force field.

Next consider the animation of chapter 7.11.2, where the particle accelerates along a downward potential energy ramp starting from point A. A typical energy eigenfunction is shown in figure A.10. Since to the left of point A, the potential energy is still zero, in that region the energy eigenfunction is still of the form

$$
\psi_{E}=C_{\mathrm{f}}^{1} \mathrm{e}^{\mathrm{i} p_{\mathrm{c}}^{1} x / \hbar}+C_{\mathrm{b}}^{\mathrm{l}} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x / \hbar} \text { for } x<x_{\mathrm{A}} \quad p_{\mathrm{c}}^{1}=\sqrt{2 m E}
$$

where $p_{\mathrm{c}}^{1}$ is the momentum that a classical particle of energy $E$ would have in the left region. (Quantum mechanics looks at the complete wave function, not just a single point of it, and would say that the momentum is uncertain.)

In this case, it can no longer be argued that the coefficient $C_{\mathrm{b}}^{1}$ must be zero to avoid a packet entering from the far right. After all, the $C_{\mathrm{b}}^{\mathrm{b}} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x / \hbar}$ term does not extend to the far right anymore. To the right of point $A$, the potential changes linearly with position, and the exponentials are no longer valid.

In fact, it is known that the solution of the Hamiltonian eigenvalue problem in a region with a linearly varying potential is a combination of two weird functions Ai and Bi that are called the "Airy" functions. The bad news is that if you are interested in learning more about their properties, you will need an advanced mathematical handbook like [1] or at least look at addendum \{A.29\}. The good news is that free software to evaluate these functions and their first derivatives is readily available on the web. The general solution for a linearly varying potential is of the form

$$
\psi_{E}=C_{\mathrm{B}} \operatorname{Bi}(\bar{x})+C_{\mathrm{A}} \operatorname{Ai}(\bar{x}) \quad \bar{x}=\sqrt[3]{\frac{2 m V^{\prime}}{\hbar^{2}}} \frac{V-E}{V^{\prime}} \quad V^{\prime} \equiv \frac{\mathrm{d} V}{\mathrm{~d} x}
$$

Note that $(V-E) / V^{\prime}$ is the $x$-position measured from the point where $V=E$. Also note that the cube root is negative, so that $\bar{x}$ is.

It may be deduced from the approximate analysis of addendum $\{\mathrm{A} .28\}$ that to prevent a second wave packet coming in from the far right, Ai and Bi must appear together in the combination $\mathrm{Bi}+\mathrm{iAi}$ as shown in figure A.10. The fact that no second packet comes in from the far right in the animation can be taken as an experimental confirmation of that result, so there seems little justification to go over the messy argument.

To complete the determination of the eigenfunction for a given value of $E$, the constants $C_{\mathrm{f}}^{\mathrm{l}}, C_{\mathrm{b}}^{\mathrm{l}}$ and $C^{\mathrm{r}}$ must still be determined. That goes as follows. For now, assume that $C^{\mathrm{r}}$ has the provisional value $c^{\mathrm{r}}=1$. Then provisional values $c_{\mathrm{f}}^{1}$ and $c_{\mathrm{b}}^{1}$ for the other two constants may be found from the requirements that the left and right regions give the same values for $\psi_{E}$ and $\mathrm{d} \psi_{E} / \mathrm{d} x$ at the point A in figure A. 10 where they meet:

$$
\begin{gathered}
c_{\mathrm{f}}^{1} e^{\mathrm{i} p_{\mathrm{c}}^{1} x_{\mathrm{A}} / \hbar}+c_{\mathrm{b}}^{1} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x_{\mathrm{A}} / \hbar}=c^{\mathrm{r}}\left[\operatorname{Bi}\left(\bar{x}_{\mathrm{A}}\right)+\mathrm{iAi}\left(\bar{x}_{\mathrm{A}}\right)\right] \\
c_{\mathrm{f}}^{1} \frac{\mathrm{i} p_{\mathrm{c}}^{1}}{\hbar} e^{\mathrm{i} p_{c}^{1} x_{\mathrm{A}} / \hbar}-c_{\mathrm{b}}^{1} \frac{\mathrm{i} p_{\mathrm{c}}^{1}}{\hbar} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x_{\mathrm{A}} / \hbar}=c^{\mathrm{r}}\left[\operatorname{Bi}^{\prime}\left(\bar{x}_{\mathrm{A}}\right)+\mathrm{i} \mathrm{Ai}^{\prime}\left(\bar{x}_{\mathrm{A}}\right)\right] \frac{\mathrm{d} \bar{x}}{\mathrm{~d} x}
\end{gathered}
$$

That is equivalent to two equations for the two constants $c_{\mathrm{f}}^{1}$ and $c_{\mathrm{b}}^{1}$, since everything else can be evaluated, using the mentioned software. So $c_{f}^{l}$ and $c_{\mathrm{b}}^{\mathrm{b}}$ can be found from solving these two equations.

As the final step, it is desirable to normalize the eigenfunction $\psi_{E}$ so that $C_{\mathrm{f}}^{\mathrm{I}}$ $=1$. To do so, the entire provisional eigenfunction can be divided by $c_{\mathrm{f}}^{1}$, giving $C_{\mathrm{b}}^{\mathrm{l}}=c_{\mathrm{b}}^{\mathrm{l}} / c_{\mathrm{f}}^{\mathrm{l}}$ and $C^{\mathrm{r}}=c^{\mathrm{r}} / c_{\mathrm{f}}^{\mathrm{l}}$. The energy eigenfunction has now been found. And since $C_{\mathrm{f}}^{\mathrm{p}}=1$, the $e^{\mathrm{i} p_{\mathrm{c}} x / \hbar}$ term is exactly the same as the free space energy eigenfunction of the first example. That means that if the eigenfunctions $\psi_{E}$ are combined into a wave packet in the same way as in the free space case, (A.206) with $p$ replaced by $p_{\mathrm{c}}^{1}$, the $e^{\mathrm{i} \mathrm{p}_{\mathrm{c}}^{1} x / \hbar}$ terms produce the exact same wave packet coming in from the far left as in the free space case.

For larger times, the $C_{\mathrm{b}}^{\mathrm{l}} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x / \hbar}$ terms produce a "reflected" wave packet that returns toward the far left. Note that $e^{-\mathrm{i} p_{c}^{1} x / \hbar}$ is the complex conjugate of $e^{\mathrm{i} p_{c}^{1} x / \hbar}$,
and it can be seen from the unsteady Schrödinger equation that if the complex conjugate of a wave function is taken, it produces a reversal of time. Wave packets coming in from the far left at large negative times become wave packets leaving toward the far left at large positive times. However, the constant $C_{\mathrm{b}}^{\mathrm{l}}$ turns out to be very small in this case, so there is little reflection.

Figure A.11: Example energy eigenfunction for a particle entering a constant decelerating force field.

Next consider the animation of chapter 7.11.3, where the particle is turned back by an upward potential energy ramp. A typical energy eigenfunction for this case is shown in figure A.11. Unlike in the previous example, where the argument $\bar{x}$ of the Airy functions was negative at the far right, here it is positive. Table books that cover the Airy functions will tell you that the Airy function Bi blows up very strongly with increasing positive argument $\bar{x}$. Therefore, if the solution in the right hand region would involve any amount of Bi , it would locate the particle at infinite $x$ for all times. For a particle not at infinity, the solution in the right hand region can only involve the Airy function Ai. That function decays rapidly with positive argument $\bar{x}$, as seen in figure A.11.

The further determination of the energy eigenfunctions proceeds along the same lines as in the previous example: give $C^{\mathrm{r}}$ a provisional value $c^{\mathrm{r}}=1$, then compute $c_{\mathrm{f}}^{1}$ and $c_{\mathrm{b}}^{1}$ from the requirements that the left and right regions produce the same values for $\psi$ and $\mathrm{d} \psi / \mathrm{d} x$ at the point A where they meet. Finally divide the eigenfunction by $c_{\mathrm{f}}^{1}$. The big difference is that now $C_{\mathrm{b}}^{\mathrm{l}}$ is no longer small; $C_{\mathrm{b}}^{1}$ turns out to be of unit magnitude just like $C_{\mathrm{f}}^{\mathrm{l}}$. It means that the incoming wave packet is reflected back completely.

Figure A.12: Example energy eigenfunction for the harmonic oscillator.
For the harmonic oscillator of chapter 7.11.4, the analysis is somewhat different. In particular, chapter 4.1.2 showed that the energy levels of the one-dimensional harmonic oscillator are discrete,

$$
E_{n}=\frac{2 n+1}{2} \hbar \omega \text { for } n=0,1,2, \ldots
$$

so that unlike the motions just discussed, the solution of the Schrödinger equation is a sum, rather than the integral (A.206),

$$
\Psi(x, t)=\sum_{n=0}^{\infty} c_{n} e^{-\mathrm{i} E_{n} t / \hbar} h_{n}(x)
$$

However, for large $n$ the difference between summation and integration is small.
Also, while the energy eigenfunctions $h_{n}(x)$ are not exponentials as for the free particle, for large $n$ they can be pairwise combined to approximate such exponentials. For example, eigenfunction $h_{50}$, shown in figure A.12, behaves near the center point much like a cosine if you scale it properly. Similarly, $h_{51}$ behaves much like a sine. A cosine plus i times a sine gives an exponential, according to the Euler formula (2.5). Create similar exponential combinations of eigenfunctions with even and odd values of $n$ for a range of $n$ values, and there are the approximate exponentials that allow you to create a wave packet that is at the center point at time $t=0$. In the animation, the range of $n$ values was centered around $n=50$, making the nominal energy hundred times the ground state energy. The exponentials degenerate over time, since their component eigenfunctions have slightly different energy, hence time evolution. That explains why after some time, the wave packet can return to the center point going the other way.

Figure A.13: Example energy eigenfunction for a particle encountering a brief accelerating force.

For the particle of chapter 7.12.1 that encounters a brief accelerating force, an example eigenfunction looks like figure A.13. In this case, the solution in the far right region is similar to the one in the far left region. However, there cannot be a term of the form $e^{-\mathrm{i} p_{c}^{r} x / \hbar}$ in the far right region, because when the eigenfunctions are combined, it would produce an unwanted wave packet coming in from the far right. In the middle region of linearly varying potential, the wave function is again a combination of the two Airy functions. The way to find the constants now has an additional step. First give the constant $C^{r}$ of the far right exponential the provisional value $c^{r}=1$ and from that, compute provisional values $c_{\mathrm{A}}^{\mathrm{m}}$ and $c_{\mathrm{B}}^{\mathrm{m}}$ by demanding that the Airy functions give the same values for $\psi$ and $\mathrm{d} \psi / \mathrm{d} x$ as the far-right exponential at point B , where they meet. Next compute provisional values $c_{\mathrm{f}}^{1}$ and $c_{\mathrm{b}}^{\mathrm{b}}$ by demanding that the far-left exponentials give the same values for $\psi$ and $\mathrm{d} \psi / \mathrm{d} x$ as the Airy functions

Figure A.14: Example energy eigenfunction for tunneling through a barrier.
at point A, where they meet. Finally, divide all the constants by $c_{\mathrm{f}}^{1}$ to make $C_{\mathrm{f}}^{\mathrm{l}}$ $=1$.

For the tunneling particle of chapter 7.12.2, an example eigenfunction is as shown in figure A.14. In this case, the solution in the middle part is not a combination of Airy functions, but of real exponentials. It is essentially the same solution as in the left and right parts, but in the middle region the potential energy is greater than the total energy, making $p_{\mathrm{c}}^{\mathrm{m}}=\sqrt{2 m\left(E-V_{\mathrm{m}}\right)}$ an imaginary number. Therefore the arguments of the exponentials become real when written in terms of the absolute value of the momentum $\left|p_{\mathrm{c}}^{\mathrm{m}}\right|=\sqrt{2 m\left(V_{\mathrm{m}}-E\right)}$. The rest of the analysis is similar to that of the previous example.

Figure A.15: Tunneling through a delta function barrier.
For the particle tunneling through the delta function potential in chapter 7.12.2, an example energy eigenfunction is shown in figure A.15. The potential energy in this case is $V=\nu \delta\left(x-x_{\mathrm{A}}\right)$, where $\delta\left(x-x_{\mathrm{A}}\right)$ is a spike at point A that integrates to one and the strength $\nu$ is a chosen constant. In the example, $\nu$ was chosen to be $\sqrt{2 \hbar^{2} E_{\text {nom }} / m}$ with $E_{\text {nom }}$ the nominal energy. For that strength, half the wave packet will pass through.

For a delta function potential, a modification must be made in the analysis as used so far. As figure A. 15 illustrates, there are kinks in the energy eigenfunction at the location A of the delta function. The left and right expressions for the eigenfunction do not predict the same value for its derivative $\mathrm{d} \psi / \mathrm{d} x$ at point A. To find the difference, integrate the Hamiltonian eigenvalue problem from a point a very short distance $\varepsilon$ before point A to a point the same very short distance behind it:

$$
-\frac{\hbar^{2}}{2 m} \int_{x=x_{\mathrm{A}}-\varepsilon}^{x_{\mathrm{A}}+\varepsilon} \frac{\mathrm{d}^{2} \psi}{\mathrm{~d} x^{2}} \mathrm{~d} x+\nu \int_{x=x_{\mathrm{A}}-\varepsilon}^{x_{\mathrm{A}}+\varepsilon} \delta\left(x-x_{\mathrm{A}}\right) \psi \mathrm{d} x=\int_{x=x_{\mathrm{A}}-\varepsilon}^{x_{\mathrm{A}}+\varepsilon} E \psi \mathrm{~d} x
$$

The integral in the right hand side is zero because of the vanishingly small interval of integration. But the delta function spike in the left hand side integrates
to one regardless of the small integration range, so

$$
-\left.\frac{\hbar^{2}}{2 m} \frac{\mathrm{~d} \psi}{\mathrm{~d} x}\right|_{x_{\mathrm{A}}-\varepsilon} ^{x_{\mathrm{A}}+\varepsilon}+\nu \psi\left(x_{\mathrm{A}}\right)=0
$$

For vanishingly small $\varepsilon, \mathrm{d} \psi / \mathrm{d} x$ at $x_{\mathrm{A}}+\varepsilon$ becomes what the right hand part of the eigenfunction gives for $\mathrm{d} \psi / \mathrm{d} x$ at $x_{\mathrm{A}}$, while $\mathrm{d} \psi / \mathrm{d} x$ at $x_{\mathrm{A}}-\varepsilon$ becomes what the left hand part gives for it. As seen from the above equation, the difference is not zero, but $2 m \nu \psi\left(x_{\mathrm{A}}\right) / \hbar^{2}$.

So the correct equations for the provisional constants are in this case

$$
\begin{gathered}
c_{\mathrm{f}}^{1} e^{\mathrm{i} p_{c}^{1} x_{\mathrm{A}} / \hbar}+c_{\mathrm{b}}^{1} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x_{\mathrm{A}} / \hbar}=c^{\mathrm{r}} e^{\mathrm{i} p_{\mathrm{c}}^{\mathrm{r}} x_{\mathrm{A}} / \hbar} \\
\frac{\mathrm{i} p_{\mathrm{c}}^{1}}{\hbar} c_{\mathrm{f}}^{1} e^{\mathrm{i} p_{\mathrm{c}}^{1} x_{\mathrm{A}} / \hbar}-\frac{\mathrm{i} p_{\mathrm{c}}^{1}}{\hbar} c_{\mathrm{b}}^{1} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x_{\mathrm{A}} / \hbar}=\frac{\mathrm{i} p_{\mathrm{c}}^{\mathrm{r}}}{\hbar} c^{\mathrm{r}} e^{\mathrm{i} p_{c}^{r} x_{\mathrm{A}} / \hbar}-\frac{2 m \nu}{\hbar^{2}} c^{\mathrm{r}} e^{\mathrm{i} p_{c}^{\mathrm{c}} x_{\mathrm{A}} / \hbar}
\end{gathered}
$$

Compared to the analysis as used previously, the difference is the final term in the second equation that is added by the delta function.

The remainder of this note gives some technical details for if you are actually planning to do your own animations. It is a good idea to assume that the units of mass, length, and time are chosen such that $\hbar$ and the nominal energy are one, while the mass of the particle is one-half. That avoids having to guesstimate suitable values for all sorts of very small numbers. The Hamiltonian eigenvalue problem then simplifies to

$$
-\frac{\mathrm{d}^{2} \psi}{\mathrm{~d} x^{2}}+V \psi=E \psi
$$

where the values of $E$ of interest cluster around 1 . The nominal momentum will be one too. In those units, the length of the plotted range was one hundred in all but the harmonic oscillator case.

It should be noted that to select a good function $c(p)$ in (A.206) is somewhat of an art. The simplest idea would be to choose $c(p)$ equal to one in some limited range around the nominal momentum, and zero elsewhere, as in

$$
c(p)=1 \quad \text { if }(1-r) p_{\text {nom }}<p<(1+r) p_{\text {nom }} \quad c(p)=0 \quad \text { otherwise }
$$

where $r$ is the relative deviation from the nominal momentum below which $c(p)$ is nonzero. However, it is know from Fourier analysis that the locations where $c(p)$ jumps from one to zero lead to lengthy wave packets when viewed in physical space. \{D.44\}. Functions $c(p)$ that do lead to nice compact wave packets are known to be of the form

$$
c(p)=\exp \left(-\frac{\left(p-p_{\mathrm{nom}}\right)^{2}}{r^{2} p_{\mathrm{nom}}^{2}}\right)
$$

And that is essentially the function $c(p)$ used in this study. The typical width of the momentum range was chosen to be $r=0.15$, or $15 \%$, by trial and error.

However, it is nice if $c(p)$ becomes not just very small, but exactly zero beyond some point, for one because it cuts down on the number of energy eigenfunctions that have to be evaluated numerically. Also, it is nice not to have to worry about the possibility of $p$ being negative in writing energy eigenfunctions. Therefore, the final function used was
$c(p)=\exp \left(-\frac{\left(p-p_{\text {nom }}\right)^{2}}{r^{2}\left[p_{\text {nom }}^{2}-\left(p-p_{\text {nom }}\right)^{2}\right]}\right)$ for $0<p<2 p_{\text {nom }} \quad c(p)=0$ otherwise

The actual difference in numerical values is small, but it does make $c(p)$ exactly zero for negative momenta and those greater than twice the nominal value. Strictly speaking, $c(p)$ should still be multiplied by a constant to make the total probability of finding the particle equal to one. But if you do not tell people what numbers for $\Psi$ are on the vertical axes, you do not need to bother.

In doing the numerical integrations to find $\Psi(x, t)$, note that the mid point and trapezium rules of numerical integration are exponentially accurate under the given conditions, so there is probably not much motivation to try more advanced methods. The mid point rule was used.

The animations in this book used the numerical implementations daie.f, dbie.f, daide.f, and dbide.f from netlib.org for the Airy functions and their first derivatives. These offer some basic protection against underflow and overflow by splitting off an exponential for positive $\bar{x}$. It may be a good idea to check for underflow and overflow in general and use 64 bit precision. The examples here did.

For the harmonic oscillator, the larger the nominal energy is compared to the ground state energy, the more the wave packet can resemble a single point compared to the limits of motion. However, the computer program used to create the animation computed the eigenfunctions by evaluating the analytical expression given in derivation \{D.12\}, and explicitly evaluating the Hermite polynomials is very round-off sensitive. That limited it to a maximum of about hundred times the ground state energy when allowing for enough uncertainty to localize the wave packet. Round-off is a general problem for power series, not just for the Hermite polynomials. If you want to go to higher energies to get a smaller wave packet, you will want to use a finite difference or finite element method to find the eigenfunctions.

The plotting software used to produce the animations was a mixture of different programs. There are no doubt much simpler and better ways of doing it. In the animations presented here, first plots were created of $\Psi$ versus $x$ for a large number of closely spaced times covering the duration of the animation. These plots were converted to gifs using a mixture of personal software, netpbm, and ghostview. The gifs were then combined into a single movie using gifsicle.

## A. 28 WKB Theory of Nearly Classical Motion

WKB theory provides simple approximate solutions for the energy eigenfunctions when the conditions are almost classical, like for the wave packets of chapter 7.11. The approximation is named after Wentzel, Kramers, and Brillouin, who refined the ideas of Liouville and Green. The bandit scientist Jeffreys tried to rob WKB of their glory by doing the same thing two years earlier, and is justly denied all credit.

Figure A.16: Harmonic oscillator potential energy $V$, eigenfunction $h_{50}$, and its energy $E_{50}$.

The WKB approximation is based on the rapid spatial variation of energy eigenfunctions with almost macroscopic energies. As an example, figure A. 16 shows the harmonic oscillator energy eigenfunction $h_{50}$. Its energy $E_{50}$ is hundred times the ground state energy. That makes the kinetic energy $E-V$ quite large over most of the range, and that in turn makes the linear momentum large. In fact, the classical Newtonian linear momentum $p_{\mathrm{c}}=m v$ is given by

$$
\begin{equation*}
p_{\mathrm{c}} \equiv \sqrt{2 m(E-V)} \tag{A.207}
\end{equation*}
$$

In quantum mechanics, the large momentum implies rapid oscillation of the wave function: quantum mechanics associates the linear momentum with the operator $\hbar \mathrm{d} / \mathrm{id} x$ that denotes spatial variation.

The WKB approximation is most appealing in terms of the classical momentum $p_{c}$ as defined above. To find its form, in the Hamiltonian eigenvalue problem

$$
-\frac{\hbar^{2}}{2 m} \frac{\mathrm{~d}^{2} \psi}{\mathrm{~d} x^{2}}+V \psi=E \psi
$$

take the $V \psi$ term to the other side and then rewrite $E-V$ in terms of the classical linear momentum. That produces

$$
\begin{equation*}
\frac{\mathrm{d}^{2} \psi}{\mathrm{~d} x^{2}}=-\frac{p_{\mathrm{c}}^{2}}{\hbar^{2}} \psi \tag{A.208}
\end{equation*}
$$

Now under almost classical conditions, a single period of oscillation of the wave function is so short that normally $p_{\mathrm{c}}$ is almost constant over it. Then
by approximation the solution of the eigenvalue problem over a single period is simply an arbitrary combination of two exponentials,

$$
\psi \sim c_{\mathrm{f}} e^{\mathrm{i} p_{\mathrm{c}} x / \hbar}+c_{\mathrm{b}} e^{-\mathrm{i} p_{\mathrm{c}} x / \hbar}
$$

where the constants $c_{\mathrm{f}}$ and $c_{\mathrm{b}}$ are arbitrary. (The subscripts denote whether the wave speed of the corresponding term is forward or backward.)

It turns out that to make the above expression work over more than one period, it is necessary to replace $p_{\mathrm{c}} x$ by the antiderivative $\int p_{\mathrm{c}} \mathrm{d} x$. Furthermore, the "constants" $c_{\mathrm{f}}$ and $c_{\mathrm{b}}$ must be allowed to vary from period to period proportional to $1 / \sqrt{p_{c}}$.

In short, the WKB approximation of the wave function is, $\{\mathrm{D} .46\}$ :

$$
\begin{equation*}
\text { classical WKB: } \quad \psi \approx \frac{1}{\sqrt{p_{\mathrm{c}}}}\left[C_{\mathrm{f}} e^{\mathrm{i} \theta}+C_{\mathrm{b}} e^{-\mathrm{i} \theta}\right] \quad \theta \equiv \frac{1}{\hbar} \int p_{\mathrm{c}} \mathrm{~d} x \tag{A.209}
\end{equation*}
$$

where $C_{\mathrm{f}}$ and $C_{\mathrm{b}}$ are now true constants.
If you ever glanced at notes such as $\{$ D.12 $\}$, $\{$ D. 14\}, and $\{$ D. 15$\}$, in which the eigenfunctions for the harmonic oscillator and hydrogen atom were found, you recognize what a big simplification the WKB approximation is. Just do the integral for $\theta$ and that is it. No elaborate transformations and power series to grind down. And the WKB approximation can often be used where no exact solutions exist at all.

In many applications, it is more convenient to write the WKB approximation in terms of a sine and a cosine. That can be done by taking the exponentials apart using the Euler formula (2.5). It produces

$$
\text { rephrased WKB: } \quad \psi \approx \frac{1}{\sqrt{p_{\mathrm{c}}}}\left[C_{\mathrm{c}} \cos \theta+C_{\mathrm{s}} \sin \theta\right] \quad \theta \equiv \frac{1}{\hbar} \int p_{\mathrm{c}} \mathrm{~d} x
$$

(A.210)

The constants $C_{\mathrm{c}}$ and $C_{\mathrm{s}}$ are related to the original constants $C_{\mathrm{f}}$ and $C_{\mathrm{b}}$ as

$$
\begin{array}{|lll}
\hline C_{\mathrm{c}}=C_{\mathrm{f}}+C_{\mathrm{b}} \quad C_{\mathrm{s}}=\mathrm{i} C_{\mathrm{f}}-\mathrm{i} C_{\mathrm{b}} & C_{\mathrm{f}}=\frac{1}{2}\left(C_{\mathrm{c}}-\mathrm{i} C_{\mathrm{s}}\right) & C_{\mathrm{b}}=\frac{1}{2}\left(C_{\mathrm{c}}+\mathrm{i} C_{\mathrm{s}}\right) \\
\hline \mathrm{A} .211)
\end{array}
$$

which allows you to convert back and forward between the two formulations as needed. Do note that either way, the constants depend on what you chose for the integration constant in the $\theta$ integral.

As an application, consider a particle stuck between two impenetrable walls at positions $x_{1}$ and $x_{2}$. An example would be the particle in a pipe that was studied way back in chapter 3.5. The wave function $\psi$ must become zero at both $x_{1}$ and $x_{2}$, since there is zero possibility of finding the particle outside the impenetrable walls. It is now smart to chose the integration constant in $\theta$ so that $\theta_{1}=0$. In that case, $C_{\mathrm{c}}$ must be zero for $\psi$ to be zero at $x_{1}$, (A.210). The
wave function must be just the sine term. Next, for $\psi$ also to be zero at $x_{2}, \theta_{2}$ must be a whole multiple $n$ of $\pi$, because that are the only places where sines are zero. So $\theta_{2}-\theta_{1}=n \pi$, which means that

$$
\begin{array}{|ll|}
\hline \text { particle between impenetrable walls: } & \frac{1}{\hbar} \int_{\underline{x}=x_{1}}^{x_{2}} p_{\mathrm{c}}(\underline{x}) \mathrm{d} \underline{x}=n \pi  \tag{A.212}\\
\hline
\end{array}
$$

Recall that $p_{\mathrm{c}}$ was $\sqrt{2 m(E-V)}$, so this is just an equation for the energy eigenvalues. It is an equation involving just an integral; it does not even require you to find the corresponding eigenfunctions!

It does get a bit more tricky for a case like the harmonic oscillator where the particle is not caught between impenetrable walls, but merely prevented to escape by a gradually increasing potential. Classically, such a particle would still be rigorously constrained between the so called "turning points" where the potential energy $V$ becomes equal to the total energy $E$, like the points 1 and 2 in figure A.16. But as the figure shows, in quantum mechanics the wave function does not become zero at the turning points; there is some chance for the particle to be found somewhat beyond the turning points.

A further complication arises since the WKB approximation becomes inaccurate in the immediate vicinity of the turning points. The problem is the requirement that the classical momentum can be approximated as a nonzero constant on a small scale. At the turning points the momentum becomes zero and that approximation fails.

However, it is possible to solve the Hamiltonian eigenvalue problem near the turning points assuming that the potential energy is not constant, but varies approximately linearly with position, \{A.29\}. Doing so and fixing up the WKB solution away from the turning points produces a simple result. The classical WKB approximation remains a sine, but at the turning points, $\sin \theta$ stays an angular amount $\pi / 4$ short of becoming zero. (Or to be precise, it just seems to stay $\pi / 4$ short, because the classical WKB approximation is no longer valid at the turning points.) Assuming that there are turning points with gradually increasing potential at both ends of the range, like for the harmonic oscillator, the total angular range will be short by an amount $\pi / 2$.

Therefore, the expression for the energy eigenvalues becomes:

$$
\begin{equation*}
\text { particle trapped between turning points: } \frac{1}{\hbar} \int_{\underline{x}=x_{1}}^{x_{2}} p_{\mathrm{c}}(\underline{x}) \mathrm{d} \underline{x}=\left(n-\frac{1}{2}\right) \pi \tag{A.213}
\end{equation*}
$$

The WKB approximation works fine in regions where the total energy $E$ is less than the potential energy $V$. The classical momentum $p_{\mathrm{c}}=\sqrt{2 m(E-V)}$ is imaginary in such regions, reflecting the fact that classically the particle does not have enough energy to enter them. But, as the nonzero wave function beyond the turning points in figure A. 16 shows, quantum mechanics does allow
some possibility for the particle to be found in regions where $E$ is less than $V$. It is loosely said that the particle can "tunnel" through, after a popular way for criminals to escape from jail. To use the WKB approximation in these regions, just rewrite it in terms of the magnitude $\left|p_{\mathrm{c}}\right|=\sqrt{2 m(V-E)}$ of the classical momentum:
tunneling WKB: $\quad \psi \approx \frac{1}{\sqrt{\left|p_{\mathrm{c}}\right|}}\left[C_{\mathrm{p}} e^{\gamma}+C_{\mathrm{n}} e^{-\gamma}\right] \quad \gamma \equiv \frac{1}{\hbar} \int\left|p_{\mathrm{c}}\right| \mathrm{d} x$
Note that $\gamma$ is the equivalent of the angle $\theta$ in the classical approximation.

## Key Points

0- The WKB approximation applies to situations of almost macroscopic energy.
0- The WKB solution is described in terms of the classical momentum $p_{\mathrm{c}} \equiv \sqrt{2 m(E-V)}$ and in particular its antiderivative $\theta=\int p_{\mathrm{c}} \mathrm{d} x / \hbar$.
$0-$ The wave function can be written as (A.209) or (A.210), whatever is more convenient.
$0-$ For a particle stuck between impenetrable walls, the energy eigenvalues can be found from (A.212).
$0-$ For a particle stuck between a gradually increasing potential at both sides, the energy eigenvalues can be found from (A.213).
0- The "tunneling" wave function in regions that classically the particle is forbidden to enter can be approximated as (A.214). It is in terms of the antiderivative $\gamma=\int\left|p_{c}\right| \mathrm{d} x / \hbar$.

1. Use the equation

## A. 28 Review Questions

$$
\frac{1}{\hbar} \int_{\underline{x}=x_{1}}^{x_{2}} p_{\mathrm{c}}(\underline{x}) \mathrm{d} \underline{x}=n \pi
$$

to find the WKB approximation for the energy levels of a particle stuck in a pipe of chapter 3.5.5. The potential $V$ is zero inside the pipe, given by $0 \leqslant x \leqslant \ell_{x}$
In this case, the WKB approximation produces the exact result, since the classical momentum really is constant. If there was a force field in the pipe, the solution would only be approximate.

> Solution wkb-a
2. Use the equation

$$
\frac{1}{\hbar} \int_{\underline{x}=x_{1}}^{x_{2}} p_{\mathrm{c}}(\underline{x}) \mathrm{d} \underline{x}=\left(n-\frac{1}{2}\right) \pi
$$

to find the WKB approximation for the energy levels of the harmonic oscillator. The potential energy is $\frac{1}{2} m \omega x^{2}$ where the constant $\omega$ is the
classical natural frequency. So the total energy, expressed in terms of the turning points $x_{2}=-x_{1}$ at which $E=V$, is $E=\frac{1}{2} m \omega x_{2}{ }^{2}$.
In this case too, the WKB approximation produces the exact energy eigenvalues. That, however, is just a coincidence; the classical WKB wave functions are certainly not exact; they become infinite at the turning points. As the example $h_{50}$ above shows, the true wave functions most definitely do not.

Solution wkb-b

## A. 29 WKB solution near the turning points

Both the classical and tunneling WKB approximations of addendum \{A.28\} fail near so-called "turning points" where the classical kinetic energy $E-V$ becomes zero. This note explains how the problem can be fixed.

Figure A.17: The Airy Ai and Bi functions that solve the Hamiltonian eigenvalue problem for a linearly varying potential energy. Bi very quickly becomes too large to plot for positive values of its argument.

The trick is to use a different approximation near turning points. In a small vicinity of a turning point, it can normally be assumed that the $x$-derivative $V^{\prime}$ of the potential is about constant, so that the potential varies linearly with position. Under that condition, the exact solution of the Hamiltonian eigenvalue problem is known to be a combination of two special functions Ai and Bi that are called the "Airy" functions. These functions are shown in figure A.17. The general solution near a turning point is:

$$
\psi=C_{\mathrm{A}} \operatorname{Ai}(\bar{x})+C_{\mathrm{B}} \operatorname{Bi}(\bar{x}) \quad \bar{x}=\sqrt[3]{\frac{2 m V^{\prime}}{\hbar^{2}}} \frac{V-E}{V^{\prime}} \quad V^{\prime} \equiv \frac{\mathrm{d} V}{\mathrm{~d} x}
$$

Note that $(V-E) / V^{\prime}$ is the $x$-position measured from the point where $V=E$, so that $\bar{x}$ is a local, stretched $x$-coordinate.

The second step is to relate this solution to the normal WKB approximations away from the turning point. Now from a macroscopic point of view, the WKB
approximation follows from the assumption that Planck's constant $\hbar$ is very small. That implies that the validity of the Airy functions normally extends to region where $|\bar{x}|$ is relatively large. For example, if you focus attention on a point where $V-E$ is a finite multiple of $\hbar^{1 / 3}, V-E$ is small, so the value of $V^{\prime}$ will deviate little from its value at the turning point: the assumption of linearly varying potential remains valid. Still, if $V-E$ is a finite multiple of $\hbar^{1 / 3},|\bar{x}|$ will be proportional to $1 / \hbar^{1 / 3}$, and that is large. Such regions of large, but not too large, $|\bar{x}|$ are called "matching regions," because in them both the Airy function solution and the WKB solution are valid. It is where the two meet and must agree.

It is graphically depicted in figures A. 18 and A.19. Away from the turning points, the classical or tunneling WKB approximations apply, depending on whether the total energy is more than the potential energy or less. In the vicinity of the turning points, the solution is a combination of the Airy functions. If you look up in a mathematical handbook like [1] how the Airy functions can be approximated for large positive respectively negative $\bar{x}$, you find the expressions listed in the bottom lines of the figures. (After you rewrite what you find in table books in terms of useful quantities, that is!)

The expressions in the bottom lines must agree with what the classical, respectively tunneling WKB approximation say about the matching regions. At one side of the turning point, that relates the coefficients $C_{\mathrm{p}}$ and $C_{\mathrm{n}}$ of the tunneling approximation to the coefficients of $C_{\mathrm{A}}$ and $C_{\mathrm{B}}$ of the Airy functions. At the other side, it relates the coefficients $C_{\mathrm{f}}$ and $C_{\mathrm{b}}$ (or $C_{\mathrm{c}}$ and $C_{\mathrm{s}}$ ) of the classical WKB approximation to $C_{\mathrm{A}}$ and $C_{\mathrm{B}}$. The net effect of it all is to relate, "connect," the coefficients of the classical WKB approximation to those of the tunneling one. That is why the formulae in figures A. 18 and A. 19 are called the "connection formulae."

You may have noted the appearance of an additional constant $c$ in figures A. 18 and A.19. This nasty constant is defined as

$$
\begin{equation*}
c=\frac{\sqrt{\pi}}{\left(2 m\left|V^{\prime}\right| \hbar\right)^{1 / 6}} \tag{A.215}
\end{equation*}
$$

and shows up uninvited when you approximate the Airy function solution for large $|\bar{x}|$. By cleverly absorbing it in a redefinition of the constants $C_{\mathrm{A}}$ and $C_{\mathrm{B}}$, figures A. 18 and A. 19 achieve that you do not have to worry about it unless you specifically need the actual solution at the turning points.

As an example of how the connection formulae are used, consider a right turning point for the harmonic oscillator or similar. Near such a turning point, the connection formulae of figure A. 18 apply. In the tunneling region towards the right, the term $C_{\mathrm{p}} \mathrm{e}^{\gamma}$ better be zero, because it blows up at large $x$, and that would put the particle at infinity for sure. So the constant $C_{\mathrm{p}}$ will have to be zero. Now the matching at the right side equates $C_{\mathrm{p}}$ to $C_{\mathrm{B}} e^{-\gamma_{t}}$ so $C_{\mathrm{B}}$ will have to be zero. That means that the solution in the vicinity of the turning

$\left.\begin{array}{c}\frac{1}{\sqrt{p_{\mathrm{c}}}}\left[C_{\mathrm{f}} e^{\mathrm{i} \theta}+C_{\mathrm{b}} e^{-\mathrm{i} \theta}\right] \\ \frac{1}{\sqrt{p_{\mathrm{c}}}}\left[C_{\mathrm{c}} \cos \theta+C_{\mathrm{s}} \sin \theta\right]\end{array}\right\}$

$$
C_{\mathrm{B}} c \operatorname{Bi}(\overline{\mathrm{x}})+C_{\mathrm{A}} c \operatorname{Ai}(\overline{\mathrm{x}}) \quad \frac{1}{\sqrt{\left|p_{\mathrm{c}}\right|}}\left[C_{\mathrm{p}} e^{\gamma}+C_{\mathrm{n}} e^{-\gamma}\right]
$$

equate $\Uparrow$
$\Downarrow$ equate

$$
\frac{1}{\sqrt{p_{\mathrm{c}}}}\left[C_{\mathrm{B}} \cos \left(\theta-\theta_{t}-\frac{\pi}{4}\right)-C_{\mathrm{A}} \sin \left(\theta-\theta_{t}-\frac{\pi}{4}\right)\right] \quad \frac{1}{\sqrt{\left|p_{\mathrm{c}}\right|}}\left[C_{\mathrm{B}} e^{\gamma-\gamma_{t}}+\frac{1}{2} C_{\mathrm{A}} e^{\gamma_{t}-\gamma}\right]
$$

Figure A.18: Connection formulae for a turning point from normal motion to tunneling.

Figure A.19: Connection formulae for a turning point from tunneling to normal motion.
point will have to be a pure Ai function. Then the matching towards the left shows that the solution in the classical WKB region must take the form of a sine that, when extrapolated to the turning point $\theta=\theta_{t}$, stops short of reaching zero by an angular amount $\pi / 4$. Hence the assertion in addendum \{A.28\} that the angular range of the classical WKB solution should be shortened by $\pi / 4$ for each end at which the particle is trapped by a gradually increasing potential instead of an impenetrable wall.

Figure A.20: WKB approximation of tunneling.
As another example, consider tunneling as discussed in chapter 7.12 and 7.13. Figure A. 20 shows a sketch. The WKB approximation may be used if the barrier through which the particle tunnels is high and wide. In the far right region, the energy eigenfunction only involves a term $C^{\mathrm{r}} e^{\mathrm{i} \theta}$ with a forward wave speed. To simplify the analysis, the constant $C^{\mathrm{r}}$ can be taken to be one, because it does not make a difference how the wave function is normalized. Also, the integration constant in $\theta$ can be chosen such that $\theta=\pi / 4$ at turning point 2 ; then the connection formulae of figure A. 19 along with the Euler formula (2.5) show that the coefficients of the Airy functions at turning point 2 are $C_{\mathrm{B}}=1$ and $C_{\mathrm{A}}=$ i. Next, the integration constant in $\gamma$ can be taken such that $\gamma=0$ at turning point 2; then the connection formulae of figure A. 19 imply that $C_{\mathrm{p}}^{\mathrm{m}}$ $=\frac{1}{2} \mathrm{i}$ and $C_{\mathrm{n}}^{\mathrm{m}}=1$.

Next consider the connection formulae for turning point 1 in figure A.18. Note that $e^{-\gamma_{1}}$ can be written as $e^{\gamma_{12}}$, where $\gamma_{12}=\gamma_{2}-\gamma_{1}$, because the integration constant in $\gamma$ was chosen such that $\gamma_{2}=0$. The advantage of using $e^{\gamma_{12}}$ instead of $e^{-\gamma_{1}}$ is that it is independent of the choice of integration constant. Furthermore, under the typical conditions that the WKB approximation applies, for a high and wide barrier, $e^{\gamma_{12}}$ will be a very large number. It is then seen from figure A. 18 that near turning point $1, C_{\mathrm{A}}=2 e^{\gamma_{12}}$ which is large while $C_{\mathrm{B}}$ is small and will be ignored. And that then implies, using the Euler formula to convert Ai's sine into exponentials, that $\left|C_{\mathrm{f}}^{1}\right|=e^{\gamma_{12}}$. As discussed in chapter 7.13, the transmission coefficient is given by

$$
T=\frac{p_{\mathrm{c}}^{\mathrm{r}}}{p_{\mathrm{c}}^{1}}\left|C^{\mathrm{r}} / \sqrt{p_{\mathrm{c}}^{\mathrm{r}}}\right|^{2}, C_{\mathrm{f}}^{\mathrm{l}} /\left.\sqrt{p_{\mathrm{c}}^{1}}\right|^{2}
$$

and plugging in $C^{\mathrm{r}}=1$ and $\left|C_{\mathrm{f}}^{\mathrm{f}}\right|=e^{\gamma_{12}}$, the transmission coefficient is found to be $e^{-2 \gamma_{12}}$.

## A. 30 Three-dimensional scattering

This note introduces some of the general concepts of three-dimensional scattering, in case you run into them. For more details and actual examples, a quantum mechanics text for physicists will need to be consulted; it is a big thing for them.

Figure A.21: Scattering of a beam off a target.
The basic idea is as sketched in figure A.21. A beam of particles is sent in from the far left towards a three-dimensional target. Part of the beam hits the target and is scattered, to be picked up by surrounding detection equipment.

It will be assumed that the collision with the target is elastic, and that the particles in the beam are sufficiently light that they scatter off the target without transferring kinetic energy to it. In that case, the target can be modeled as a steady potential energy field. And if the target and/or incoming particles are electrically neutral, it can also be assumed that the potential energy decays fairly quickly to zero away from the target. (In fact, a lot of results in this note turn out not apply to a slowly decaying potential like the Coulomb one.)

It is convenient to use a spherical coordinate system $(r, \theta, \phi)$ with its origin at the scattering object and with its axis aligned with the direction of the incoming beam. Since the axis of a spherical coordinate system is usually called the $z$ axis, the horizontal coordinate will now be indicated as $z$, not $x$ like in the one-dimensional analysis done earlier.

In the energy eigenfunctions, the incoming particle beam can be represented as a one-dimensional wave. However, unlike for the one-dimensional scattering of figure 7.22 , now the wave is not just scattered to the left and right, but in all directions, in other words to all angles $\theta$ and $\phi$. The far-field behavior of the
energy eigenfunctions is

$$
\begin{equation*}
\psi_{E} \sim C_{\mathrm{f}}^{\mathrm{l}} e^{\mathrm{i} p_{\infty} z / \hbar}+C_{\mathrm{f}}(\theta, \phi) \frac{e^{\mathrm{i} p_{\infty} r / \hbar}}{r} \quad \text { for } \quad r \rightarrow \infty \quad p_{\infty} \equiv \sqrt{2 m E} \tag{A.216}
\end{equation*}
$$

Here $E$ is the kinetic energy of the incoming particles and $m$ the mass. Therefore $p_{\infty}$ is what classical physics would take to be the momentum of the particles at infinity. The first term in the far field behavior allows the incoming particles to be described, as well as the same particles going out again unperturbed. If some joker removes the target, that is all there is.

The second term describes the outgoing scattered particles. The constant $C_{\mathrm{f}}(\theta, \phi)$ is called the "scattering amplitude." The second term also contains a factor $e^{i p_{\infty} r / \hbar}$ consistent with wave packets that move radially away from the target in the far field.

Finally, the second term contains a factor $1 / r$. Therefore the magnitude of the second term decreases with the distance $r$ from the target. This happens because the probability of finding a particle in a given detection area should decrease with distance. Indeed, the total detection area is $4 \pi r^{2}$, where $r$ is the distance at which the detectors are located. That increases proportional to $r^{2}$, and the total number of particles to detect per unit time is the same regardless of where the detectors are located. Therefore the probability of finding a particle per unit area should decrease proportional to $1 / r^{2}$. Since the probability of finding a particle is proportional to the square of the wave function, the wave function itself must be proportional to $1 / r$. The second term above makes it so.

Consider now the number of particles that is detected in a given small detection area $\mathrm{d} A$. The scattered stream of particles moving towards the detection area has a velocity $v=p_{\infty} / m$. Therefore in a time interval $\mathrm{d} t$, the detection area samples a volume of the scattered particle stream equal to $\mathrm{d} A \times v \mathrm{~d} t$. The chances of finding particles are proportional to the square magnitude of the wave function times that volume. Using the asymptotic wave function above, the number of particles detected will be

$$
\mathrm{d} I=[\text { constant }]\left|C_{\mathrm{f}}(\theta, \phi)\right|^{2} \frac{\mathrm{~d} A}{r^{2}} \mathrm{~d} t
$$

The constant includes the factor $p_{\infty} / m$. The constant must also account for the fact that the wave function is not normalized, and that there is a continuous stream of particles to be found, rather than just one particle.

According to the above expression, the number of particles detected in a given area $\mathrm{d} A$ is proportional to its three-dimensional angular extent

$$
\mathrm{d} \Omega \equiv \frac{\mathrm{~d} A}{r^{2}}
$$

This is the so-called "solid angle" occupied by the detection area element. It is the three-dimensional generalization of two-dimensional angles. In two dimensions, an element of a circle with arc length $\mathrm{d} s$ occupies an angle $\mathrm{d} s / r$ when
expressed in radians. Similarly, in three dimensions, an element of a sphere with area $\mathrm{d} A$ occupies a solid angle $\mathrm{d} A / r^{2}$ when expressed in "steradians."

In those terms, the number $\mathrm{d} I$ of particles detected in an infinitesimal solid angle $\mathrm{d} \Omega$ is

$$
\mathrm{d} I=[\text { constant }]\left|C_{\mathrm{f}}(\theta, \phi)\right|^{2} \mathrm{~d} \Omega \mathrm{~d} t
$$

As noted, the constant of proportionality depends on the rate at which particles are sent at the target. The more particles are sent at the target, the more will be deflected. The number of particles in the incoming beam per unit beam cross-sectional area and per unit time is called the "luminosity" of the beam. It is related to the square of the wave function of the incoming beam through the relation

$$
\mathrm{d} I_{\mathrm{b}}=[\text { constant }]\left|C_{\mathrm{f}}^{1}\right|^{2} \mathrm{~d} A_{\mathrm{b}} \mathrm{~d} t
$$

Here $\mathrm{d} A_{\mathrm{b}}$ is a cross sectional area element of the incoming particle beam and $\mathrm{d} I_{\mathrm{b}}$ the number of particles passing through that area.

Physicist like to relate the scattered particle flow in a given infinitesimal solid angle $\mathrm{d} \Omega$ to an equivalent incoming beam area $\mathrm{d} A_{b}$ through which the same number of particles flow. Therefore they define the so-called "differential cross-section" as

$$
\begin{equation*}
\frac{\mathrm{d} \sigma}{\mathrm{~d} \omega} \equiv \frac{\mathrm{~d} A_{\mathrm{b}, \text { equiv }}}{\mathrm{d} \Omega} \tag{A.217}
\end{equation*}
$$

The quantity $\mathrm{d} A_{\mathrm{b}, \text { equiv }}$ can be thought of as the infinitesimal area of the incoming beam that ends up in the infinitesimal solid angle $d \Omega$. So the differential crosssection is a scattered particle density expressed in suitable terms.

Note how well chosen the term "differential cross-section" really is. If physicists had called it something like "scattered cross-section density," or even simply "scattered cross-section," nonexperts would probably have a pretty good guess what physicists were talking about. But "cross section" by itself can mean anything. There is nothing in the term to indicate that it is a measure for how many particles are scattered. And preceding it by "differential" is a stroke of genius because it is not a differential, it is a differential quotient. This will confuse mathematically literate nonexperts even more.

The differential cross section does not depend on how many particles are sent at the target, nor on wave function normalization. Following the expressions for the particle flows given above, the differential cross section is simply

$$
\begin{equation*}
\frac{\mathrm{d} \sigma}{\mathrm{~d} \omega}=\frac{\left|C_{\mathrm{f}}(\theta, \phi)\right|^{2}}{\left|C_{\mathrm{f}}^{1}\right|^{2}} \tag{A.218}
\end{equation*}
$$

Moreover, the particle flow in an incoming beam area $\mathrm{d} A_{\mathrm{b}}$ may be measured using the same experimental techniques as are used to measure the deflected particle flow. Various systematic errors in the experimental method will then cancel in the ratio, giving more accurate values.

The total area of the incoming beam that gets scattered is called the "total cross-section" $\sigma$ :

$$
\begin{equation*}
\sigma \equiv A_{\mathrm{b}, \text { total }} \tag{A.219}
\end{equation*}
$$

Of course, the name is quite below the normal standards of physicists, since it really is a total cross-section. Fortunately, physicist are clever enough not to say what cross section it is, and cross-section can mean many things. Also, by using the symbol $\sigma$ instead of something logical like $A_{\mathrm{b}}$ for the differential cross-section, physicists do their best to reduce the damage as well as possible.

If you remain disappointed in physicists, take some comfort in the following term for scattering that can be described using classical mechanics: the "impact parameter." If you guess that it describes the local physics of the particle impact process, it is really hilarious to physicists. Instead, think "centerline offset;" it describes the location relative to the centerline of the incoming beam at which the particles come in; it has no direct relation whatsoever to what sort of impact (if any) these particles end up experiencing.

The total cross section can be found by integrating the differential cross section over all deflection angles:

$$
\sigma=\int_{\text {all }} \frac{\mathrm{d} A_{\text {b,equiv }}}{\mathrm{d} \Omega} \mathrm{~d} \Omega
$$

In spherical coordinates this can be written out explicitly as

$$
\begin{equation*}
\sigma=\int_{\theta=0^{+}}^{\pi} \int_{\phi=0}^{2 \pi} \frac{\left|C_{\mathrm{f}}(\theta, \phi)\right|^{2}}{\left|C_{\mathrm{f}}^{\mid}\right|^{2}} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \tag{A.220}
\end{equation*}
$$

## A.30.1 Partial wave analysis

Jim Napolitano from RPI and Cornell notes:
The term"Partial Wave Analysis" is poorly defined and overused.
Gee, what a surprise! For one, they are component waves, not partial waves. But you already componently assumed that they might be.

This discussion will restrict itself to spherically symmetric scattering potentials. In that case, the analysis of the energy eigenfunctions can be done much like the analysis of the hydrogen atom of chapter 4.3. However, the boundary conditions at infinity will be quite different; the objective is not to describe bound particles, but particles that come in from infinity with positive kinetic energy and are scattered back to infinity. Also, the potential will of course not normally be a Coulomb one.

But just like for the hydrogen atom, the energy eigenfunctions can be taken to be radial functions times spherical harmonics $Y_{l}^{m}$ :

$$
\begin{equation*}
\psi_{E l m}(r, \theta, \phi)=R_{E l}(r) Y_{l}^{m}(\theta, \phi) \tag{A.221}
\end{equation*}
$$

These energy eigenfunctions have definite angular momentum in the $z$-direction $m \hbar$, as well definite square angular momentum $l(l+1) \hbar^{2}$. The radial functions $R_{E l}$ will not be the same as the hydrogen $R_{n l}$ ones.

The incoming plane wave $e^{\mathrm{ip}_{\infty} z / \hbar}$ has zero angular momentum in the $z$-direction. Unfortunately, it does not have definite square angular momentum. Instead, it can be written as a linear combination of free-space energy eigenfunctions with different values of $l$, hence with different square angular momentum:

$$
\begin{equation*}
e^{\mathrm{i} p_{\infty} z / \hbar}=\sum_{l=0}^{\infty} c_{\mathrm{w}, l} j_{l}\left(p_{\infty} r / \hbar\right) Y_{l}^{0}(\theta) \quad c_{\mathrm{w}, l}=\mathrm{i}^{l} \sqrt{4 \pi(2 l+1)} \tag{A.222}
\end{equation*}
$$

See $\{$ A. 6$\}$ for a derivation and the precise form of the "spherical Bessel functions" $j_{l}$.

Now finding the complete energy eigenfunction corresponding to the incoming wave directly is typically awkward, especially analytically. Often it is easier to solve the problem for each term in the above sum separately and then add these solutions all together. That is where the name "partial wave analysis" comes from. Each term in the sum corresponds to a partial wave, if you use sufficiently lousy terminology.

The partial wave analysis requires that for each term in the sum, an energy eigenfunction is found of the form $\psi_{E l}=R_{E l} Y_{l}^{0}$. The required behavior of this eigenfunction in the far field is

$$
\begin{equation*}
\psi_{E l} \sim\left[c_{\mathrm{w}, l} j_{l}\left(p_{\infty} r / \hbar\right)+c_{\mathrm{f}, l} h_{l}^{(1)}\left(p_{\infty} r / \hbar\right)\right] Y_{l}^{0}(\theta) \quad \text { for } r \rightarrow \infty \tag{A.223}
\end{equation*}
$$

Here the first term is the component of the incoming plane wave corresponding to spherical harmonic $Y_{l}^{0}$. The second term represents the outgoing deflected particles. The value of the coefficient $c_{\mathrm{f}, l}$ is determined in the solution process.

Note that the above far field behavior is quite similar to that of the complete energy eigenfunction as given earlier in (A.216). However, here the coefficient $C_{\mathrm{f}}^{\mathrm{l}}$ was set to 1 for simplicity. Also, the radial part of the reflected wave function was written using a "Hankel function of the first kind" $h_{l}^{(1)}$. This Hankel function produces the same $e^{i p_{\infty} r / \hbar} / r$ radial behavior as the second term in (A.216), $\{\mathrm{A} .6\}$ (A.25). However, the Hankel function has the advantage that it becomes exact as soon as the scattering potential becomes zero. It is not just valid at very large $r$ like the bare exponential.

To be sure, for a slowly decaying potential like the Coulomb one, the Hankel function is no better than the exponential. However, the Hankel function is very
closely related to the Bessel function $j_{l}$, \{A. 6$\}$, allowing various helpful results to be found in table books. If the potential energy is piecewise constant, it is even possible to solve the complete problem using Bessel and Hankel functions. These functions can be tied together at the jumps in potential in a way similar to addendum \{A.27\}.

In terms of the asymptotic behavior above, the differential cross section is

$$
\begin{equation*}
\frac{\mathrm{d} \sigma}{\mathrm{~d} \omega}=\frac{\hbar^{2}}{p_{\infty}^{2}} \sum_{l=0}^{\infty} \sum_{\underline{l}=0}^{\infty} \mathrm{i}^{l-\underline{l}} c_{\mathrm{f}, l}^{*} c_{\mathrm{f}, \underline{l}} Y_{l}^{0}(\theta) Y_{\underline{l}}^{0}(\theta) \tag{A.224}
\end{equation*}
$$

This can be verified using $\{\mathrm{A} .6\}$ (A.25), (A.216), and (A.218). The Bessel functions form the incoming wave and do not contribute. For the total crosssection, note that the spherical harmonics are orthonormal, so

$$
\sigma=\frac{\hbar^{2}}{p_{\infty}^{2}} \sum_{l=0}^{\infty}\left|c_{f, l}\right|^{2}
$$

One special case is worth mentioning. Consider particles of such low momentum that their typical quantum wave length, $2 \pi \hbar / p_{\infty}$, is gigantic compared to the radial size of the scattering potential. Particles of such large wave lengths do not notice the fine details of the scattering potential at all. Conversely, normally the scattering potential only "notices" the incoming partial wave with $l$ $=0$. That is because the Bessel functions are proportional to

$$
\left(p_{\infty} r / \hbar\right)^{l}
$$

for small arguments. If the wave length is large compared to the typical radial size $r$ of the scattering potential, this is negligible unless $l=0$. Now $l=0$ corresponds to a wave function that is the same in all directions; it is proportional to the constant spherical harmonic $Y_{0}^{0}$. If only the partial wave that is the same in all directions gets scattered, then the particles get scattered equally in all directions (if they get scattered at all.)

Coincidently, equal scattering in all directions also happens in another case: scattering of classical point particles from a hard elastic sphere. That is very much the opposite case, because negligible uncertainty in position requires high, not low, energy of the particles. In any case, the similarity between the two cases is is superficial. If a beam of classical particles is directed at a hard sphere, only an area of the beam equal to the frontal area of the sphere gets scattered. But if you work out the scattering of low-energy quantum particles from a hard sphere, you get a total scattering cross section that is 4 times bigger.

## A.30.2 Partial wave amplitude

This subsection gives some further odds and ends on partial wave analysis, for the incurably curious.

Recall that a partial wave has an asymptotic behavior

$$
\psi_{E l} \sim\left[c_{\mathrm{w}, l} j_{l}\left(p_{\infty} r / \hbar\right)+c_{\mathrm{f}, l} h_{l}^{(1)}\left(p_{\infty} r / \hbar\right)\right] Y_{l}^{0}(\theta) \quad \text { for } r \rightarrow \infty
$$

The first term corresponds to the wave function of the incoming particles. The second term is the effect of the scattering potential.

Physicists like to write the coefficient of the scattered wave as

$$
\begin{equation*}
c_{\mathrm{f}, l}=\mathrm{i} k c_{\mathrm{w}, l} a_{l} \tag{A.225}
\end{equation*}
$$

They call the so-defined constant $a_{l}$ the "partial wave amplitude" because obviously it is not a partial wave amplitude. Confusing people is always funny.

Now every partial wave by itself is a solution to the Hamiltonian eigenvalue problem. That means that every partial wave must ensure that particles cannot just simply disappear. That restricts what the partial wave amplitude can be. It turns out that it can be written in terms of a real number $\delta_{l}$ :

$$
\begin{equation*}
a_{l}=\frac{1}{k} e^{\mathrm{i} \delta_{l}} \sin \delta_{l} \tag{A.226}
\end{equation*}
$$

The real number $\delta_{l}$ is called the "phase shift."
Some physicist must have got confused here, because it really is a phase shift. To see that, consider the derivation of the above result. First the asymptotic behavior of the partial wave is rewritten in terms of exponentials using \{A.6\} (A.24) and (A.25). That gives

$$
\psi_{E l} \sim \ldots\left[e^{-\mathrm{i} p_{\infty} r / \hbar}+(-1)^{l+1} e^{\mathrm{i} p_{\infty} r / \hbar}\left(1+2 \mathrm{i} k a_{l}\right)\right]
$$

The dots stand for common factors that are not important for the discussion. Physically, the first term above describes spherical wave packets that move radially inwards toward the target. The second term describes wave packets that move radially outwards away from the target.

Now particles cannot just disappear. Wave packets that go in towards the target must come out again with the same amplitude. And that means that the two terms in the asymptotic behavior above must have the same magnitude. (This may also be shown mathematically using procedures like in \{A.32\}.)

Obviously the two terms do have the same magnitude in the absence of scattering, where $a_{l}$ is zero. But in the presence of scattering, the final parenthetical factor will have to stay of magnitude one. And that means that it can be written in the form

$$
\begin{equation*}
1+2 \mathrm{i} k a_{l}=e^{\mathrm{i} 2 \delta_{l}} \tag{A.227}
\end{equation*}
$$

for some real number $\delta_{l}$. (The factor 2 in the exponential is put in because physicists like to think of the wave being phase shifted twice, once on the way
in to the target and once on the way out.) Cleaning up the above expression using the Euler formula (2.5) gives the stated result.

If you add in the time dependent factor $e^{\mathrm{i} E t / \hbar}$ of the complete unsteady wave function, you can see that indeed the waves are shifted by a phase angle $2 \delta_{l}$ compared to the unperturbed wave function. Without any doubt, the name of the physicist responsible for calling the phase angle a "phase angle" has been ostracized from physics. She will never be heard of again.

## A.30.3 The Born approximation

The Born approximation assumes that the scattering potential is weak to derive approximate expressions for the scattering.

Consider first the case that the scattering potential is zero. In that case, the wave function is just that of the incoming particles:

$$
\psi_{E}=e^{\mathrm{i} p_{\infty} z / \hbar} \quad p_{\infty}=\sqrt{2 m E}
$$

where $E$ is the energy of the particle and $m$ its mass.
Born considered the case that the scattering potential $V$ is not zero, but small. Then the wave function $\psi_{E}$ will still be close to the incoming wave function, but no longer exactly the same. In that case an approximation to the wave function can be obtained from the so-called integral Schrödinger equation, $\{$ A.13\} (A.42):

$$
\psi_{E}(\vec{r})=e^{\mathrm{i} p_{\infty} z / \hbar}-\frac{m}{2 \pi \hbar^{2}} \int_{\text {all } \vec{r}^{\prime}} \frac{e^{\mathrm{i} p_{\infty}\left|\vec{r}-\vec{r}^{\prime}\right| / \hbar}}{\left|\vec{r}-\vec{r}^{\prime}\right|} V\left(\vec{r}^{\prime}\right) \psi_{E}\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime}
$$

In particular, inside the integral the true wave function $\psi_{E}$ can be replaced by the incoming wave function:

$$
\begin{equation*}
\psi_{E}(\vec{r}) \approx e^{\mathrm{i} p_{\infty} z / \hbar}-\frac{m}{2 \pi \hbar^{2}} \int_{\text {all } \vec{r}^{\prime}} \frac{e^{\mathrm{i} p_{\infty}\left|\vec{r}-\vec{r}^{\prime}\right| / \hbar}}{\left|\vec{r}-\vec{r}^{\prime}\right|} V\left(\vec{r}^{\prime}\right) e^{\mathrm{i} p_{\infty} z^{\prime} / \hbar} \mathrm{d}^{3} \vec{r}^{\prime} \tag{A.228}
\end{equation*}
$$

It is not exact, but it is much better than just setting the integral to zero. The latter would make the wave function equal to the incoming wave. With the approximate integral, you get a valid approximation to the particle deflections.

To get the differential cross section, examine the behavior of (A.228) at given scattering angles $\theta$ and $\phi$ for large $r$. That produces, $\{D .47\}$ :

$$
\begin{equation*}
\frac{\mathrm{d} \sigma}{\mathrm{~d} \omega}(\theta, \phi) \approx\left|\frac{m}{2 \pi \hbar^{2}} \int_{\text {all }} e^{-\mathrm{i}\left(\vec{p}_{\infty}-\vec{p}_{\infty}^{1}\right) \cdot \vec{r}^{\prime} / \hbar} V\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime}\right|^{2} \quad(V \text { small }) \tag{A.229}
\end{equation*}
$$

Here

$$
\begin{equation*}
\vec{p}_{\infty}^{1}=p_{\infty} \hat{k} \quad \vec{p}_{\infty}=p_{\infty} \hat{\imath}_{r} \quad\left(\text { with } p_{\infty}=\sqrt{2 m E}\right) \tag{A.230}
\end{equation*}
$$

are the classical momentum vectors of the incoming and scattered particles. Note that the direction of $\vec{p}_{\infty}$ depends on the considered scattering angles $\theta$ and $\phi$. And that apparently the momentum change of the particles is a key factor affecting the amount of scattering.

One additional approximation is worth mentioning. Consider particles of such low momentum that their quantum wave length, $2 \pi \hbar / p_{\infty}$, is gigantic compared to the radial size of the scattering potential. Particles of such wave lengths do not notice the fine details of the scattering potential at all. Mathematically, $p_{\infty}$ is so small that the argument of the exponential in the differential cross section above can be assumed zero. Then:

$$
\begin{equation*}
\frac{\mathrm{d} \sigma}{\mathrm{~d} \omega} \approx\left|\frac{m}{2 \pi \hbar^{2}} \int_{\text {all }} V\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime}\right|^{2} \quad\left(V \text { and } p_{\infty} \text { small }\right) \tag{A.231}
\end{equation*}
$$

The differential cross section no longer depends on the angular position. If particles get scattered at all, they get scattered equally in all directions.

Note that the integral is infinite for a Coulomb potential.

## A. 31 The Born series

The Born approximation is concerned with the problem of a particle of a given momentum that is slightly perturbed by a nonzero potential that it encounters. This note gives a description how this problem may be solved to high accuracy. The solution provides a model for the so-called "Feynman diagrams" of quantum electrodynamics.

It is assumed that in the absence of the perturbation, the wave function of the particle would be

$$
\psi_{0}=e^{\mathrm{i} k z}
$$

In this state, the particle has a momentum $\hbar k$ that is purely in the $z$-direction. Note that the above state is not normalized, and cannot be. That reflects the Heisenberg uncertainty principle: since the particle has precise momentum, it has infinite uncertainty in position. For real particles, wave functions of the form above must be combined into wave packets, chapter 7.10. That is not important for the current discussion.

The perturbed wave function $\psi$ can in principle be obtained from the socalled integral Schrödinger equation, $\{\mathrm{A} .13\}$ (A.42):

$$
\psi(\vec{r})=\psi_{0}(\vec{r})-\frac{m}{2 \pi \hbar^{2}} \int_{\text {all } \vec{r}^{\prime}} \frac{e^{\mathrm{i} k\left|\vec{r}-\vec{r}^{\prime}\right|}}{\left|\vec{r}-\vec{r}^{\prime}\right|} V\left(\vec{r}^{\prime}\right) \psi\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime}
$$

Evaluating the right hand side in this equation would give $\psi$. Unfortunately, the right hand side cannot be evaluated because the integral contains the unknown wave function $\psi$ still to be found. However, Born noted that if the perturbation
is small, then so is the difference between the true wave function $\psi$ and the unperturbed one $\psi_{0}$. So a valid approximation to the integral can be obtained by replacing $\psi$ in it by the known $\psi_{0}$. That is certainly much better than just leaving the integral away completely, which would give $\psi=\psi_{0}$.

And note that you can repeat the process. Since you now have an approximation for $\psi$ that is better than $\psi_{0}$, you can put that approximation into the integral instead. Evaluating the right hand side then produces a still better approximation for $\psi$. Which can then be put into the integral. Etcetera.

Figure A.22: Graphical interpretation of the Born series.
Graphically, the process is illustrated in figure A.22. The most inaccurate approximation is to take the perturbed wave function as the unperturbed wave function at the same position $\vec{r}$ :

$$
\psi \approx \psi_{0}
$$

An improvement is to add the integral evaluated using the unperturbed wave function:

$$
\psi(\vec{r})=\psi_{0}(\vec{r})-\frac{m}{2 \pi \hbar^{2}} \int_{\text {all }} \frac{e^{\prime} \vec{r}^{\mathrm{i} k\left|\vec{r}-\vec{r}^{\prime}\right|}}{\left|\vec{r}-\vec{r}^{\prime}\right|} V\left(\vec{r}^{\prime}\right) \psi_{0}\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime}
$$

To represent this concisely, it is convenient to introduce some shorthand notations:

$$
\psi_{0}^{\prime} \equiv \psi_{0}\left(\vec{r}^{\prime}\right) \quad v^{\prime} \equiv V\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime} \quad g_{1}=-\frac{m}{2 \pi \hbar^{2}} \frac{e^{\mathrm{i} k\left|\vec{r}-\vec{r}^{\prime}\right|}}{\left|\vec{r}-\vec{r}^{\prime}\right|}
$$

Using those notations the improved approximation to the wave function is

$$
\psi \approx \psi_{0}+\int \psi_{0}^{\prime} v^{\prime} g^{\prime}
$$

Note what the second term does: it takes the unperturbed wave function at some different location $\vec{r}^{\prime}$, multiplies it by a "vertex factor" $v^{\prime}$, and then adds it to the wave function at $\vec{r}$ multiplied by a "propagator" $g_{l}$. This is then summed over all locations $\vec{r}^{\prime}$. The second term is illustrated in the second graph in the right hand side of figure A. 22 .

The next better approximation is obtained by putting the two-term approximation above in the integral:

$$
\psi \approx \psi_{0}+\int\left[\psi_{0}^{\prime}+\int \psi_{0}^{\prime \prime} v^{\prime \prime} g_{\prime \prime}^{\prime}\right] v^{\prime} g_{\prime}
$$

where

$$
\psi_{0}^{\prime \prime} \equiv \psi_{0}\left(\vec{r}^{\prime \prime}\right) \quad v^{\prime \prime} \equiv V\left(\vec{r}^{\prime \prime}\right) \mathrm{d}^{3} \vec{r}^{\prime \prime} \quad g_{\prime \prime}^{\prime}=-\frac{m}{2 \pi \hbar^{2}} \frac{e^{\mathrm{i} k\left|\vec{r}^{\prime}-\vec{r}^{\prime \prime}\right|}}{\left|\vec{r}^{\prime}-\vec{r}^{\prime \prime}\right|}
$$

Note that it was necessary to change the notation for one integration variable to $\vec{r}^{\prime \prime}$ to avoid using the same symbol for two different things. Compared to the previous approximation, there is now a third term:

$$
\psi=\psi_{0}+\int \psi_{0}^{\prime} v^{\prime} g_{l}+\iint \psi_{0}^{\prime \prime} v^{\prime \prime} g_{\prime \prime}^{\prime \prime} v^{\prime} g_{\prime}
$$

This third term takes the unperturbed wave function at some position $\vec{r}^{\prime \prime}$, multiplies it by the local vertex factor $v^{\prime \prime}$, propagates that to a location $\vec{r}^{\prime}$ using propagator $g_{\prime \prime}^{\prime}$, multiplies it by the vertex factor $v^{\prime}$, and propagates it to the location $\vec{r}$ using propagator $g_{\ell}$. That is summed over all combinations of locations $\vec{r}^{\prime \prime}$ and $\vec{r}^{\prime}$. The idea is shown in the third graph in the right hand side of figure A. 22 .

Continuing this process produces the Born series:

$$
\psi=\psi_{0}+\int \psi_{0}^{\prime} v^{\prime} g_{1}+\iint \psi_{0}^{\prime \prime} v^{\prime \prime} g_{\prime \prime}^{\prime} v^{\prime} g_{1}+\iiint \psi_{0}^{\prime \prime \prime} v^{\prime \prime \prime} g_{\prime \prime \prime}^{\prime \prime} v^{\prime \prime} g_{\prime \prime}^{\prime} v^{\prime} g_{1}+\ldots
$$

The Born series inspired Feynman to formulate relativistic quantum mechanics in terms of vertices connected together into "Feynman diagrams." Since there is a nontechnical, very readable discussion available from the master himself, [19], there does not seem much need to go into the details here.

## A. 32 The evolution of probability

This note looks at conservation of probability, and the resulting definitions of the reflection and transmission coefficients in scattering. It also explains the concept of the "probability current" that you may occasionally run into.

For the unsteady Schrödinger equation to provide a physically correct description of nonrelativistic quantum mechanics, particles should not be able to disappear into thin air. In particular, during the evolution of the wave function of a single particle, the total probability of finding the particle if you look everywhere should stay one at all times:

$$
\int_{x=-\infty}^{\infty}|\Psi|^{2} \mathrm{~d} x=1 \text { at all times }
$$

Fortunately, the Schrödinger equation

$$
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \Psi}{\partial x^{2}}+V \Psi
$$

does indeed conserve this total probability, so all is well.
To verify this, note first that $|\Psi|^{2}=\Psi^{*} \Psi$, where the star indicates the complex conjugate, so

$$
\frac{\partial|\Psi|^{2}}{\partial t}=\Psi^{*} \frac{\partial \Psi}{\partial t}+\Psi \frac{\partial \Psi^{*}}{\partial t}
$$

To get an expression for that, take the Schrödinger equation above times $\Psi^{*} / \mathrm{i} \hbar$ and add the complex conjugate of the Schrödinger equation,

$$
-\mathrm{i} \hbar \frac{\partial \Psi^{*}}{\partial t}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \Psi^{*}}{\partial x^{2}}+V \Psi^{*}
$$

times $-\Psi / \mathrm{i} \hbar$. The potential energy terms drop out, and what is left is

$$
\frac{\partial|\Psi|^{2}}{\partial t}=\frac{\mathrm{i} \hbar}{2 m}\left(\Psi^{*} \frac{\partial^{2} \Psi}{\partial x^{2}}-\Psi \frac{\partial^{2} \Psi^{*}}{\partial x^{2}}\right)
$$

Now it can be verified by differentiating out that the right hand side can be rewritten as a derivative:

$$
\begin{equation*}
\frac{\partial|\Psi|^{2}}{\partial t}=-\frac{\partial J}{\partial x} \quad \text { where } J=\frac{\mathrm{i} \hbar}{2 m}\left(\Psi \frac{\partial \Psi^{*}}{\partial x}-\Psi^{*} \frac{\partial \Psi}{\partial x}\right) \tag{A.232}
\end{equation*}
$$

For reasons that will become evident below, $J$ is called the "probability current." Note that $J$, like $\Psi$, will be zero at infinite $x$ for proper, normalized wave functions.

If (A.232) is integrated over all $x$, the desired result is obtained:

$$
\frac{\mathrm{d}}{\mathrm{~d} t} \int_{x=-\infty}^{\infty}|\Psi|^{2} \mathrm{~d} x=-\left.J\right|_{x=-\infty} ^{\infty}=0
$$

Therefore, the total probability of finding the particle does not change with time. If a proper initial condition is provided to the Schrödinger equation in which the total probability of finding the particle is one, then it stays one for all time.

It gets a little more interesting to see what happens to the probability of finding the particle in some given finite region $a \leqslant x \leqslant b$. That probability is given by

$$
\int_{x=a}^{b}|\Psi|^{2} \mathrm{~d} x
$$

and it can change with time. A wave packet might enter or leave the region. In particular, integration of (A.232) gives

$$
\frac{\mathrm{d}}{\mathrm{~d} t} \int_{x=a}^{b}|\Psi|^{2} \mathrm{~d} x=J_{a}-J_{b}
$$

This can be understood as follows: $J_{a}$ is the probability flowing out of the region $x<a$ into the interval $[a, b]$ through the end $a$. That increases the probability
within $[a, b]$. Similarly, $J_{b}$ is the probability flowing out of $[a, b]$ at $b$ into the region $x>b$; it decreases the probability within $[a, b]$. Now you see why $J$ is called probability current; it is equivalent to a stream of probability in the positive $x$-direction.

The probability current can be generalized to more dimensions using vector calculus:

$$
\begin{equation*}
\vec{J}=\frac{\mathrm{i} \hbar}{2 m}\left(\Psi \nabla \Psi^{*}-\Psi^{*} \nabla \Psi\right) \tag{A.233}
\end{equation*}
$$

and the net probability flowing out of a region is given by

$$
\begin{equation*}
\int \vec{J} \cdot \vec{n} \mathrm{~d} A \tag{A.234}
\end{equation*}
$$

where $A$ is the outside surface area of the region, and $\vec{n}$ is a unit vector normal to the surface. A surface integral like this can often be simplified using the divergence (Gauss or whatever) theorem of calculus.

Returning to the one-dimensional case, it is often desirable to relate conservation of probability to the energy eigenfunctions of the Hamiltonian,

$$
-\frac{\hbar^{2}}{2 m} \frac{\mathrm{~d}^{2} \psi}{\mathrm{~d} x^{2}}+V \psi=E \psi
$$

because the energy eigenfunctions are generic, not specific to one particular example wave function $\Psi$.

To do so, first an important quantity called the "Wronskian" must be introduced. Consider any two eigenfunctions $\psi_{1}$ and $\psi_{2}$ of the Hamiltonian:

$$
\begin{aligned}
& -\frac{\hbar^{2}}{2 m} \frac{\mathrm{~d}^{2} \psi_{1}}{\mathrm{~d} x^{2}}+V \psi_{1}=E \psi_{1} \\
& -\frac{\hbar^{2}}{2 m} \frac{\mathrm{~d}^{2} \psi_{2}}{\mathrm{~d} x^{2}}+V \psi_{2}=E \psi_{2}
\end{aligned}
$$

If you multiply the first equation above by $\psi_{2}$, the second by $\psi_{1}$ and then subtract the two, you get

$$
\frac{\hbar^{2}}{2 m}\left(\psi_{1} \frac{\mathrm{~d}^{2} \psi_{2}}{\mathrm{~d} x^{2}}-\psi_{2} \frac{\mathrm{~d}^{2} \psi_{1}}{\mathrm{~d} x^{2}}\right)=0
$$

The constant $\hbar^{2} / 2 m$ can be divided out, and by differentiation it can be verified that the remainder can be written as

$$
\frac{\mathrm{d} W}{\mathrm{~d} x}=0 \quad \text { where } W=\psi_{1} \frac{\mathrm{~d} \psi_{2}}{\mathrm{~d} x}-\psi_{2} \frac{\mathrm{~d} \psi_{1}}{\mathrm{~d} x}
$$

The quantity $W$ is called the Wronskian. It is the same at all values of $x$.
As an application, consider the example potential of figure A. 11 in addendum \{A.27\} that bounces a particle coming in from the far left back to where it came
from. In the left region, the potential $V$ has a constant value $V_{1}$. In this region, an energy eigenfunction is of the form

$$
\psi_{E}=C_{\mathrm{f}}^{\mathrm{l}} \mathrm{e}^{\mathrm{i} p_{\mathrm{c}}^{1} x / \hbar}+C_{\mathrm{b}}^{\mathrm{l}} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x / \hbar} \text { for } x<x_{\mathrm{A}} \quad \text { where } p_{\mathrm{c}}^{1}=\sqrt{2 m\left(E-V_{1}\right)}
$$

At the far right, the potential grows without bound and the eigenfunction becomes zero rapidly. To make use of the Wronskian, take the first solution $\psi_{1}$ to be $\psi_{E}$ itself, and $\psi_{2}$ to be its complex conjugate $\psi_{E}^{*}$. Since at the far right the eigenfunction becomes zero rapidly, the Wronskian is zero there. And since the Wronskian is constant, that means it must be zero everywhere. Next, if you plug the above expression for the eigenfunction in the left region into the definition of the Wronskian and clean up, you get

$$
W=\frac{2 \mathrm{i} p_{\mathrm{c}}^{1}}{\hbar}\left(\left|C_{\mathrm{b}}^{1}\right|^{2}-\left|C_{\mathrm{f}}^{1}\right|^{2}\right)
$$

If that is zero, the magnitude of $C_{\mathrm{b}}^{\mathrm{l}}$ must be the same as that of $C_{\mathrm{f}}^{1}$.
This can be understood as follows: if a wave packet is created from eigenfunctions with approximately the same energy, then the terms $C_{\mathrm{f}}^{1} \mathrm{e}^{\mathrm{ip} \mathrm{p}_{x}^{1} x / \hbar}$ combine for large negative times into a wave packet coming in from the far left. The probability of finding the particle in that wave packet is proportional to the integrated square magnitude of the wave function, hence proportional to the square magnitude of $C_{\mathrm{f}}^{\mathrm{l}}$. For large positive times, the $C_{\mathrm{b}}^{\mathrm{l}} e^{-\mathrm{i} p_{\mathrm{c}}{ }^{1} x / \hbar}$ terms combine in a similar wave packet, but one that returns towards the far left. The probability of finding the particle in that departing wave packet must still be the same as that for the incoming packet, so the square magnitude of $C_{\mathrm{b}}^{1}$ must be the same as that of $C_{\mathrm{f}}^{\mathrm{p}}$.

Next consider a generic scattering potential like the one in figure 7.22. To the far left, the eigenfunction is again of the form

$$
\psi_{E}=C_{\mathrm{f}}^{\mathrm{l}} e^{\mathrm{i} \mathrm{p}_{\mathrm{c}}^{1} x / \hbar}+C_{\mathrm{b}}^{\mathrm{l}} e^{-\mathrm{i} p_{\mathrm{c}}^{1} x / \hbar} \text { for } x \ll 0 \quad \text { where } p_{\mathrm{c}}^{1}=\sqrt{2 m\left(E-V_{1}\right)}
$$

while at the far right it is now of the form

$$
\psi_{E}=C^{\mathrm{r}} e^{\mathrm{ip} p_{\mathrm{c}}^{\mathrm{r}} x / \hbar} \text { for } x \gg 0 \quad \text { where } p_{\mathrm{c}}^{\mathrm{r}}=\sqrt{2 m\left(E-V_{\mathrm{r}}\right)}
$$

The Wronskian can be found the same way as before:

$$
W=\frac{2 \mathrm{i} p_{\mathrm{c}}^{1}}{\hbar}\left(\left|C_{\mathrm{b}}^{\mathrm{l}}\right|^{2}-\left|C_{\mathrm{f}}^{\mathrm{l}}\right|^{2}\right)=-\frac{2 \mathrm{i} p_{\mathrm{c}}^{\mathrm{r}}}{\hbar}\left|C^{\mathrm{r}}\right|^{2}
$$

The fraction of the incoming wave packet that ends up being reflected back towards the far left is called the "reflection coefficient" $R$. Following the same reasoning as above, it can be computed from the coefficients in the far left region of constant potential as:

$$
R=\frac{\left|C_{\mathrm{b}}^{1}\right|^{2}}{\left|C_{\mathrm{f}}^{1}\right|^{2}}
$$

The reflection coefficient gives the probability that the particle can be found to the left of the scattering region at large times.

Similarly, the fraction of the incoming wave packet that passes through the potential barrier towards the far right is called the "transmission coefficient" $T$. It gives the probability that the particle can be found to the right of the scattering region at large times. Because of conservation of probability, $T=$ $1-R$.

Alternatively, because of the Wronskian expression above, the transmission coefficient can be explicitly computed from the coefficient of the eigenfunction in the far right region as

$$
T=\frac{p_{\mathrm{c}}^{\mathrm{r}}\left|C^{\mathrm{r}}\right|^{2}}{p_{\mathrm{c}}^{1}\left|C_{\mathrm{f}}^{1}\right|^{2}} \quad p_{\mathrm{c}}^{1}=\sqrt{2 m\left(E-V_{1}\right)} \quad p_{\mathrm{c}}^{\mathrm{r}}=\sqrt{2 m\left(E-V_{\mathrm{r}}\right)}
$$

If the potential energy is the same at the far right and far left, the two classical momenta are the same, $p_{\mathrm{c}}^{\mathrm{r}}=p_{\mathrm{c}}^{1}$. Otherwise, the reason that the ratio of classical momenta appears in the transmission coefficient is because the classical momenta in a wave packet have a different spacing with respect to energy if the potential energy is different. (The above expression for the transmission coefficient can also be derived explicitly using the Parseval equality of Fourier analysis, instead of inferred from conservation of probability and the constant Wronskian.)

## A. 33 Explanation of the London forces

To fully understand the details of the London forces, it helps to first understand the popular explanation of them, and why it is all wrong. To keep things simple, the example will be the London attraction between two neutral hydrogen atoms that are well apart. (This will also correct a small error that the earlier discussion of the hydrogen molecule made; that discussion implied incorrectly that there is no attraction between two neutral hydrogen atoms that are far apart. The truth is that there really is some Van der Waals attraction. It was ignored because it is small compared to the chemical bond that forms when the atoms are closer together and would distract from the real story.)

The popular explanation for the London force goes something like this: "Sure, there would not be any attraction between two distant hydrogen atoms if they were perfectly spherically symmetric. But according to quantum mechanics, nature is uncertain. So sometimes the electron clouds of the two atoms are somewhat to the left of the nuclei, like in figure A. 23 (b). This polarization [dipole creation] of the atoms turns out to produce some electrostatic attraction between the atoms. At other times, the electron clouds are somewhat to the right of the nuclei like in figure A. $23(c)$; it is really the same thing seen in the mirror. In cases like figure A. 23 (a), where the electron clouds move towards

Figure A.23: Possible polarizations of a pair of hydrogen atoms.
each other, and (b), where they move away from each other, there is some repulsion between the atoms; however, the wave functions become correlated so that (b) and (c) are more likely than (a) and (d). Hence a net attraction results."

Before examining what is wrong with this explanation, first consider what is right. It is perfectly right that figure A. 23 (b) and (c) produce some net attraction between the atoms, and that (a) and (d) produce some repulsion. This follows from the net Coulomb potential energy between the atoms for given positions of the electrons:

$$
V_{\mathrm{lr}}=\frac{e^{2}}{4 \pi \epsilon_{0}}\left(\frac{1}{d}-\frac{1}{r_{1}}-\frac{1}{r_{\mathrm{r}}}+\frac{1}{r_{\mathrm{lr}}}\right)
$$

where $e=1.610^{-19} \mathrm{C}$ is the magnitude of the charges of the protons and electrons, $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is the permittivity of space, $d$ is the distance between the nuclei, $r_{1}$ is the distance between the left electron and the right nucleus, $r_{\mathrm{r}}$ the one between the right electron and the left nucleus, and $r_{\mathrm{lr}}$ is the distance between the two electrons. If the electrons charges are distributed over space according to densities $n_{1}\left(\vec{r}_{1}\right)$ and $n_{\mathrm{r}}\left(\vec{r}_{\mathrm{r}}\right)$, the classical potential energy is

$$
V_{\text {lr }}=\frac{e^{2}}{4 \pi \epsilon_{0}} \int_{\text {all } \vec{r}_{1}} \int_{\text {all } \vec{r}_{\mathrm{r}}}\left(\frac{1}{d}-\frac{1}{r_{1}}-\frac{1}{r_{\mathrm{r}}}+\frac{1}{r_{\text {lr }}}\right) n_{\mathrm{l}}\left(\vec{r}_{1}\right) n_{\mathrm{r}}\left(\vec{r}_{\mathrm{r}}\right) \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{\mathrm{r}}
$$

(Since the first, $1 / d$, term represents the repulsion between the nuclei, it may seem strange to integrate it against the electron charge distributions, but the charge distributions integrate to one, so they disappear. Similarly in the second and third term, the charge distribution of the uninvolved electron integrates away.)

Since it is assumed that the atoms are well apart, the integrand above can be simplified using Taylor series expansions to give:

$$
V_{\mathrm{lr}}=\frac{e^{2}}{4 \pi \epsilon_{0}} \int_{\text {all } \vec{r}_{1}} \int_{\text {all } \vec{r}_{\mathrm{r}}} \frac{x_{1} x_{\mathrm{r}}+y_{1} y_{\mathrm{r}}-2 z_{1} z_{\mathrm{r}}}{d^{3}} n_{\mathrm{l}}\left(\vec{r}_{\mathrm{l}}\right) n_{\mathrm{r}}\left(\vec{r}_{\mathrm{r}}\right) \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{\mathrm{r}}
$$

where the positions of the electrons are measured from their respective nuclei. Also, the two $z$ axes are both taken horizontal and positive towards the left. For charge distributions as shown in figure A.23, the $x_{1} x_{\mathrm{r}}$ and $y_{1} y_{\mathrm{r}}$ terms integrate to zero because of odd symmetry. However, for a distribution like in figure A. 23 $(c), n_{1}$ and $n_{\mathrm{r}}$ are larger at positive $z_{1}$, respectively $z_{\mathrm{r}}$, than at negative one, so the integral will integrate to a negative number. That means that the potential is lowered, there is attraction between the atoms. In a similar way, distribution (b) produces attraction, while $(a)$ and (d) produce repulsion.

So there is nothing wrong with the claim that $(b)$ and $(c)$ produce attraction, while $(a)$ and ( $d$ ) produce repulsion. It is also perfectly right that the combined quantum wave function gives a higher probability to $(b)$ and $(c)$ than to $(a)$ and (d).

So what is wrong? There are two major problems with the story.

1. Energy eigenstates are stationary. If the wave function oscillated in time like the story suggests, it would require uncertainty in energy, which would act to kill off the lowering of energy. True, states with the electrons at the same side of their nuclei are more likely to show up when you measure them, but to reap the benefits of this increased probability, you must not do such a measurement and just let the electron wave function sit there unchanging in time.
2. The numbers are all wrong. Suppose the wave functions in figures (b) and (c) shift (polarize) by a typical small amount $\varepsilon$. Then the attractive potential is of order $\varepsilon^{2} / d^{3}$. Since the distance $d$ between the atoms is assumed large, the energy gained is a small amount times $\varepsilon^{2}$. But to shift atom energy eigenfunctions by an amount $\varepsilon$ away from their ground state takes an amount of energy $C \varepsilon^{2}$ where $C$ is some constant that is not small. So it would take more energy to shift the electron clouds than the dipole attraction could recover. In the ground state, the electron clouds should therefore stick to their original centered positions.
On to the correct quantum explanation. First the wave function is needed. If there were no Coulomb potentials linking the atoms, the combined ground-state electron wave function would simply take the form

$$
\psi\left(\vec{r}_{1}, \vec{r}_{\mathrm{r}}\right)=\psi_{100}\left(\vec{r}_{1}\right) \psi_{100}\left(\vec{r}_{\mathrm{r}}\right)
$$

where $\psi_{100}$ is the ground state wave function of a single hydrogen atom. To get a suitable correlated polarization of the atoms, throw in a bit of the $\psi_{210}$ " $2 \mathrm{p}_{z}$ " states, as follows:

$$
\psi\left(\vec{r}_{1}, \vec{r}_{\mathrm{r}}\right)=\sqrt{1-\varepsilon^{2}} \psi_{100}\left(\vec{r}_{1}\right) \psi_{100}\left(\vec{r}_{\mathrm{r}}\right)+\varepsilon \psi_{210}\left(\vec{r}_{1}\right) \psi_{210}\left(\vec{r}_{\mathrm{r}}\right)
$$

For $\varepsilon>0$, it produces the desired correlation between the wave functions: $\psi_{100}$ is always positive, and $\psi_{210}$ is positive if the electron is at the positive- $z$ side of
its nucleus and negative otherwise. So if both electrons are at the same side of their nucleus, the product $\psi_{210}\left(\vec{r}_{1}\right) \psi_{210}\left(\vec{r}_{\mathrm{r}}\right)$ is positive, and the wave function is increased, giving increased probability of such states. Conversely, if the electrons are at opposite sides of their nucleus, $\psi_{210}\left(\vec{r}_{1}\right) \psi_{210}\left(\vec{r}_{\mathrm{r}}\right)$ is negative, and the wave function is reduced.

Now write the expectation value of the energy:

$$
\langle E\rangle=\left\langle\sqrt{1-\varepsilon^{2}} \psi_{100} \psi_{100}+\varepsilon \psi_{210} \psi_{210}\right| H_{1}+H_{\mathrm{r}}+V_{\mathrm{lr}}\left|\sqrt{1-\varepsilon^{2}} \psi_{100} \psi_{100}+\varepsilon \psi_{210} \psi_{210}\right\rangle
$$

where $H_{1}$ and $H_{\mathrm{r}}$ are the Hamiltonians of the individual electrons and

$$
V_{\mathrm{lr}}=\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{x_{1} x_{\mathrm{r}}+y_{1} y_{\mathrm{r}}-2 z_{1} z_{\mathrm{r}}}{d^{3}}
$$

is again the potential between atoms. Working out the inner product, noting that the $\psi_{100}$ and $\psi_{210}$ are orthonormal eigenfunctions of the atom Hamiltonians $H_{1}$ and $H_{\mathrm{r}}$ with eigenvalues $E_{1}$ and $E_{2}$, and that most $V_{\mathrm{lr}}$ integrals are zero on account of odd symmetry, you get

$$
\langle E\rangle=2 E_{1}+2 \varepsilon^{2}\left(E_{2}-E_{1}\right)-4 \varepsilon \sqrt{1-\varepsilon^{2}} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{d^{3}}\left\langle\psi_{100} \psi_{100}\right| z_{1} z_{\mathrm{r}}\left|\psi_{210} \psi_{210}\right\rangle
$$

The final term is the savior for deriving the London force. For small values of $\varepsilon$, for which the square root can be approximated as one, this energy-lowering term dominates the energy $2 \varepsilon^{2}\left(E_{2}-E_{1}\right)$ needed to distort the atom wave functions. The best approximation to the true ground state is then obtained when the quadratic in $\varepsilon$ is minimal. That happens when the energy has been lowered by an amount

$$
\frac{2}{E_{2}-E_{1}}\left(\frac{e^{2}}{4 \pi \epsilon_{0}}\left\langle\psi_{100}\right| z\left|\psi_{210}\right\rangle^{2}\right)^{2} \frac{1}{d^{6}}
$$

Since the assumed eigenfunction is not exact, this variational approximation will underestimate the actual London force. For example, it can be seen that the energy can also be lowered similar amounts by adding some of the $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ states; these cause the atom wave functions to move in opposite directions normal to the line between the nuclei.

So what is the physical meaning of the savior term? Consider the inner product that it represents:

$$
\left\langle\psi_{100} \psi_{100}\right| V_{\text {Ir }}\left|\psi_{210} \psi_{210}\right\rangle
$$

That is the energy if both electrons are in the spherically symmetric $\psi_{100}$ ground state if both electrons are in the antisymmetric $2 \mathrm{p}_{z}$ state. The savior term is a twilight term, like the ones discussed earlier in chapter 5.3 for chemical bonds. It reflects nature's habit of doing business in terms of an unobservable wave function instead of observable probabilities.

## A. 34 Explanation of Hund's first rule

Hund's first rule of spin-alignment applies because electrons in atoms prefer to go into spatial states that are antisymmetric with respect to electron exchange. Spin alignment is then an unavoidable consequence of the weird antisymmetrization requirement.

To understand why electrons want to go into antisymmetric spatial states, the interactions between the electrons need to be considered. Sweeping them below the carpet as the discussion of atoms in chapter 5.9 did is not going to cut it.

To keep it as simple as possible, the case of the carbon atom will be considered. As the crude model of chapter 5.9 did correctly deduce, the carbon atom has two 1 s electrons locked into a zero-spin singlet state, and similarly two 2 s electrons also in a singlet state. Hund's rule is about the final two electrons that are in 2 p states. As far as the simple model of chapter 5.9 was concerned, these electrons can do whatever they want within the 2 p subshell.

To go one better than that, the correct interactions between the two 2 p electrons will need to be considered. To keep the arguments manageable, it will still be assumed that the effects of the 1 s and 2 s electrons are independent of where the 2 p electrons are.

Call the 2 p electrons $\alpha$ and $\beta$. Under the stated conditions, their Hamiltonian takes the form

$$
H_{\alpha}+H_{\beta}+V_{\alpha \beta}
$$

where $H_{\alpha}$ and $H_{\beta}$ are the single-electron Hamiltonians for the electrons $\alpha$ and $\beta$, consisting of their kinetic energy, their attraction to the nucleus, and the repulsion by the 1 s and 2 s electrons. Note that in the current analysis, it is not required that the 1 s and 2 s electrons are treated as located in the nucleus. Lack of shielding can be allowed now, but it must still be assumed that the 1s and 2 s electrons are unaffected by where the 2 p electrons are. In particular, $H_{\alpha}$ is assumed to be be independent of the position of electron $\beta$, and $H_{\beta}$ independent of the position of electron $\alpha$. The mutual repulsion of the two 2 p electrons is given by $V_{\alpha \beta}=e^{2} / 4 \pi \epsilon_{0}\left|\vec{r}_{\alpha}-\vec{r}_{\beta}\right|$.

Now assume that electrons $\alpha$ and $\beta$ appropriate two single-electron spatial 2 p states for themselves, call them $\psi_{1}$ and $\psi_{2}$. For carbon, $\psi_{1}$ can be thought of as the $2 \mathrm{p}_{z}$ state and $\psi_{2}$ as the $2 \mathrm{p}_{x}$ state, The general spatial wave function describing the two electrons takes the generic form

$$
a \psi_{1}\left(\vec{r}_{1}\right) \psi_{2}\left(\vec{r}_{2}\right)+b \psi_{2}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)
$$

The two states $\psi_{1}$ and $\psi_{2}$ will be taken to be orthonormal, like $\mathrm{p}_{z}$ and $\mathrm{p}_{x}$ are, and then the normalization requirement is that $|a|^{2}+|b|^{2}=1$.

The expectation value of energy is

$$
\left\langle a \psi_{1} \psi_{2}+b \psi_{2} \psi_{1}\right| H_{\alpha}+H_{\beta}+V_{\alpha \beta}\left|a \psi_{1} \psi_{2}+b \psi_{2} \psi_{1}\right\rangle
$$

That can be multiplied out and then simplified by noting that in the various inner product integrals involving the single-electron Hamiltonians, the integral over the coordinate unaffected by the Hamiltonian is either zero or one because of orthonormality. Also, the inner product integrals involving $V_{\alpha \beta}$ are pairwise the same, the difference being just a change of names of integration variables.

The simplified expectation energy is then:

$$
E_{\psi_{1}}+E_{\psi_{2}}+\left\langle\psi_{1} \psi_{2}\right| V_{\alpha \beta}\left|\psi_{1} \psi_{2}\right\rangle+\left(a^{*} b+b^{*} a\right)\left\langle\psi_{1} \psi_{2}\right| V_{\alpha \beta}\left|\psi_{2} \psi_{1}\right\rangle .
$$

The first two terms are the single-electron energies of states $\psi_{1}$ and $\psi_{2}$. The third term is the classical repulsion between between two electron charge distributions of strengths $\left|\psi_{1}\right|^{2}$ and $\left|\psi_{2}\right|^{2}$. The electrons minimize this third term by going into spatially separated states like the $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{z}$ ones, rather than into the same spatial state or into greatly overlapping ones.

The final one of the four terms is the interesting one for Hund's rule; it determines how the two electrons occupy the two states $\psi_{1}$ and $\psi_{2}$, symmetrically or antisymmetrically. Consider the detailed expression for the inner product integral appearing in the term:

$$
\left\langle\psi_{1} \psi_{2}\right| V_{\alpha \beta}\left|\psi_{2} \psi_{1}\right\rangle=\int_{\text {all } \vec{r}_{1}} \int_{\text {all } \vec{r}_{2}} V_{\alpha \beta} f\left(\vec{r}_{1}, \vec{r}_{2}\right) f^{*}\left(\vec{r}_{2}, \vec{r}_{1}\right) \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}
$$

where $f\left(\vec{r}_{1}, \vec{r}_{2}\right)=\psi_{2}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)$.
The sign of this inner product can be guesstimated. If $V_{\alpha \beta}$ would be the same for all electron separation distances, the integral would be zero because of orthonormality of $\psi_{1}$ and $\psi_{2}$. However, $V_{\alpha \beta}$ favors positions where $\vec{r}_{1}$ and $\vec{r}_{2}$ are close to each other; in fact $V_{\alpha \beta}$ is infinitely large if $\vec{r}_{1}=\vec{r}_{2}$. At such a location $f\left(\vec{r}_{1}, \vec{r}_{2}\right) f^{*}\left(\vec{r}_{2}, \vec{r}_{1}\right)$ is a positive real number, so it tends to have a positive real part in regions it really counts. That means the inner product integral should have the same sign as $V_{\alpha \beta}$; it should be repulsive.

And since this integral is multiplied by $a^{*} b+b^{*} a$, the energy is smallest when that is most negative, which is for the antisymmetric spatial state $a=-b$. Since this state takes care of the sign change in the antisymmetrization requirement, the spin state must be unchanged under particle exchange; the spins must be aligned. More precisely, the spin state must be some linear combination of the three triplet states with net spin one. There you have Hund's rule, as an accidental byproduct of the Coulomb repulsion.

This leaves the philosophical question why for the two electrons of the hydrogen molecule in chapter 5.2 the symmetric state is energetically most favorable, while the antisymmetric state is the one for the 2 p electrons. The real difference is in the kinetic energy. In both cases, the antisymmetric combination reduces the Coulomb repulsion energy between the electrons, and in the hydrogen molecule model, it also increases the nuclear attraction energy. But in the hydrogen molecule model, the symmetric state achieves a reduction in kinetic
energy that is more than enough to make up for it all. For the 2p electrons, the reduction in kinetic energy is nil. When the positive component wave functions of the hydrogen molecule model are combined into the symmetric state, they allow greater access to fringe areas farther away from the nuclei. Because of the uncertainty principle, less confined electrons tend to have less indeterminacy in momentum, hence less kinetic energy. On the other hand, the 2 p states are half positive and half negative, and even their symmetric combination reduces spatial access for the electrons in half the locations.

## A. 35 The third law

In the simplest formulation, the third law of thermodynamics says that the entropy at absolute zero temperature is zero.

The original theorem is due to Nernst. A more recent formulation is
"The contribution to the entropy of a system due to each component that is in internal equilibrium disappears at absolute zero." [D. Ter Haar (1966) Elements of Thermostatistics. Holt, Rinehart \& Winston.]

A more readable version is
"The entropy of every chemically simple, perfectly crystalline, body equals zero at the absolute zero of temperature." [G.H. Wannier (1966) Statistical Physics. Wiley.]
These formulations allow for the existence of meta-stable equilibria. The third law in its simple form assumes that strictly speaking every ground state is reasonably unique and that the system is in true thermal equilibrium. Experimentally however, many substances do not appear to approach zero entropy. Random mixtures as well as ice are examples. They may not be in true equilibrium, but if true equilibrium is not observed, it is academic.

The zero of entropy is important for mixtures, in which you need to add the entropies of the components together correctly. It also has implications for the behavior of various quantities at low temperatures. For example, it implies that the specific heats become zero at absolute zero. To see why, note that in a constant volume or constant pressure process the entropy changes are given by

$$
\int \frac{C}{T} \mathrm{~d} T
$$

If the specific heat $C$ would not become zero at $T=0$, this integral would give an infinite entropy at that temperature instead of zero.

Another consequence of the third law is that it is not possible to bring a system to absolute zero temperature completely even in ideal processes. That
seems pretty self-evident from a classical point of view, but it is not so obvious in quantum terms. The third law also implies that isothermal processes become isentropic when absolute zero temperature is approached.

It may seem that the third law is a direct consequence of the quantum expression for the entropy,

$$
S=-k_{\mathrm{B}} \sum P_{q} \ln \left(P_{q}\right)
$$

At absolute zero temperature, the system is in the ground state. Assuming that the ground state is not degenerate, there is then only one nonzero probability $P_{q}=1$ and for that probability $\ln \left(P_{q}\right)$ is zero. So the entropy is zero.

Even if the ground state is not unique, often it does not make much of a difference. For example, consider the case of a system of $I$ noninteracting spin 1 bosons in a box. If you could really ignore the effect of all particle interactions on the energy, the $I$ spin states would be arbitrary in the ground state. But even then there would be only about $\frac{1}{2} I^{2}$ different system states with the ground state energy, chapter 5.7. That produces an entropy of only about $-k_{\mathrm{B}} \ln \left(2 / I^{2}\right)$. It would make the specific entropy proportional to $\ln (I) / I$, which is zero for a large-enough system.

On the other hand, if you ignore electromagnetic spin couplings of nuclei in a crystal, it becomes a different matter. Since the nuclear wave functions have no measurable overlap, to any conceivable accuracy the nuclei can assume independent spatial states. That gets rid of the (anti) symmetrization restrictions on their spin. And then the associated entropy can be nonzero. But of course, if the nuclear spin does not interact with anything, you may be able to ignore its existence altogether.

Even if a system has a unique ground state, the third law is not as trivial as it may seem. Thermodynamics deals not with finite systems but with idealized systems of infinite size. A very simple example illustrates why it makes a difference. Consider the possibility of a hypothetical system whose specific entropy depends on the number of particles $I$, temperature $T$, and pressure $P$ as

$$
s_{\mathrm{h} . \mathrm{s} .}(I, T, P)=\frac{I T}{1+I T}
$$

This system is consistent with the expression for the third law given above: for a given system size $I$, the entropy becomes zero at zero temperature. However, the idealized infinite system always has entropy 1 ; its entropy does not go to zero for zero temperature. The third law should be understood to say that this hypothetical system does not exist.

If infinite systems seem unphysical, translate it into real-life terms. Suppose your test tube has say $I=10^{20}$ particles of the hypothetical system in it instead of infinitely many. Then to reduce the specific entropy from 1 to 0.5 would require the temperature to be reduced to a completely impossible $10^{-20} \mathrm{~K}$. And
if you double the number of particles in the test tube, you would need another factor two reduction in temperature. In short, while formally the entropy for the finite hypothetical system goes to zero at absolute zero, the temperatures required to do so have no actual meaning.

## A. 36 Alternate Dirac equations

If you look in advanced books on quantum mechanics, you will likely find the Dirac equation written in a different form than given in chapter 12.12.

The Hamiltonian eigenvalue problem as given in that section was

$$
\left(\alpha_{0} m c^{2}+\sum_{i} \alpha_{i} \widehat{p}_{i} c\right) \vec{\psi}=E \vec{\psi}
$$

where $\vec{\psi}$ was a vector with four components.
Now assume for a moment that $\psi$ is a state of definite momentum. Then the above equation can be rewritten in the form

$$
\left(\gamma_{0} \frac{E}{c}-\sum_{i} \gamma_{i} p_{i}\right) \vec{\psi}=m c \vec{\psi}
$$

The motivation for doing so is that the coefficients of the $\gamma$ matrices are the components of the relativistic momentum four-vector, chapter 1.3.1.

It is easy to check that the only difference between the $\alpha$ and $\gamma$ matrices is that $\gamma_{1}$ through $\gamma_{3}$ get a minus sign in front of their bottom element. (Just multiply the original equation by $\alpha_{0}^{-1} / c$ and rearrange.)

The parenthetical expression above is essentially a four-vector dot product between the gamma matrices and the momentum four-vector. Especially if you give the dot product the wrong sign, as many physicists do. In particular, in the index notation of chapter 1.2.5, the parenthetical expression is then $\gamma^{\mu} p_{\mu}$. Feynman hit upon the bright idea to indicate dot products with $\gamma$ matrices by a slash through the name. So you are likely to find the above equation as

$$
\not p \vec{\psi}=m c \vec{\psi}
$$

Isn't it beautifully concise? Isn't it completely incomprehensible?
Also consider the case that $\vec{\psi}$ is not an energy and momentum eigenfunction. In that case, the equation of interest is found from the usual quantum substitutions that $E$ becomes $\mathrm{i} \hbar \partial / \partial t$ and $\vec{p}$ becomes $\hbar \partial / \mathrm{i} \partial t$. So the rewritten Dirac equation is then:

$$
\mathrm{i} \hbar\left(\gamma_{0} \frac{1}{c} \frac{\partial}{\partial t}+\sum_{i} \gamma_{i} \frac{\partial}{\partial x_{i}}\right) \vec{\psi}=m c \vec{\psi}
$$

In index notation, the parenthetical expression reads $\gamma^{\mu} \partial_{\mu}$. So following Feynman

$$
\mathrm{i} \hbar \not \partial \vec{\psi}=m c \vec{\psi}
$$

Now all that the typical physics book wants to add to that is a suitable non-SI system of units. If you use the electron mass $m$ as your unit of mass instead of the $\mathrm{kg}, c$ as unit of velocity instead of $\mathrm{m} / \mathrm{s}$, and $\hbar$ as your unit of angular momentum instead of $\mathrm{kg} \mathrm{m}^{2} / \mathrm{s}$, you get

$$
\mathrm{i} \not \partial \vec{\psi}=\vec{\psi}
$$

No outsider will ever guess what that stands for!

## A. 37 Maxwell's wave equations

This note derives the wave equations satisfied by electromagnetic fields. The derivation will use standard formulae of vector analysis, as found in, for example, [41, 20.35-45].

The starting point is Maxwell's equations for the electromagnetic field in vacuum:

$$
\begin{array}{rlc}
\nabla \cdot \overrightarrow{\mathcal{E}}=\frac{\rho}{\epsilon_{0}} & \nabla \cdot \overrightarrow{\mathcal{B}}=0 \\
\nabla \times \overrightarrow{\mathcal{E}} & =-\frac{\partial \overrightarrow{\mathcal{B}}}{\partial t} & (3) \\
\nabla \times \overrightarrow{\mathcal{B}}=\frac{\vec{\jmath}}{\epsilon_{0}}+\frac{\partial \overrightarrow{\mathcal{E}}}{\partial t}
\end{array}
$$

Here $\overrightarrow{\mathcal{E}}$ is the electric field, $\overrightarrow{\mathcal{B}}$ the magnetic field, $\rho$ the charge density, $\vec{\jmath}$ the current density, $c$ the constant speed of light, and $\epsilon_{0}$ is a constant called the permittivity of space. The charge and current densities are related by the continuity equation

$$
\begin{equation*}
\frac{\partial \rho}{\partial t}+\nabla \cdot \vec{\jmath}=0 \tag{5}
\end{equation*}
$$

To get a wave equation for the electric field, take the curl, $\nabla \times$, of (3) and apply the standard vector identity (D.1), (1) and (4) to get

$$
\begin{equation*}
\frac{1}{c^{2}} \frac{\partial^{2} \overrightarrow{\mathcal{E}}}{\partial t^{2}}-\nabla^{2} \overrightarrow{\mathcal{E}}=-\frac{1}{\epsilon_{0} c^{2}} \frac{\partial \vec{\jmath}}{\partial t}-\frac{1}{\epsilon_{0}} \nabla \rho \tag{A.235}
\end{equation*}
$$

Similarly, for the magnetic field take the curl of (4) and use (2) and (3) to get

$$
\begin{equation*}
\frac{1}{c^{2}} \frac{\partial^{2} \overrightarrow{\mathcal{B}}}{\partial t^{2}}-\nabla^{2} \overrightarrow{\mathcal{B}}=\frac{1}{\epsilon_{0} c^{2}} \nabla \times \vec{\jmath} \tag{A.236}
\end{equation*}
$$

These are uncoupled inhomogeneous wave equations for the components of $\overrightarrow{\mathcal{E}}$ and $\overrightarrow{\mathcal{B}}$, for given charge and current densities. According to the theory of partial differential equations, these equations imply that effects propagate no faster than the speed of light. You can also see the same thing pretty clearly from the fact that the homogeneous wave equation has solutions like

$$
\sin (k(y-c t)+\varphi)
$$

which are waves that travel with speed $c$ in the $y$-direction.
The wave equations for the potentials $\varphi$ and $\vec{A}$ are next. First note from (2) that the divergence of $\overrightarrow{\mathcal{B}}$ is zero. Then vector calculus says that it can be written as the curl of some vector. Call that vector $\vec{A}_{0}$.

$$
\begin{equation*}
\overrightarrow{\mathcal{B}}=\nabla \times \vec{A}_{0} \tag{6a}
\end{equation*}
$$

Next define

$$
\overrightarrow{\mathcal{E}}_{\varphi} \equiv \overrightarrow{\mathcal{E}}+\frac{\partial \vec{A}_{0}}{\partial t}
$$

Plug this into (3) to show that the curl of $\overrightarrow{\mathcal{E}}_{\varphi}$ is zero. Then vector calculus says that it can be written as minus the gradient of a scalar. Call this scalar $\varphi_{0}$. Plug that into the expression above to get

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=-\nabla \varphi_{0}-\frac{\partial \vec{A}_{0}}{\partial t} \tag{7a}
\end{equation*}
$$

Next, note that if you define modified versions $\vec{A}$ and $\varphi$ of $\vec{A}_{0}$ and $\varphi_{0}$ by setting

$$
\varphi=\varphi_{0}-\frac{\partial \chi}{\partial t} \quad \vec{A}=\vec{A}_{0}+\nabla \chi
$$

where $\chi$ is any arbitrary function of $x, y, z$, and $t$, then still

$$
\begin{equation*}
\overrightarrow{\mathcal{B}}=\nabla \times \vec{A} \tag{6}
\end{equation*}
$$

since the curl of a gradient is always zero, and

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=-\nabla \varphi-\frac{\partial \vec{A}}{\partial t} \tag{7}
\end{equation*}
$$

because the two $\chi$ terms drop out against each other.
The fact that $\vec{A}_{0}, \varphi_{0}$ and $\vec{A}, \varphi$ produce the same physical fields is the famous "gauge property" of the electromagnetic field.

Now you can select $\chi$ so that

$$
\begin{equation*}
\nabla \cdot \vec{A}+\frac{1}{c^{2}} \frac{\partial \varphi}{\partial t}=0 \tag{8}
\end{equation*}
$$

That is known as the "Lorenz condition." A corresponding gauge function is a "Lorenz gauge."

To find the gauge function $\chi$ that produces this condition, plug the definitions for $\vec{A}$ and $\varphi$ in terms of $\vec{A}_{0}$ and $\varphi_{0}$ into the left hand side of the Lorentz condition. That produces, after a change of sign,

$$
\frac{1}{c^{2}} \frac{\partial^{2} \chi}{\partial t^{2}}-\nabla^{2} \chi-\nabla \cdot \vec{A}_{0}-\frac{1}{c^{2}} \frac{\partial \varphi_{0}}{\partial t}=0
$$

That is a second order inhomogeneous wave equation for $\chi$.
Now plug the expressions (6) and (7) for $\overrightarrow{\mathcal{E}}$ and $\overrightarrow{\mathcal{B}}$ in terms of $\vec{A}$ and $\varphi$ into the Maxwell's equations. Equations (2) and (3) are satisfied automatically. From (2), after using (8),

$$
\begin{equation*}
\frac{1}{c^{2}} \frac{\partial^{2} \varphi}{\partial t^{2}}-\nabla^{2} \varphi=\frac{\rho}{\epsilon_{0}} \tag{A.237}
\end{equation*}
$$

From (4), after using (8),

$$
\begin{equation*}
\frac{1}{c^{2}} \frac{\partial^{2} \vec{A}}{\partial t^{2}}-\nabla^{2} \vec{A}=\frac{\vec{\jmath}}{\epsilon_{0} c^{2}} \tag{A.238}
\end{equation*}
$$

You can still select the two initial conditions for $\chi$. The smart thing to do is select them so that $\varphi$ and its time derivative are zero at time zero. In that case, if there is no charge density, $\varphi$ will stay zero for all time. That is because its wave equation is then homogeneous. The Lorenz condition will then ensure that $\nabla \cdot \vec{A}$ is zero too.

Instead of the Lorenz condition, you could select $\chi$ to make $\nabla \cdot \vec{A}$ zero. That is called the "Coulomb gauge" or "transverse gauge" or "transverse gauge." It requires that $\chi$ satisfies the Poisson equation

$$
-\nabla^{2} \chi=\nabla \cdot \vec{A}_{0}
$$

Then the governing equations become

$$
\begin{gathered}
-\nabla^{2} \varphi=\frac{\rho}{\epsilon_{0}} \\
\frac{1}{c^{2}} \frac{\partial^{2} \vec{A}}{\partial t^{2}}-\nabla^{2} \vec{A}=\frac{\vec{\jmath}}{\epsilon_{0} c^{2}}-\frac{1}{c^{2}} \nabla \frac{\partial \varphi}{\partial t}
\end{gathered}
$$

Note that $\varphi$ now satisfies a purely spatial Poisson equation.

## A. 38 Perturbation Theory

Most of the time in quantum mechanics, exact solution of the Hamiltonian eigenvalue problem of interest is not possible. To deal with that, approximations are made.

Perturbation theory can be used when the Hamiltonian $H$ consists of two parts $H_{0}$ and $H_{1}$, where the problem for $H_{0}$ can be solved and where $H_{1}$ is small. The idea is then to adjust the found solutions for the "unperturbed Hamiltonian" $H_{0}$ so that they become approximately correct for $H_{0}+H_{1}$.

This addendum explains how perturbation theory works. It also gives a few simple but important examples: the helium atom and the Zeeman and Stark effects. Addendum, $\{$ A. 39$\}$ will use the approach to study relativistic effects on the hydrogen atom.

## A.38.1 Basic perturbation theory

To use perturbation theory, the eigenfunctions and eigenvalues of the unperturbed Hamiltonian $H_{0}$ must be known. These eigenfunctions will here be indicated as $\psi_{\vec{n}, 0}$ and the corresponding eigenvalues by $E_{\vec{n}, 0}$. Note the use of the generic $\vec{n}$ to indicate the quantum numbers of the eigenfunctions. If the basic system is an hydrogen atom, as is often the case in textbook examples, and spin is unimportant, $\vec{n}$ would likely stand for the set of quantum numbers $n, l$, and $m$. But for a three-dimensional harmonic oscillator, $\vec{n}$ might stand for the quantum numbers $n_{x}, n_{y}$, and $n_{z}$. In a three-dimensional problem with one spinless particle, it takes three quantum numbers to describe an energy eigenfunction. However, which three depends on the problem and your approach to it. The additional subscript 0 in $\psi_{\vec{n}, 0}$ and $E_{\vec{n}, 0}$ indicates that they ignore the perturbation Hamiltonian $H_{1}$. They are called the unperturbed wave functions and energies.

The key to perturbation theory are the "Hamiltonian perturbation coefficients" defined as

$$
\begin{equation*}
H_{\overrightarrow{\underline{\underline{n}}, \overrightarrow{ }, 1}} \equiv\left\langle\psi_{\vec{n}, 0} \mid H_{1} \psi_{\vec{n}, 0}\right\rangle \tag{A.239}
\end{equation*}
$$

If you can evaluate these for every pair of energy eigenfunctions, you should be OK. Note that evaluating inner products is just summation or integration; it is generally a lot simpler than trying to solve the eigenvalue problem $\left(H_{0}+H_{1}\right) \psi$ $=E \psi$.

In the application of perturbation theory, the idea is to pick one unperturbed eigenfunction $\psi_{\vec{n}, 0}$ of $H_{0}$ of interest and then correct it to account for $H_{1}$, and especially correct its energy $E_{\vec{n}, 0}$. Caution! If the energy $E_{\vec{n}, 0}$ is degenerate, i.e. there is more than one unperturbed eigenfunction $\psi_{\vec{n}, 0}$ of $H_{0}$ with that energy, you must use a "good" eigenfunction to correct the energy. How to do that will be discussed in subsection A.38.3.

For now just assume that the energy is not degenerate or that you picked a good eigenfunction $\psi_{\vec{n}, 0}$. Then a first correction to the energy $E_{\vec{n}, 0}$ to account for the perturbation $H_{1}$ is very simple, \{D.79\}; just add the corresponding Hamiltonian perturbation coefficient:

$$
\begin{equation*}
E_{\vec{n}}=E_{\vec{n}, 0}+H_{\vec{n} \vec{n}, 1}+\ldots \tag{A.240}
\end{equation*}
$$

This is a quite user-friendly result, because it only involves the selected energy eigenfunction $\psi_{\vec{n}, 0}$. The other energy eigenfunctions are not involved. In a numerical solution, you might only have computed one state, say the ground state of $H_{0}$. Then you can use this result to correct the ground state energy for a perturbation even if you do not have data about any other energy states of $H_{0}$.

Unfortunately, it does happen quite a lot that the above correction $H_{\vec{n} \vec{n}, 1}$ is zero because of some symmetry or the other. Or it may simply not be accurate enough. In that case, to find the energy change you have to use what is called "second order perturbation theory:"

$$
\begin{equation*}
E_{\vec{n}}=E_{\vec{n}, 0}+H_{\vec{n} \vec{n}, 1}-\sum_{E_{\vec{n}, 0} \neq E_{\vec{n}, 0}} \frac{\left|H_{\vec{n} \vec{n}, \vec{n}, 0}\right|^{2}}{E_{\vec{n}, 0}-E_{\vec{n}, 0}}+\ldots \tag{A.241}
\end{equation*}
$$

Now all eigenfunctions of $H_{0}$ will be needed, which makes second order theory a lot nastier. Then again, even if the "first order" correction $H_{\vec{n} \vec{n}, 1}$ to the energy is nonzero, the second order formula will likely give a much more accurate result.

Sometimes you may also be interested in what happens to the energy eigenfunctions, not just the energy eigenvalues. The corresponding formula is

$$
\begin{equation*}
\psi_{\vec{n}}=\psi_{\vec{n}, 0}-\sum_{E_{\vec{n}, 0} \neq E_{\overrightarrow{\vec{n}}, 0}} \frac{H_{\vec{n} \vec{n}, 1}}{E_{\vec{n}, 0}-E_{\vec{n}, 0}} \psi_{\vec{n}, 0}+\sum_{\substack{E_{\vec{n}, 0}=E_{\vec{n}}, 0 \\ \vec{n} \neq \vec{n}}} c_{\overrightarrow{\underline{n}}} \psi_{\vec{n}, 0}+\ldots \tag{A.242}
\end{equation*}
$$

That is the first order result. The second sum is zero if the problem is not degenerate. Otherwise its coefficients $c_{\vec{n}}$ are determined by considerations found in derivation $\{\mathrm{D} .79\}$.

In some cases, instead of using second order theory as above, it may be simpler to compute the first order wave function perturbation and the second order energy change from

$$
\begin{array}{|c}
\left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 1}=-\left(H_{1}-E_{\vec{n}, 1}\right) \psi_{\vec{n}, 0} \quad E_{\vec{n}, 2}=\left\langle\psi_{\vec{n}, 0} \mid\left(H_{1}-E_{\vec{n}, 1}\right) \psi_{\vec{n}, 1}\right\rangle \\
\text { (A.243) }
\end{array}
$$

Eigenfunction $\psi_{\vec{n}, 0}$ must be good. The good news is that this does not require all the unperturbed eigenfunctions. The bad news is that it requires solution of a nontrivial equation involving the unperturbed Hamiltonian instead of just
integration. It may be the best way to proceed for a perturbation of a numerical solution.

One application of perturbation theory is the "Hellmann-Feynman theorem." Here the perturbation Hamiltonian is an infinitesimal change $\partial H$ in the unperturbed Hamiltonian caused by an infinitesimal change in some parameter that it depends on. If the parameter is called $\lambda$, perturbation theory says that the first order energy change is

$$
\begin{equation*}
\frac{\partial E_{\vec{n}}}{\partial \lambda}=\left\langle\psi_{\vec{n}, 0} \left\lvert\, \frac{\partial H}{\partial \lambda} \psi_{\vec{n}, 0}\right.\right\rangle \tag{A.244}
\end{equation*}
$$

when divided by the change in parameter $\partial \lambda$. If you can figure out the inner product, you can figure out the change in energy. But more important is the reverse: if you can find the derivative of the energy with respect to the parameter, you have the inner product. For example, the Hellmann-Feynman theorem is helpful for finding the expectation value of $1 / r^{2}$ for the hydrogen atom, a nasty problem, $\{\mathrm{D} .83\}$. Of course, always make sure the eigenfunction $\psi_{\vec{n}, 0}$ is a good one for the derivative of the Hamiltonian.

## A.38.2 Ionization energy of helium

One prominent deficiency in the approximate analysis of the heavier atoms in chapter 5.9 was the poor ionization energy that it gave for helium. The purpose of this example is to derive a much more reasonable value using perturbation theory.

Exactly speaking, the ionization energy is the difference between the energy of the helium atom with both its electrons in the ground state and the helium ion with its second electron removed. Now the energy of the helium ion with electron 2 removed is easy; the Hamiltonian for the remaining electron 1 is

$$
H_{\mathrm{He} \text { ion }}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla_{1}^{2}-2 \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{1}}
$$

where the first term represents the kinetic energy of the electron and the second its attraction to the two-proton nucleus. The helium nucleus normally also contains two neutrons, but they do not attract the electron.

This Hamiltonian is exactly the same as the one for the hydrogen atom in chapter 4.3 , except that it has $2 e^{2}$ where the hydrogen one, with just one proton in its nucleus, has $e^{2}$. So the solution for the helium ion is simple: just take the hydrogen solution, and everywhere where there is an $e^{2}$ in that solution, replace it by $2 e^{2}$. In particular, the Bohr radius $a$ for the helium ion is half the Bohr radius $a_{0}$ for hydrogen,

$$
a=\frac{4 \pi \epsilon_{0} \hbar^{2}}{m_{\mathrm{e}} 2 e^{2}}=\frac{1}{2} a_{0}
$$

and so its energy and wave function become

$$
E_{\mathrm{gs}, \text { ion }}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} a^{2}}=4 E_{1} \quad \psi_{\mathrm{gs}, \text { ion }}(\vec{r})=\frac{1}{\sqrt{\pi a^{3}}} e^{-r / a}
$$

where $E_{1}=-13.6 \mathrm{eV}$ is the energy of the hydrogen atom.
It is interesting to see that the helium ion has four times the energy of the hydrogen atom. The reasons for this much higher energy are both that the nucleus is twice as strong, and that the electron is twice as close to it: the Bohr radius is half the size. More generally, in heavy atoms the electrons that are poorly shielded from the nucleus, which means the inner electrons, have energies that scale with the square of the nuclear strength. For such electrons, relativistic effects are much more important than they are for the electron in a hydrogen atom.

The neutral helium atom is not by far as easy to analyze as the ion. Its Hamiltonian is, from (5.34):

$$
H_{\mathrm{He}}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla_{1}^{2}-2 \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{1}}-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla_{2}^{2}-2 \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{2}}+\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{\left|\vec{r}_{2}-\vec{r}_{1}\right|}
$$

The first two terms are the kinetic energy and nuclear attraction of electron 1 , and the next two the same for electron 2. The final term is the electron to electron repulsion, the curse of quantum mechanics. This final term is the reason that the ground state of helium cannot be found analytically.

Note however that the repulsion term is qualitatively similar to the nuclear attraction terms, except that there are four of these nuclear attraction terms versus a single repulsion term. So maybe then, it may work to treat the repulsion term as a small perturbation, call it $H_{1}$, to the Hamiltonian $H_{0}$ given by the first four terms? Of course, if you ask mathematicians whether $25 \%$ is a small amount, they are going to vehemently deny it; but then, so they would for any amount if there is no limit process involved, so just don't ask them, OK?

The solution of the eigenvalue problem $H_{0} \psi=E \psi$ is simple: since the electrons do not interact with this Hamiltonian, the ground state wave function is the product of the ground state wave functions for the individual electrons, and the energy is the sum of their energies. And the wave functions and energies for the separate electrons are given by the solution for the ion above, so

$$
\psi_{\mathrm{gs}, 0}=\frac{1}{\pi a^{3}} e^{-\left(r_{1}+r_{2}\right) / a} \quad E_{\mathrm{gs}, 0}=8 E_{1}
$$

According to this result, the energy of the atom is $8 E_{1}$ while the ion had $4 E_{1}$, so the ionization energy would be $4\left|E_{1}\right|$, or 54.4 eV . Since the experimental value is 24.6 eV , this is no better than the 13.6 eV chapter 5.9 came up with.

To get a better ionization energy, try perturbation theory. According to first order perturbation theory, a better value for the energy of the hydrogen atom should be

$$
E_{\mathrm{gs}}=E_{\mathrm{gs}, 0}+\left\langle\psi_{\mathrm{gs}, 0} \mid H_{1} \psi_{\mathrm{gs}, 0}\right\rangle
$$

or substituting in from above,

$$
E_{\mathrm{gs}}=8 E_{1}+\frac{e^{2}}{4 \pi \epsilon_{0}}\left\langle\frac{1}{\pi a^{3}} e^{-\left(r_{1}+r_{2}\right) / a} \left\lvert\, \frac{1}{\left|\vec{r}_{2}-\vec{r}_{1}\right|} \frac{1}{\pi a^{3}} e^{-\left(r_{1}+r_{2}\right) / a}\right.\right\rangle
$$

The inner product of the final term can be written out as

$$
\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{\pi^{2} a^{6}} \int_{\text {all } \vec{r}_{1}} \int_{\text {all }} \frac{e^{-2\left(r_{1}+r_{2}\right) / a}}{\left|\vec{r}_{2}-\vec{r}_{1}\right|} \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}
$$

This integral can be done analytically. Try it, if you are so inclined; integrate $\mathrm{d}^{3} \vec{r}_{1}$ first, using spherical coordinates with $\vec{r}_{2}$ as their axis and doing the azimuthal and polar angles first. Be careful, $\sqrt{\left(r_{1}-r_{2}\right)^{2}}=\left|r_{1}-r_{2}\right|$, not $r_{1}-r_{2}$, so you will have to integrate $r_{1}<r_{2}$ and $r_{1}>r_{2}$ separately in the final integration over $\mathrm{d} r_{1}$. Then integrate $\mathrm{d}^{3} \vec{r}_{2}$.

The result of the integration is

$$
\frac{e^{2}}{4 \pi \epsilon_{0}}\left\langle\frac{1}{\pi a^{3}} e^{-\left(r_{1}+r_{2}\right) / a} \left\lvert\, \frac{1}{\left|\vec{r}_{2}-\vec{r}_{1}\right|} \frac{1}{\pi a^{3}} e^{-\left(r_{1}+r_{2}\right) / a}\right.\right\rangle=\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{5}{8 a}=\frac{5}{2}\left|E_{1}\right|
$$

Therefore, the helium atom energy increases by $2.5\left|E_{1}\right|$ due to the electron repulsion, and with it, the ionization energy decreases to $1.5\left|E_{1}\right|$, or 20.4 eV . It is not 24.6 eV , but it is clearly much more reasonable than 54 or 13.6 eV were.

The second order perturbation result should give a much more accurate result still. However, if you did the integral above, you may feel little inclination to try the ones involving all possible products of hydrogen energy eigenfunctions.

Instead, the result can be improved using a variational approach, like the ones that were used earlier for the hydrogen molecule and molecular ion, and this requires almost no additional work. The idea is to accept the hint from perturbation theory that the wave function of helium can be approximated as $\psi_{a}\left(\vec{r}_{1}\right) \psi_{a}\left(\vec{r}_{2}\right)$ where $\psi_{a}$ is the hydrogen ground state wave function using a modified Bohr radius $a$ instead of $a_{0}$ :

$$
\psi_{\mathrm{gs}}=\psi_{a}\left(\vec{r}_{1}\right) \psi_{a}\left(\vec{r}_{2}\right) \quad \psi_{a}(\vec{r}) \equiv \frac{1}{\sqrt{\pi a^{3}}} e^{-r / a}
$$

However, instead of accepting the perturbation theory result that $a$ should be half the normal Bohr radius $a_{0}$, let $a$ be optimized to make the expectation energy for the ground state

$$
E_{\mathrm{gs}}=\left\langle\psi_{\mathrm{gs}} \mid H_{\mathrm{He}} \psi_{\mathrm{gs}}\right\rangle
$$

as small as possible. This will produce the most accurate ground state energy possible for a ground state wave function of this form, guaranteed no worse than assuming that $a=\frac{1}{2} a_{0}$, and probably better.

No new integrals need to be done to evaluate the inner product above. Instead, noting that for the hydrogen atom according to the virial theorem of chapter 7.2 the expectation kinetic energy equals $-E_{1}=\hbar^{2} / 2 m_{\mathrm{e}} a_{0}^{2}$ and the potential energy equals $2 E_{1}$, two of the needed integrals can be inferred from the hydrogen solution: chapter 4.3,

$$
\begin{gathered}
\left\langle\psi_{a} \left\lvert\,-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla^{2} \psi_{a}\right.\right\rangle=\frac{\hbar^{2}}{2 m_{\mathrm{e}} a^{2}} \\
-\frac{e^{2}}{4 \pi \epsilon_{0}}\left\langle\psi_{a} \left\lvert\, \frac{1}{r} \psi_{a}\right.\right\rangle=-\frac{\hbar^{2}}{m_{\mathrm{e}} a_{0}}\left\langle\psi_{a} \left\lvert\, \frac{1}{r} \psi_{a}\right.\right\rangle=-\frac{\hbar^{2}}{m_{\mathrm{e}} a_{0}} \frac{1}{a}
\end{gathered}
$$

and this subsection added

$$
\left\langle\psi_{a} \psi_{a} \left\lvert\, \frac{1}{\left|\vec{r}_{2}-\vec{r}_{1}\right|} \psi_{a} \psi_{a}\right.\right\rangle=\frac{5}{8 a}
$$

Using these results with the helium Hamiltonian, the expectation energy of the helium atom can be written out to be

$$
\left\langle\psi_{a} \psi_{a} \mid H_{\mathrm{He}} \psi_{a} \psi_{a}\right\rangle=\frac{\hbar^{2}}{m_{\mathrm{e}} a^{2}}-\frac{27}{8} \frac{\hbar^{2}}{m_{\mathrm{e}} a_{0} a}
$$

Setting the derivative with respect to $a$ to zero locates the minimum at $a=\frac{16}{27} a_{0}$, rather than $\frac{1}{2} a_{0}$. Then the corresponding expectation energy is $-3^{6} \hbar^{2} / 2^{8} m_{\mathrm{e}} a_{0}^{2}$, or $3^{6} E_{1} / 2^{7}$. Putting in the numbers, the ionization energy is now found as 23.1 eV , in quite good agreement with the experimental 24.6 eV .

## A.38.3 Degenerate perturbation theory

Energy eigenvalues are degenerate if there is more than one independent eigenfunction with that energy. Now, if you try to use perturbation theory to correct a degenerate eigenvalue of a Hamiltonian $H_{0}$ for a perturbation $H_{1}$, there may be a problem. Assume that there are $d>1$ independent eigenfunctions with energy $E_{\vec{n}, 0}$ and that they are numbered as

$$
\psi_{\vec{n}_{1}, 0}, \psi_{\vec{n}_{2}, 0}, \ldots, \psi_{\vec{n}_{d}, 0}
$$

Then as far as $H_{0}$ is concerned, any combination

$$
\psi_{\vec{n}, 0}=c_{1} \psi_{\vec{n}_{1}, 0}+c_{2} \psi_{\vec{n}_{2}, 0}+\ldots+c_{d} \psi_{\vec{n}_{d}, 0}
$$

with arbitrary coefficients $c_{1}, c_{2}, \ldots, c_{d}$, (not all zero, of course), is just as good an eigenfunction with energy $E_{\vec{n}, 0}$ as any other.

Unfortunately, the full Hamiltonian $H_{0}+H_{1}$ is not likely to agree with $H_{0}$ about that. As far as the full Hamiltonian is concerned, normally only very specific combinations are acceptable, the "good" eigenfunctions. It is said that
the perturbation $H_{1}$ "breaks the degeneracy" of the energy eigenvalue. The single energy eigenvalue splits into several eigenvalues of different energy. Only good combinations will show up these changed energies; the bad ones will pick up uncertainty in energy that hides the effect of the perturbation.

The various ways of ensuring good eigenfunctions are illustrated in the following subsections for example perturbations of the energy levels of the hydrogen atom. Recall that the unperturbed energy eigenfunctions of the hydrogen atom electron, as derived in chapter 4.3, and also including spin, are given as $\psi_{n l m} \uparrow$ and $\psi_{n l m} \downarrow$. They are highly degenerate: all the eigenfunctions with the same value of $n$ have the same energy $E_{n}$, regardless of what is the value of the azimuthal quantum number $0 \leqslant l \leqslant n-1$ corresponding to the square orbital angular momentum $L^{2}=l(l+1) \hbar^{2}$; regardless of what is the magnetic quantum number $|m| \leqslant l$ corresponding to the orbital angular momentum $L_{z}=m \hbar$ in the $z$-direction; and regardless of what is the spin quantum number $m_{s}= \pm \frac{1}{2}$ corresponding to the spin angular momentum $m_{s} \hbar$ in the $z$-direction. In particular, the ground state energy level $E_{1}$ is two-fold degenerate, it is the same for both $\psi_{100} \uparrow$, i.e. $m_{s}=\frac{1}{2}$ and $\psi_{100 \downarrow} \downarrow, m_{s}=-\frac{1}{2}$. The next energy level $E_{2}$ is eight-fold degenerate, it is the same for $\psi_{200} \uparrow, \psi_{211} \uparrow, \psi_{210} \mathfrak{\imath}$, and $\psi_{21-1} \uparrow$, and so on for higher values of $n$.

There are two important rules to identify the good eigenfunctions, $\{\mathrm{D} .79\}$ :

1. Look for good quantum numbers. The quantum numbers that make the energy eigenfunctions of the unperturbed Hamiltonian $H_{0}$ unique correspond to the eigenvalues of additional operators besides the Hamiltonian. If the perturbation Hamiltonian $H_{1}$ commutes with one of these additional operators, the corresponding quantum number is good. You do not need to combine eigenfunctions with different values of that quantum number.
In particular, if the perturbation Hamiltonian commutes with all additional operators that make the eigenfunctions of $H_{0}$ unique, stop worrying: every eigenfunction is good already.
For example, for the usual hydrogen energy eigenfunctions $\psi_{n l m} \downarrow$, the quantum numbers $l, m$, and $m_{s}$ make the eigenfunctions at a given unperturbed energy level $n$ unique. They correspond to the operators $\widehat{L}^{2}, \widehat{L}_{z}$, and $\widehat{S}_{z}$. If the perturbation Hamiltonian $H_{1}$ commutes with any one of these operators, the corresponding quantum number is good. If the perturbation commutes with all three, all eigenfunctions are good already.
2. Even if some quantum numbers are bad because the perturbation does not commute with that operator, eigenfunctions are still good if there are no other eigenfunctions with the same unperturbed energy and the same good quantum numbers.

Otherwise linear algebra is required. For each set of energy eigen-
functions

$$
\psi_{\vec{n}_{1}, 0}, \psi_{\vec{n}_{2}, 0}, \ldots
$$

with the same unperturbed energy and the same good quantum numbers, but different bad ones, form the matrix of Hamiltonian perturbation coefficients

$$
\left(\begin{array}{ccc}
\left\langle\psi_{\vec{n}_{1}, 0} \mid H_{1} \psi_{\vec{n}_{1}, 0}\right\rangle & \left\langle\psi_{\vec{n}_{1}, 0} \mid H_{1} \psi_{\vec{n}_{2}, 0}\right\rangle & \ldots \\
\left\langle\psi_{\vec{n}_{2}, 0} \mid H_{1} \psi_{\vec{n}_{1}, 0}\right\rangle & \left\langle\psi_{\vec{n}_{2}, 0} \mid H_{1} \psi_{\vec{n}_{2}, 0}\right\rangle & \ldots \\
\vdots & \vdots & \ddots
\end{array}\right)
$$

The eigenvalues of this matrix are the first order energy corrections Also, the coefficients $c_{1}, c_{2}, \ldots$ of each good eigenfunction

$$
c_{1} \psi_{\vec{n}_{1}, 0}+c_{2} \psi_{\vec{n}_{2}, 0}+\ldots
$$

must be an eigenvector of the matrix.
Unfortunately, if the eigenvalues of this matrix are not all different, the eigenvectors are not unique, so you remain unsure about what are the good eigenfunctions. In that case, if the second order energy corrections are needed, the detailed analysis of derivation \{D.79\} will need to be followed.
If you are not familiar with linear algebra at all, in all cases mentioned here the matrices are just two by two, and you can find that solution spelled out in the notations under "eigenvector."
The following, related, practical observation can also be made:
Hamiltonian perturbation coefficients can only be nonzero if all the good quantum numbers are the same.

## A.38.4 The Zeeman effect

If you put an hydrogen atom in an external magnetic field $\overrightarrow{\mathcal{B}}_{\text {ext }}$, the energy levels of the electron change. That is called the "Zeeman effect."

If for simplicity a coordinate system is used with its $z$-axis aligned with the magnetic field, then according to chapter 13.4, the Hamiltonian of the hydrogen atom acquires an additional term

$$
\begin{equation*}
H_{1}=\frac{e}{2 m_{\mathrm{e}}} \mathcal{B}_{\mathrm{ext}}\left(\widehat{L}_{z}+2 \widehat{S}_{z}\right) \tag{A.245}
\end{equation*}
$$

beyond the basic hydrogen atom Hamiltonian $H_{0}$ of chapter 4.3.1. Qualitatively, it expresses that a spinning charged particle is equivalent to a tiny electromagnet, and a magnet wants to align itself with a magnetic field, just like a compass needle aligns itself with the magnetic field of earth.

For this perturbation, the $\psi_{n m l} \mathfrak{\downarrow}$ energy eigenfunctions are already good ones, because $H_{1}$ commutes with all of $\widehat{L}^{2}, \widehat{L}_{z}$ and $\widehat{S}_{z}$. So, according to perturbation theory, the energy eigenvalues of an hydrogen atom in a magnetic field are approximately

$$
E_{n}+\left\langle\psi_{n m l} \mathfrak{\mathcal { \imath }}\right| H_{1}\left|\psi_{n m l} \mathcal{\Psi}\right\rangle=E_{n}+\frac{e}{2 m_{\mathrm{e}}} \mathcal{B}_{\text {ext }}\left(m+2 m_{s}\right) \hbar
$$

Actually, this is not approximate at all; it is the exact eigenvalue of $H_{0}+H_{1}$ corresponding to the exact eigenfunction $\psi_{n m l} \uparrow$.

The Zeeman effect can be seen in an experimental spectrum. Consider first the ground state. If there is no electromagnetic field, the two ground states $\psi_{100} \uparrow$ and $\psi_{100} \downarrow$ would have exactly the same energy. Therefore, in an experimental spectrum, they would show up as a single line. But with the magnetic field, the two energy levels are different,

$$
E_{100 \downarrow}=E_{1}-\frac{e \hbar}{2 m_{\mathrm{e}}} \mathcal{B}_{\mathrm{ext}} \quad E_{100 \uparrow}=E_{1}+\frac{e \hbar}{2 m_{\mathrm{e}}} \mathcal{B}_{\mathrm{ext}} \quad E_{1}=-13.6 \mathrm{eV}
$$

so the single line splits into two! Do note that the energy change due to even an extremely strong magnetic field of 100 Tesla is only 0.006 eV or so, chapter 13.4 , so it is not like the spectrum would become unrecognizable. The single spectral line of the eight $\psi_{2 l m} \uparrow$ "L" shell states will similarly split in five closely spaced but separate lines, corresponding to the five possible values $-2,-1,0$, 1 and 2 for the factor $m+2 m_{s}$ above.

Some disclaimers should be given here. First of all, the 2 in $m+2 m_{s}$ is only equal to 2 up to about $0.1 \%$ accuracy. More importantly, even in the absence of a magnetic field, the energy levels at a given value of $n$ do not really form a single line in the spectrum if you look closely enough. There are small errors in the solution of chapter 4.3 due to relativistic effects, and so the theoretical lines are already split. That is discussed in addendum \{A.39\}. The description given above is a good one for the "strong" Zeeman effect, in which the magnetic field is strong enough to swamp the relativistic errors.

## A.38.5 The Stark effect

If an hydrogen atom is placed in an external electric field $\overrightarrow{\mathcal{E}}_{\text {ext }}$ instead of the magnetic one of the previous subsection, its energy levels will change too. That is called the "Stark effect." Of course a Zeeman, Dutch for sea-man, would be most interested in magnetic fields. A Stark, maybe in a spark? (Apologies.)

If the $z$-axis is taken in the direction of the electric field, the contribution of the electric field to the Hamiltonian is given by:

$$
\begin{equation*}
H_{1}=e \mathcal{E}_{\mathrm{ext}} z \tag{A.246}
\end{equation*}
$$

It is much like the potential energy mgh of gravity, with the electron charge $e$ taking the place of the mass $m, \mathcal{E}_{\text {ext }}$ that of the gravity strength $g$, and $z$ that of the height $h$.

Since the typical magnitude of $z$ is of the order of a Bohr radius $a_{0}$, you would expect that the energy levels will change due to the electric field by an amount of rough size $e \mathcal{E}_{\text {ext }} a_{0}$. A strong laboratory electric field might have $e \mathcal{E}_{\text {ext }} a_{0}$ of the order of $0.0005 \mathrm{eV},[25, \mathrm{p} .339]$. That is really small compared to the typical electron energy levels.

And additionally, it turns out that for many eigenfunctions, including the ground state, the first order correction to the energy is zero. To get the energy change in that case, you need to compute the second order term, which is a pain. And that term will be much smaller still than even $e \mathcal{E}_{\text {ext }} a_{0}$ for reasonable field strengths.

Now first suppose that you ignore the warnings on good eigenfunctions, and just compute the energy changes using the inner product $\left\langle\psi_{n l m} \downarrow \mid H_{1} \psi_{n l m} \downarrow\right\rangle$. You will then find that this inner product is zero for whatever energy eigenfunction you take:

$$
\left\langle\psi_{n l m} \uparrow \mid e \mathcal{E}_{\text {ext }} z \psi_{n l m} \uparrow\right\rangle=0 \text { for all } n, l, m \text {, and } m_{s}
$$

The reason is that negative $z$ values integrate away against positive ones. (The inner products are integrals of $z$ times $\left|\psi_{n l m}\right|^{2}$, and $\left|\psi_{n l m}\right|^{2}$ is the same at opposite sides of the nucleus while $z$ changes sign, so the contributions of opposite sides to the inner product pairwise cancel.)

So, since all first order energy changes that you compute are zero, you would naturally conclude that to first order approximation none of the energy levels of a hydrogen atom changes due to the electric field. But that conclusion is wrong for anything but the ground state energy. And the reason it is wrong is because the good eigenfunctions have not been used.

Consider the operators $\widehat{L}^{2}, \widehat{L}_{z}$, and $S_{z}$ that make the energy eigenfunctions $\psi_{n l m} \mathfrak{\imath}$ unique. If $H_{1}=e \mathcal{E}_{\text {ext }} z$ commuted with them all, the $\psi_{n l m} \downarrow$ would be good eigenfunctions. Unfortunately, while $z$ commutes with $\widehat{L}_{z}$ and $S_{z}$, it does not commute with $\widehat{L}^{2}$, see chapter 4.5.4. The quantum number $l$ is bad.

Still, the two states $\psi_{100} \uparrow$ with the ground state energy are good states, because there are no states with the same energy and a different value of the bad quantum number $l$. Really, spin has nothing to do with the Stark problem. If you want, you can find the purely spatial energy eigenfunctions first, then for every spatial eigenfunction, there will be one like that with spin up and one with spin down. In any case, since the two eigenfunctions $\psi_{100} \uparrow$ are both good, the ground state energy does indeed not change to first order.

But now consider the eight-fold degenerate $n=2$ energy level. Each of the four eigenfunctions $\psi_{211} \downarrow$ and $\psi_{21-1} \downarrow$ is a good one because for each of them, there is no other $n=2$ eigenfunction with a different value of the bad quantum
number $l$. The energies corresponding to these good eigenfunctions too do indeed not change to first order.

However, the remaining two $n=2$ spin-up states $\psi_{200} \uparrow$ and $\psi_{210} \uparrow$ have different values for the bad quantum number $l$, and they have the same values $m=0$ and $m_{s}=\frac{1}{2}$ for the good quantum numbers of orbital and spin $z$ momentum. These eigenfunctions are bad and will have to be combined to produce good ones. And similarly the remaining two spin-down states $\psi_{200} \downarrow$ and $\psi_{210} \downarrow$ are bad and will have to be combined.

It suffices to just analyze the spin up states, because the spin down ones go exactly the same way. The coefficients $c_{1}$ and $c_{2}$ of the good combinations $c_{1} \psi_{200} \uparrow+c_{2} \psi_{210} \uparrow$ must be eigenvectors of the matrix

$$
\left(\begin{array}{ll}
\left\langle\psi_{200} \uparrow \mid H_{1} \psi_{200} \uparrow\right\rangle & \left\langle\psi_{200} \uparrow \mid H_{1} \psi_{210} \uparrow\right\rangle \\
\left\langle\psi_{210} \uparrow \mid H_{1} \psi_{200} \uparrow\right\rangle & \left\langle\psi_{210} \uparrow \mid H_{1} \psi_{210} \uparrow\right\rangle
\end{array}\right) \quad H_{1}=e \mathcal{E}_{\text {ext }} z
$$

The "diagonal" elements of this matrix (top left corner and bottom right corner) are zero because of cancellation of negative and positive $z$ values as discussed above. And the top right and bottom left elements are complex conjugates, (2.16), so only one of them needs to be actually computed. And the spin part of the inner product produces one and can therefore be ignored. What is left is a matter of finding the two spatial eigenfunctions involved according to (4.36), looking up the spherical harmonics in table 4.2 and the radial functions in table 4.4, and integrating it all against $e \mathcal{E}_{\text {ext }} z$. The resulting matrix is

$$
\left(\begin{array}{cc}
0 & -3 e \mathcal{E}_{\text {ext }} a_{0} \\
-3 e \mathcal{E}_{\text {ext }} a_{0} & 0
\end{array}\right)
$$

The eigenvectors of this matrix are simple enough to guess; they have either equal or opposite coefficients $c_{1}$ and $c_{2}$ :

$$
\begin{gathered}
\left(\begin{array}{cc}
0 & -3 e \mathcal{E}_{\text {ext }} a_{0} \\
-3 e \mathcal{E}_{\text {ext }} a_{0} & 0
\end{array}\right)\binom{\sqrt{\frac{1}{2}}}{\sqrt{\frac{1}{2}}}=-3 e \mathcal{E}_{\text {ext }} a_{0}\binom{\sqrt{\frac{1}{2}}}{\sqrt{\frac{1}{2}}} \\
\left(\begin{array}{cc}
0 & -3 e \mathcal{E}_{\text {ext }} a_{0} \\
-3 e \mathcal{E}_{\text {ext }} a_{0} & 0
\end{array}\right)\binom{\sqrt{\frac{1}{2}}}{-\sqrt{\frac{1}{2}}}=3 e \mathcal{E}_{\text {ext }} a_{0}\binom{\sqrt{\frac{1}{2}}}{-\sqrt{\frac{1}{2}}}
\end{gathered}
$$

If you want to check these expressions, note that the product of a matrix times a vector is found by taking dot products between the rows of the matrix and the vector. It follows that the good combination $\sqrt{\frac{1}{2}} \psi_{200} \uparrow+\sqrt{\frac{1}{2}} \psi_{210} \uparrow$ has a first order energy change $-3 e \mathcal{E}_{\text {ext }} a_{0}$, and the good combination $\sqrt{\frac{1}{2}} \psi_{200} \uparrow-\sqrt{\frac{1}{2}} \psi_{210} \uparrow$ has $+3 e \mathcal{E}_{\text {ext }} a_{0}$. The same applies for the spin down states. It follows that to first order the $n=2$ level splits into three, with energies $E_{2}-3 e \mathcal{E}_{\text {ext }} a_{0}, E_{2}$, and
$E_{2}+3 e \mathcal{E}_{\text {ext }} a_{0}$, where the value $E_{2}$ applies to the eigenfunctions $\psi_{211} \downarrow$ and $\psi_{21-1} \uparrow$ that were already good. The conclusion, based on the wrong eigenfunctions, that the energy levels do not change was all wrong.

Remarkably, the good combinations of $\psi_{200}$ and $\psi_{210}$ are the "sp" hybrids of carbon fame, as described in chapter 5.11.4. Note from figure 5.13 in that section that these hybrids do not have the same magnitude at opposite sides of the nucleus. They have an intrinsic "electric dipole moment," with the charge shifted towards one side of the atom, and the electron then wants to align this dipole moment with the ambient electric field. That is much like in Zeeman splitting, where electron wants to align its orbital and spin magnetic dipole moments with the ambient magnetic field.

The crucial thing to take away from all this is: always, always, check whether the eigenfunction is good before applying perturbation theory.

It is obviously somewhat disappointing that perturbation theory did not give any information about the energy change of the ground state beyond the fact that it is second order, i.e. very small compared to $e \mathcal{E}_{\text {ext }} a_{0}$. You would like to know approximately what it is, not just that it is very small. Of course, now that it is established that $\psi_{100} \uparrow$ is a good state with $m=0$ and $m_{s}=\frac{1}{2}$, you could think about evaluating the second order energy change (A.241), by integrating $\left\langle\psi_{100} \uparrow \mid e \mathcal{E}_{\text {ext }} z \psi_{n l 0} \uparrow\right\rangle$ for all values of $n$ and $l$. But after refreshing your memory about the analytical expression (D.8) for the $\psi_{n l m}$, you might think again.

It is however possible to find the perturbation in the wave function from the alternate approach (A.243), $\{$ D.80\}. In that way the second order ground state energy is found to be

$$
E_{100}=E_{1}-\frac{3 e \mathcal{E}_{\mathrm{ext}} a_{0}}{8\left|E_{1}\right|} 3 e \mathcal{E}_{\mathrm{ext}} a_{0} \quad E_{1}=-13.6 \mathrm{eV}
$$

Note that the atom likes an electric field: it lowers its ground state energy. Also note that the energy change is indeed second order; it is proportional to the square of the electric field strength. You can think of the attraction of the atom to the electric field as a two-stage process: first the electric field polarizes the atom by distorting its initially symmetric charge distribution. Then it interacts with this polarized atom in much the same way that it interacts with the sp hybrids. But since the polarization is now only proportional to the field strength, the net energy drop is proportional to the square of the field strength.

Finally, note that the typical value of 0.0005 eV or so for $e \mathcal{E}_{\text {ext }} a_{0}$ quoted earlier is very small compared to the about 100 eV for $8\left|E_{1}\right|$, making the fraction in the expression above very small. So, indeed the second order change in the ground state energy $E_{1}$ is much smaller than the first order energy changes $\pm 3 \mathcal{E}_{\text {ext }} a_{0}$ in the $E_{2}$ energy level.

A weird prediction of quantum mechanics is that the electron will eventually escape from the atom, leaving it ionized. The reason is that the potential is linear in $z$, so if the electron goes out far enough in the $z$-direction, it will
eventually encounter potential energies that are lower than the one it has in the atom. Of course, to get at such large values of $z$, the electron must pass positions where the required energy far exceeds the -13.6 eV it has available, and that is impossible for a classical particle. However, in quantum mechanics the position of the electron is uncertain, and the electron does have some miniscule chance of "tunneling out" of the atom through the energy barrier, chapter 7.12.2. Realistically, though, for even strong experimental fields like the one mentioned above, the "life time" of the electron in the atom before it has a decent chance of being found outside it far exceeds the age of the universe.

## A. 39 The relativistic hydrogen atom

The description of the hydrogen atom given earlier in chapter 4.3 is very accurate by engineering standards. However, it is not exact. This addendum examines various relativistic effects that were ignored in the analysis.

The approach will be to take the results of chapter 4.3 as the starting point. Then corrections are applied to them using perturbation theory as described in addendum $\{\mathrm{A} .38\}$.

## A.39.1 Introduction

According to the description of the hydrogen atom given in chapter 4.3, all energy eigenfunctions $\psi_{n l m} \downarrow$ with the same value of $n$ have the same energy $E_{n}$. Therefore they should show up as a single line in an experimental line spectrum. But actually, when these spectra are examined very precisely, the $E_{n}$ energy levels for a given value of $n$ are found to consist of several closely spaced lines, rather than a single one. That is called the "hydrogen atom fine structure." It means that eigenfunctions that all should have exactly the same energy, don't.

To explain why, the solution of chapter 4.3 must be corrected for a variety of relativistic effects. Before doing so, it is helpful to express the nonrelativistic energy levels of that chapter in terms of the "rest mass energy" $m_{\mathrm{e}} c^{2}$ of the electron, as follows:

$$
\begin{equation*}
E_{n}=-\frac{\alpha^{2}}{2 n^{2}} m_{\mathrm{e}} c^{2} \quad \text { where } \alpha=\frac{e^{2}}{4 \pi \epsilon_{0} \hbar c} \approx \frac{1}{137} \tag{A.247}
\end{equation*}
$$

The constant $\alpha$ is called the "fine structure constant." It combines the constants $e^{2} / 4 \pi \epsilon_{0}$ from electromagnetism, $\hbar$ from quantum mechanics, and the speed of light $c$ from relativity into one nondimensional number. It is without doubt the single most important number in all of physics, [19].

Nobody knows why it has the value that it has. Still, obviously it is a measurable value, so, following the stated ideas of quantum mechanics, maybe
the universe "measured" this value during its early formation by a process that we may never understand, (since we do not have other measured values for $\alpha$ to deduce any properties of that process from.) If you have a demonstrably better explanation, Sweden awaits you.

In any case, for engineering purposes it is a small number, less than $1 \%$. That makes the hydrogen energy levels really small compared to the rest mass energy of the electron, because they are proportional to the square of $\alpha$, which is as small as $0.005 \%$. In simple terms, the electron in hydrogen stays well clear of the speed of light.

And that in turn means that the relativistic errors in the hydrogen energy levels are small. Still, even small errors can sometimes be very important. The required corrections are listed below in order of decreasing magnitude.

- Fine structure.

The electron should really be described relativistically using the Dirac equation instead of classically. In classical terms, that will introduce three corrections to the energy levels:

- Einstein's relativistic correction of the classical kinetic energy $p^{2} / 2 m_{\mathrm{e}}$ of the electron.
- "Spin-orbit interaction", due to the fact that the spin of the moving electron changes the energy levels. The spin of the electron makes it act like a little electromagnet. It can be seen from classical electrodynamics that a moving magnet will interact with the electric field of the nucleus, and that changes the energy levels. Note that the name spin-orbit interaction is a well chosen one, a rarity in physics.
- There is a third correction for states of zero angular momentum, the Darwin term. It is a crude fix for the fundamental problem that the relativistic wave function is not just a modified classical one, but also involves interaction with the anti-particle of the electron, the positron.
Fortunately, all three of these effects are very small; they are smaller than the uncorrected energy levels by a factor of order $\alpha^{2}$, and the error they introduce is on the order of $0.001 \%$. So the "exact" solution of chapter 4.3 is, by engineering standards, pretty exact after all.
- Lamb shift. Relativistically, the electron is affected by virtual photons and virtual electron-positron pairs. It adds a correction of relative magnitude $\alpha^{3}$ to the energy levels, one or two orders of magnitude smaller still than the fine structure corrections. To understand the correction properly requires quantum electrodynamics.
- Hyperfine splitting. Like the electron, the proton acts as a little electromagnet too. Therefore the energy depends on how it aligns with the
magnetic field generated by the electron. This effect is a factor $m_{\mathrm{e}} / m_{\mathrm{p}}$ smaller still than the fine structure corrections, making the associated energy changes about two orders of magnitude smaller.
Hyperfine splitting couples the spins of proton and electron, and in the ground state, they combine in the singlet state. A slightly higher energy level occurs when they are in a spin-one triplet state; transitions between these states radiate very low energy photons with a wave length of 21 cm . This is the source of the " 21 centimeter line" or "hydrogen line" radiation that is of great importance in cosmology. For example, it has been used to analyze the spiral arms of the galaxy, and the hope at the time of this writing is that it can shed light on the so called "dark ages" that the universe went through. Since so little energy is released, the transition is very slow, chapter 7.6.1. It takes on the order of 10 million years, but that is a small time on the scale of the universe.

The message to take away from that is that even errors in the ground state energy of hydrogen that are two million times smaller than the energy itself can be of critical importance under the right conditions.

The following subsections discuss each correction in more detail.

## A.39.2 Fine structure

From the Dirac equation, it can be seen that three terms need to be added to the nonrelativistic Hamiltonian of chapter 4.3 to correct the energy levels for relativistic effects. The three terms are worked out in derivation $\{D .81\}$. But that mathematics really provides very little insight. It is much more instructive to try to understand the corrections from a more physical point of view.

The first term is relatively easy to understand. Consider Einstein's famous relation $E=m c^{2}$, where $E$ is energy, $m$ mass, and $c$ the speed of light. According to this relation, the kinetic energy of the electron is not $\frac{1}{2} m_{\mathrm{e}} v^{2}$, with $v$ the velocity, as Newtonian physics says. Instead it is the difference between the energy $m_{\mathrm{e}, v} c^{2}$ based on the mass $m_{\mathrm{e}, v}$ of the electron in motion and the energy $m_{\mathrm{e}} c^{2}$ based on the mass $m_{\mathrm{e}}$ of the electron at rest. In terms of momentum $p=$ $m_{\mathrm{e}, v} v$, chapter 1.1.2,

$$
\begin{equation*}
T=m_{\mathrm{e}} c^{2} \sqrt{1+\frac{p^{2}}{m_{\mathrm{e}}^{2} c^{2}}}-m_{\mathrm{e}} c^{2} \tag{A.248}
\end{equation*}
$$

Since the speed of light is large compared to the typical speed of the electron, the square root can be expanded in a Taylor series, [41, 22.12], to give:

$$
T \approx \frac{p^{2}}{2 m_{\mathrm{e}}}-\frac{p^{4}}{8 m_{\mathrm{e}}^{3} c^{2}}+\ldots
$$

The first term corresponds to the kinetic energy operator used in the nonrelativistic quantum solution of chapter 4.3. (It may be noted that the relativistic momentum $\vec{p}$ is based on the moving mass of the electron, not its rest mass. It is this relativistic momentum that corresponds to the operator $\vec{p}=\hbar \nabla / \mathrm{i}$. So the Hamiltonian used in chapter 4.3 was a bit relativistic already, because in replacing $\vec{p}$ by $\hbar \nabla / \mathrm{i}$, it used the relativistic expression.) The second term in the Taylor series expansion above is the first of the corrections needed to fix up the hydrogen energy levels for relativity. Rewritten in terms of the square of the classical kinetic energy operator, the Bohr ground state energy $E_{1}$ and the fine structure constant $\alpha$, it is

$$
\begin{equation*}
H_{1, \text { Einstein }}=-\frac{\alpha^{2}}{4\left|E_{1}\right|}\left(\frac{\widehat{p}^{2}}{2 m_{\mathrm{e}}}\right)^{2} \tag{A.249}
\end{equation*}
$$

The second correction that must be added to the nonrelativistic Hamiltonian is the so-called "spin-orbit interaction." In classical terms, it is due to the spin of the electron, which makes it into a "magnetic dipole." Think of it as a magnet of infinitesimally small size, but with infinitely strong north and south poles to make up for it. The product of the infinitesimal vector from south to north pole times the infinite strength of the poles is finite, and defines the magnetic dipole moment $\vec{\mu}$. By itself, it is quite inconsequential since the magnetic dipole does not interact directly with the electric field of the nucleus. However, moving magnetic poles create an electric field just like the moving electric charges in an electromagnet create a magnetic field. The electric fields generated by the moving magnetic poles of the electron are opposite in strength, but not quite centered at the same position. Therefore they correspond to a motion-induced electric dipole. And an electric dipole does interact with the electric field of the nucleus; it wants to align itself with it. That is just like the magnetic dipole wanted to align itself with the external magnetic field in the Zeeman effect.

So how big is this effect? Well, the energy of an electric dipole $\vec{\wp}$ in an electric field $\overrightarrow{\mathcal{E}}$ is

$$
E_{1, \text { spin-orbit }}=-\vec{\wp} \cdot \overrightarrow{\mathcal{E}}
$$

As you might guess, the electric dipole generated by the magnetic poles of the moving electron is proportional to the speed of the electron $\vec{v}$ and its magnetic dipole moment $\vec{\mu}$. More precisely, the electric dipole moment $\vec{\wp}$ will be proportional to $\vec{v} \times \vec{\mu}$ because if the vector connecting the south and north poles is parallel to the motion, you do not have two neighboring currents of magnetic poles, but a single current of both negative and positive poles that completely cancel each other out. Also, the electric field $\overrightarrow{\mathcal{E}}$ of the nucleus is minus the gradient of its potential $e / 4 \pi \epsilon_{0} r$, so

$$
E_{1, \text { spin-orbit }} \propto(\vec{v} \times \vec{\mu}) \cdot \frac{e}{4 \pi \epsilon_{0} r^{r}} \vec{r}
$$

Now the order of the vectors in this triple product can be changed, and the dipole strength $\vec{\mu}$ of the electron equals its spin $\vec{S}$ times the charge per unit mass $-e / m_{\mathrm{e}}$, so

$$
E_{1, \text { spin-orbit }} \propto \frac{e^{2}}{m_{\mathrm{e}} 4 \pi \epsilon_{0} r^{3}}(\vec{r} \times \vec{v}) \cdot \vec{S}
$$

The expression between the parentheses is the angular momentum $\vec{L}$ save for the electron mass. The constant of proportionality is worked out in derivation \{D.82\}, giving the spin-orbit Hamiltonian as

$$
\begin{equation*}
H_{1, \text { spin-orbit }}=\alpha^{2}\left|E_{1}\right|\left(\frac{a_{0}}{r}\right)^{3} \frac{1}{\hbar^{2}} \widehat{\vec{L}} \cdot \widehat{\vec{S}} \tag{A.250}
\end{equation*}
$$

The final correction that must be added to the nonrelativistic Hamiltonian is the so-called "Darwin term:"

$$
\begin{equation*}
H_{1, \text { Darwin }}=\alpha^{2}\left|E_{1}\right| \pi a_{0}^{3} \delta^{3}(\vec{r}) \tag{A.251}
\end{equation*}
$$

According to its derivation in $\{\mathrm{D} .81\}$, it is a crude fix-up for an interaction with a virtual positron that simply cannot be included correctly in a nonrelativistic analysis.

If that is not very satisfactory, the following much more detailed derivation can be found on the web. It does succeed in explaining the Darwin term fully within the nonrelativistic picture alone. First assume that the electric potential of the nucleus does not really become infinite as $1 / r$ at $r=0$, but is smoothed out over some finite nuclear size. Also assume that the electron does not "see" this potential sharply, but perceives of its features a bit vaguely, as diffused out symmetrically over a typical distance equal to the so-called Compton wave length $\hbar / m_{\mathrm{e}} c$. There are several plausible reasons why it might: (1) the electron has illegally picked up a chunk of a negative rest mass state, and it is trembling with fear that the uncertainty in energy will be noted, moving rapidly back and forwards over a Compton wave length in a so-called "Zitterbewegung"; (2) the electron has decided to move at the speed of light, which is quite possible nonrelativistically, so its uncertainty in position is of the order of the Compton wave length, and it just cannot figure out where the right potential is with all that uncertainty in position and light that fails to reach it; (3) the electron needs glasses. Further assume that the Compton wave length is much smaller than the size over which the nuclear potential is smoothed out. In that case, the potential within a Compton wave length can be approximated by a second order Taylor series, and the diffusion of it over the Compton wave length will produce an error proportional to the Laplacian of the potential (the only fully symmetric combination of derivatives in the second order Taylor series.). Now if the potential is smoothed over the nuclear region, its Laplacian, giving the charge density, is known to produce a nonzero spike only within that smoothed nuclear region, figure 13.7 or (13.30). Since the nuclear size is small compared
to the electron wave functions, that spike can then be approximated as a delta function. Tell all your friends you heard it here first.

The key question is now what are the changes in the hydrogen energy levels due to the three perturbations discussed above. That can be answered by perturbation theory as soon as the good eigenfunctions have been identified. Recall that the usual hydrogen energy eigenfunctions $\psi_{n l m} \uparrow$ are made unique by the square angular momentum operator $\widehat{L}^{2}$, giving $l$, the $z$ angular momentum operator $\widehat{L}_{z}$, giving $m$, and the spin angular momentum operator $\widehat{S}_{z}$ giving the spin quantum number $m_{s}= \pm \frac{1}{2}$ for spin up, respectively down. The decisive term whether these are good or not is the spin-orbit interaction. If the inner product in it is written out, it is

$$
H_{1, \text { spin-orbit }}=\alpha^{2}\left|E_{1}\right|\left(\frac{a_{0}}{r}\right)^{3} \frac{1}{\hbar^{2}}\left(\widehat{L}_{x} \widehat{S}_{x}+\widehat{L}_{y} \widehat{S}_{y}+\widehat{L}_{z} \widehat{S}_{z}\right)
$$

The radial factor is no problem; it commutes with every orbital angular momentum component, since these are purely angular derivatives, chapter 4.2.2. It also commutes with every component of spin because all spatial functions and operators do, chapter 5.5.3. As far as the dot product is concerned, it commutes with $\widehat{L}^{2}$ since all the components of $\widehat{\vec{L}}$ do, chapter 4.5.4, and since all the components of $\widehat{\vec{S}}$ commute with any spatial operator. But unfortunately, $\widehat{L}_{x}$ and $\widehat{L}_{y}$ do not commute with $\widehat{L}_{z}$, and $\widehat{S}_{x}$ and $\widehat{S}_{y}$ do not commute with $\widehat{S}_{z}$ (chapters 4.5.4 and 5.5.3):

$$
\left[\widehat{L}_{x}, \widehat{L}_{z}\right]=-\mathrm{i} \hbar \widehat{L}_{y} \quad\left[\widehat{L}_{y}, \widehat{L}_{z}\right]=\mathrm{i} \hbar \widehat{L}_{x} \quad\left[\widehat{S}_{x}, \widehat{S}_{z}\right]=-\mathrm{i} \hbar \widehat{S}_{y} \quad\left[\widehat{S}_{y}, \widehat{S}_{z}\right]=\mathrm{i} \hbar \widehat{S}_{x}
$$

The quantum numbers $m$ and $m_{s}$ are bad.
Fortunately, $\widehat{\vec{L}} \cdot \widehat{\vec{S}}$ does commute with the net $z$ angular momentum $\widehat{J}_{z}$, defined as $\widehat{L}_{z}+\widehat{S}_{z}$. Indeed, using the commutators above and the rules of chapter 4.5 .4 to take apart commutators:

$$
\begin{aligned}
& {\left[\widehat{L}_{x} \widehat{S}_{x}, \widehat{L}_{z}+\widehat{S}_{z}\right]=\left[\widehat{L}_{x}, \widehat{L}_{z}\right] \widehat{S}_{x}+\widehat{L}_{x}\left[\widehat{S}_{x}, \widehat{S}_{z}\right]=-\mathrm{i} \hbar \widehat{L}_{y} \widehat{S}_{x}-\mathrm{i} \hbar \widehat{L}_{x} \widehat{S}_{y}} \\
& {\left[\widehat{L}_{y} \widehat{S}_{y}, \widehat{L}_{z}+\widehat{S}_{z}\right]=\left[\widehat{L}_{y}, \widehat{L}_{z}\right] \widehat{S}_{y}+\widehat{L}_{y}\left[\widehat{S}_{y}, \widehat{S}_{z}\right]=\mathrm{i} \hbar \widehat{L}_{x} \widehat{S}_{y}+\mathrm{i} \hbar \widehat{L}_{y} \widehat{S}_{x}} \\
& {\left[\widehat{L}_{z} \widehat{S}_{z}, \widehat{L}_{z}+\widehat{S}_{z}\right]=\left[\widehat{L}_{z}, \widehat{L}_{z}\right] \widehat{S}_{z}+\widehat{L}_{z}\left[\widehat{S}_{z}, \widehat{S}_{z}\right]=0}
\end{aligned}
$$

and adding it all up, you get $\left[\widehat{\vec{L}} \cdot \widehat{\vec{S}}, \widehat{J}_{z}\right]=0$. The same way of course $\widehat{\vec{L}} \cdot \widehat{\vec{S}}$ commutes with the other components of net angular momentum $\widehat{\vec{J}}$, since the $z$-axis is arbitrary. And if $\widehat{\vec{L}} \cdot \hat{\vec{S}}$ commutes with every component of $\widehat{\vec{J}}$, then it commutes with their sum of squares $\widehat{J}^{2}$. So, eigenfunctions of $\widehat{L}^{2}, \widehat{J}^{2}$, and $\widehat{J}_{z}$ are good eigenfunctions.

Such good eigenfunctions can be constructed from the $\psi_{n l m} \downarrow$ by forming linear combinations of them that combine different $m$ and $m_{s}$ values. The
coefficients of these good combinations are called Clebsch-Gordan coefficients and are shown for $l=1$ and $l=2$ in figure 12.5. Note from this figure that the quantum number $j$ of net square momentum can only equal $l+\frac{1}{2}$ or $l-\frac{1}{2}$. The half unit of electron spin is not big enough to change the quantum number of square orbital momentum by more than half a unit. For the rest, however, the detailed form of the good eigenfunctions is of no interest here. They will just be indicated in ket notation as $\left|n l j m_{j}\right\rangle$, indicating that they have unperturbed energy $E_{n}$, square orbital angular momentum $l(l+1) \hbar^{2}$, square net (orbital plus spin) angular momentum $j(j+1) \hbar^{2}$, and net $z$ angular momentum $m_{j} \hbar$.

As far as the other two contributions to the fine structure are concerned, according to chapter 4.3.1 $\widehat{\vec{p}}^{2}$ in the Einstein term consists of radial functions and radial derivatives plus $\widehat{L}^{2}$. These commute with the angular derivatives that make up the components of $\widehat{\vec{L}}$, and as spatial functions and operators, they commute with the components of spin. So the Einstein Hamiltonian commutes with all components of $\widehat{\vec{L}}$ and $\widehat{\vec{J}}=\widehat{\vec{L}}+\widehat{\vec{S}}$, hence with $\widehat{L}^{2}, \widehat{J}^{2}$, and $\widehat{J}_{z}$. And the delta function in the Darwin term can be assumed to be the limit of a purely radial function and commutes in the same way. The eigenfunctions $\left|n l j m_{j}\right\rangle$ with given values of $l, j$, and $m_{j}$ are good ones for the entire fine structure Hamiltonian.

To get the energy changes, the Hamiltonian perturbation coefficients

$$
\left\langle m_{j} j l n\right| H_{1, \text { Einstein }}+H_{1, \text { spin-orbit }}+H_{1, \text { Darwin }}\left|n l j m_{j}\right\rangle
$$

must be found. Starting with the Einstein term, it is

$$
\left\langle m_{j} j l n\right| H_{1, \text { Einstein }}\left|n l j m_{j}\right\rangle=-\frac{\alpha^{2}}{4\left|E_{1}\right|}\left\langle m_{j} j l n\right| \frac{\widehat{p}^{4}}{4 m_{\mathrm{e}}^{2}}\left|n l j m_{j}\right\rangle
$$

Unlike what you may have read elsewhere, $\widehat{p}^{4}$ is indeed a Hermitian operator, but $\widehat{p}^{4}\left|n l j m_{j}\right\rangle$ may have a delta function at the origin, (13.30), so watch it with blindly applying mathematical manipulations to it. The trick is to take half of it to the other side of the inner product, and then use the fact that the eigenfunctions satisfy the nonrelativistic energy eigenvalue problem:

$$
\begin{aligned}
\left.\left\langle m_{j} j l n\right| \frac{\hat{p}^{2}}{2 m_{\mathrm{e}}}\left|\frac{\widehat{p}^{2}}{2 m_{\mathrm{e}}}\right| n l j m_{j}\right\rangle & \left.=\left\langle m_{j} j l n\right| E_{n}-V\left|E_{n}-V\right| n l j m_{j}\right\rangle \\
& =\left\langle m_{j} j l n\right| E_{n}^{2}-2 V E_{n}+V^{2}\left|n l j m_{j}\right\rangle
\end{aligned}
$$

Noting from chapter 4.3 that $E_{n}=E_{1} / n^{2}, V=2 E_{1} a_{0} / r$ and that the expectation values of $a_{0} / r$ and $\left(a_{0} / r\right)^{2}$ are given in derivation $\{\mathrm{D} .83\}$, you find that

$$
\left\langle m_{j} j l n\right| H_{1, \text { Einstein }}\left|n l j m_{j}\right\rangle=-\frac{\alpha^{2}}{4 n^{2}}\left(\frac{4 n}{l+\frac{1}{2}}-3\right)\left|E_{n}\right|
$$

The spin-orbit energy correction is

$$
\left\langle m_{j} j l n\right| H_{1, \text { spin-orbit }}\left|n l j m_{j}\right\rangle=\alpha^{2}\left|E_{1}\right|\left\langle m_{j} j \ln \right|\left(\frac{a_{0}}{r}\right)^{3} \frac{1}{\hbar^{2}} \widehat{\vec{L}} \cdot \widehat{\vec{S}}\left|n l j m_{j}\right\rangle
$$

For states with no orbital angular momentum, all components of $\widehat{\vec{L}}$ produce zero, so there is no contribution. Otherwise, the dot product $\widehat{\vec{L}} \cdot \widehat{\vec{S}}$ can be rewritten by expanding

$$
\widehat{J}^{2}=(\widehat{\vec{L}}+\widehat{\vec{S}})^{2}=\widehat{L}^{2}+\widehat{S}^{2}+2 \widehat{\vec{L}} \cdot \widehat{\vec{S}}
$$

to give

$$
\begin{aligned}
\widehat{\vec{L}} \cdot \widehat{\vec{S}}\left|n l j m_{j}\right\rangle & =\frac{1}{2}\left(\widehat{J}^{2}-\widehat{L}^{2}-\widehat{S}^{2}\right)\left|n l j m_{j}\right\rangle \\
& =\frac{1}{2} \hbar^{2}\left(j(j+1)-l(l+1)-\frac{1}{2}\left(1+\frac{1}{2}\right)\right)\left|n l j m_{j}\right\rangle
\end{aligned}
$$

That leaves only the expectation value of $\left(a_{0} / r\right)^{3}$ to be determined, and that can be found in derivation $\{\mathrm{D} .83\}$. The net result is

$$
\left\langle m_{j} j l n\right| H_{1, \text { spin-orbit }}\left|n l j m_{j}\right\rangle=\frac{\alpha^{2}}{4 n^{2}} 2 n \frac{j(j+1)-l(l+1)-\frac{1}{2}\left(1+\frac{1}{2}\right)}{l\left(l+\frac{1}{2}\right)(l+1)}\left|E_{n}\right| \quad \text { if } l \neq 0
$$

or zero if $l=0$.
Finally the Darwin term,

$$
\left\langle m_{j} j l n\right| H_{1, \text { Darwin }}\left|n l j m_{j}\right\rangle=\alpha^{2}\left|E_{1}\right| \pi a_{0}^{3}\left\langle m_{j} j l n\right| \delta^{3}(\vec{r})\left|n l j m_{j}\right\rangle
$$

Now a delta function at the origin has the property to pick out the value at the origin of whatever function it is in an integral with, compare chapter 7.9.1. Derivation \{D.15\}, (D.9), implies that the value of the wave functions at the origin is zero unless $l=0$, and then the value is given in (D.10). So the Darwin contribution becomes

$$
\left\langle m_{j} j l n\right| H_{1, \text { Darwin }}\left|n l j m_{j}\right\rangle=\frac{\alpha^{2}}{4 n^{2}} 4 n\left|E_{n}\right| \quad \text { if } l=0
$$

To get the total energy change due to fine structure, the three contributions must be added together. For $l=0$, add the Einstein and Darwin terms. For $l \neq$ 0 , add the Einstein and spin-orbit terms; you will need to do the two possibilities that $j=l+\frac{1}{2}$ and $j=l-\frac{1}{2}$ separately. All three produce the same final result, anyway:

$$
\begin{equation*}
E_{n l j m_{j}, 1}=-\left(\frac{1}{n\left(j+\frac{1}{2}\right)}-\frac{3}{4} \frac{1}{n^{2}}\right) \alpha^{2}\left|E_{n}\right| \tag{A.252}
\end{equation*}
$$

Since $j+\frac{1}{2}$ is at most $n$, the energy change due to fine structure is always negative. And it is the biggest fraction of $E_{n}$ for $j=\frac{1}{2}$ and $n=2$, where it is $-\frac{5}{16} \alpha^{2}\left|E_{n}\right|$, still no more than a sixth of a percent of a percent change in energy.

In the ground state $j$ can only be one half, (the electron spin), so the ground state energy does not split into two due to fine structure. You would of course not expect so, because in empty space, both spin directions are equivalent. The ground state does show the largest absolute change in energy.

Woof.

## A.39.3 Weak and intermediate Zeeman effect

The weak Zeeman effect is the effect of a magnetic field that is sufficiently weak that it leaves the fine structure energy eigenfunctions almost unchanged. The Zeeman effect is then a small perturbation on a problem in which the "unperturbed" (by the Zeeman effect) eigenfunctions $\left|n l j m_{j}\right\rangle$ derived in the previous subsection are degenerate with respect to $l$ and $m_{j}$.

The Zeeman Hamiltonian

$$
H_{1}=\frac{e}{2 m_{\mathrm{e}}} \mathcal{B}_{\mathrm{ext}}\left(\widehat{L}_{z}+2 \widehat{S}_{z}\right)
$$

commutes with both $\widehat{L}^{2}$ and $\widehat{J}_{z}=\widehat{S}_{z}+\widehat{L}_{z}$, so the eigenfunctions $\left|n l j m_{j}\right\rangle$ are good. Therefore, the energy perturbations can be found as

$$
\frac{e}{2 m_{\mathrm{e}}} \mathcal{B}_{\mathrm{ext}}\left\langle m_{j} j \ln \right| \widehat{L}_{z}+2 \widehat{S}_{z}\left|n l j m_{j}\right\rangle
$$

To evaluate this rigorously would require that the $\left|n l j m_{j}\right\rangle$ state be converted into the one or two $\psi_{n l m} \downarrow$ states with $-l \leqslant m=m_{j} \pm \frac{1}{2} \leqslant l$ and $m_{s}=\mp \frac{1}{2}$ using the appropriate Clebsch-Gordan coefficients from figure 12.5.

However, the following simplistic derivation is usually given instead, including in this book. First get rid of $L_{z}$ by replacing it by $\widehat{J}_{z}-\widehat{S}_{z}$. The inner product with $\widehat{J}_{z}$ can then be evaluated as being $m_{j} \hbar$, giving the energy change as

$$
\frac{e}{2 m_{\mathrm{e}}} \mathcal{B}_{\mathrm{ext}}\left[m_{j} \hbar+\left\langle m_{j} j \ln \right| \widehat{S}_{z}\left|n l j m_{j}\right\rangle\right]
$$

For the final inner product, make a semi-classical argument that only the component of $\widehat{\vec{S}}$ in the direction of $\vec{J}$ gives a contribution. Don't worry that $\vec{J}$ does not exist. Just note that the component in the direction of $\vec{J}$ is constrained by the requirement that $\widehat{\vec{L}}$ and $\widehat{\vec{S}}$ must add up to $\widehat{\vec{J}}$, but the component normal to $\vec{J}$ can be in any direction and presumably averages out to zero. Dismissing this component, the component in the direction of $\vec{J}$ is

$$
\widehat{\vec{S}}_{J}=\frac{1}{J^{2}}(\widehat{\vec{S}} \cdot \widehat{\vec{J}}) \widehat{\vec{J}}
$$

and the dot product in it can be found from expanding

$$
\widehat{L}^{2}=\widehat{\vec{L}} \cdot \widehat{\vec{L}}=(\widehat{\vec{J}}-\widehat{\vec{S}}) \cdot(\widehat{\vec{J}}-\widehat{\vec{S}})=J^{2}-2 \widehat{\vec{J}} \cdot \widehat{\vec{S}}+S^{2}
$$

to give

$$
\widehat{\vec{S}}_{J}=\frac{J^{2}-\widehat{L}^{2}+S^{2}}{2 J^{2}} \widehat{\vec{J}}
$$

For a given eigenfunction $\left|n l j m_{j}\right\rangle, J^{2}=\hbar^{2} j(j+1), \widehat{L}^{2}=\hbar^{2} l(l+1)$, and $S^{2}=$ $\hbar^{2} s(s+1)$ with $s=\frac{1}{2}$.

If the $z$-component of $\widehat{\vec{S}}_{J}$ is substituted for $\widehat{S}_{z}$ in the expression for the Hamiltonian perturbation coefficients, the energy changes are

$$
\begin{equation*}
\left[1+\frac{j(j+1)-l(l+1)+s(s+1)}{2 j(j+1)}\right] \frac{e \hbar}{2 m_{\mathrm{e}}} \mathcal{B}_{\mathrm{ext}} m_{j} \tag{A.253}
\end{equation*}
$$

(Rigorous analysis using figure 12.5, or more generally item 2 in chapter 12.8, produces the same results.) The factor within the brackets is called the "Landé $g$-factor." It is the factor by which the magnetic moment of the electron in the atom is larger than for a classical particle with the same charge and total angular momentum. It generalizes the $g$-factor of the electron in isolation to include the effect of orbital angular momentum. Note that it equals 2 , the Dirac $g$-factor, if there is no orbital momentum, and 1 , the classical value, if the orbital momentum is so large that the half unit of spin can be ignored.

In the intermediate Zeeman effect, the fine structure and Zeeman effects are comparable in size. The dominant perturbation Hamiltonian is now the combination of the fine structure and Zeeman ones. Since the Zeeman part does not commute with $\widehat{J}^{2}$, the eigenfunctions $\left|n l j m_{j}\right\rangle$ are no longer good. Eigenfunctions with the same values of $l$ and $m_{j}$, but different values of $j$ must be combined into good combinations. For example, if you look at $n=2$, the eigenfunctions $\left|21 \frac{3}{2} \frac{1}{2}\right\rangle$ and $\left|21 \frac{1}{2} \frac{1}{2}\right\rangle$ have the same unperturbed energy and good quantum numbers $l$ and $m_{j}$. You will have to write a two by two matrix of Hamiltonian perturbation coefficients for them, as in addendum \{A.38.3\}, to find the good combinations and their energy changes. And the same for the $\left|21 \frac{3}{2}-\frac{1}{2}\right\rangle$ and $\left|21 \frac{1}{2}-\frac{1}{2}\right\rangle$ eigenfunctions. To obtain the matrix coefficients, use the Clebsch-Gordan coefficients from figure 12.5 to evaluate the effect of the Zeeman part. The fine structure contributions to the matrices are given by (A.252) when the $j$ values are equal, and zero otherwise. This can be seen from the fact that the energy changes must be the fine structure ones when there is no magnetic field; note that $j$ is a good quantum number for the fine structure part, so its perturbation coefficients involving different $j$ values are zero.

## A.39.4 Lamb shift

A famous experiment by Lamb \& Retherford in 1947 showed that the hydrogen atom state $n=2, l=0, j=\frac{1}{2}$, also called the $2 \mathrm{~S}_{1 / 2}$ state, has a somewhat
different energy than the state $n=2, l=1, j=\frac{1}{2}$, also called the $2 \mathrm{P}_{1 / 2}$ state. That was unexpected, because even allowing for the relativistic fine structure correction, states with the same principal quantum number $n$ and same total angular momentum quantum number $j$ should have the same energy. The difference in orbital angular momentum quantum number $l$ should not affect the energy.

The cause of the unexpected energy difference is called Lamb shift. To explain why it occurs would require quantum electrodynamics, and that is well beyond the scope of this book. Roughly speaking, the effect is due to a variety of interactions with virtual photons and electron/positron pairs. A good qualitative discussion on a nontechnical level is given by Feynman [19].

Here it must suffice to list the approximate energy corrections involved. For states with zero orbital angular momentum, the energy change due to Lamb shift is

$$
\begin{equation*}
E_{\vec{n}, 1, \mathrm{Lamb}}=-\frac{\alpha^{3}}{2 n} k(n, 0) E_{n} \quad \text { if } l=0 \tag{A.254}
\end{equation*}
$$

where $k(n, 0)$ is a numerical factor that varies a bit with $n$ from about 12.7 to 13.2. For states with nonzero orbital angular momentum,

$$
\begin{equation*}
E_{\vec{n}, 1, \mathrm{Lamb}}=-\frac{\alpha^{3}}{2 n}\left[k(n, l) \pm \frac{1}{\pi\left(j+\frac{1}{2}\right)\left(l+\frac{1}{2}\right)}\right] E_{n} \quad \text { if } l \neq 0 \text { and } j=l \pm \frac{1}{2} \tag{A.255}
\end{equation*}
$$

where $k(n, l)$ is less than 0.05 and varies somewhat with $n$ and $l$.
It follows that the energy change is really small for states with nonzero orbital angular momentum, which includes the $2 \mathrm{P}_{1 / 2}$ state. The change is biggest for the $2 \mathrm{~S}_{1 / 2}$ state, the other state in the Lamb \& Retherford experiment. (True, the correction would be bigger still for the ground state $n=1$, but since there are no states with nonzero angular momentum in the ground state, there is no splitting of spectral lines involved there.)

Qualitatively, the reason that the Lamb shift is small for states with nonzero angular momentum has to do with distance from the nucleus. The nontrivial effects of the cloud of virtual particles around the electron are most pronounced in the strong electric field very close to the nucleus. In states of nonzero angular momentum, the wave function is zero at the nucleus, (D.9). So in those states the electron is unlikely to be found very close to the nucleus. In states of zero angular momentum, the square magnitude of the wave function is $1 / n^{3} \pi a_{0}^{3}$ at the nucleus, reflected in both the much larger Lamb shift as well as its approximate $1 / n^{3}$ dependence on the principal quantum number $n$.

## A.39.5 Hyperfine splitting

Hyperfine splitting of the hydrogen atom energy levels is due to the fact that the nucleus acts as a little magnet just like the electron. The single-proton nucleus
and electron have magnetic dipole moments due to their spin equal to

$$
\vec{\mu}_{\mathrm{p}}=\frac{g_{p} e}{2 m_{\mathrm{p}}} \widehat{\vec{S}}_{\mathrm{p}} \quad \vec{\mu}_{\mathrm{e}}=-\frac{g_{e} e}{2 m_{\mathrm{e}}} \widehat{\vec{S}}_{\mathrm{e}}
$$

in which the $g$-factor of the proton is about 5.59 and that of the electron 2. The magnetic moment of the nucleus is much less than the one of the electron, since the much greater proton mass appears in the denominator. That makes the energy changes associated with hyperfine splitting really small compared to other effects such as fine structure.

This discussion will restrict itself to the ground state, which is by far the most important case. For the ground state, there is no orbital contribution to the magnetic field of the electron. There is only a "spin-spin coupling" between the magnetic moments of the electron and proton, The energy involved can be thought of most simply as the energy $-\vec{\mu}_{\mathrm{e}} \cdot \overrightarrow{\mathcal{B}}_{p}$ of the electron in the magnetic field $\overrightarrow{\mathcal{B}}_{\mathrm{p}}$ of the nucleus. If the nucleus is modelled as an infinitesimally small electromagnet, its magnetic field is that of an ideal current dipole as given in table 13.2. The perturbation Hamiltonian then becomes

$$
H_{1, \text { spin-spin }}=\frac{g_{\mathrm{p}} g_{\mathrm{e}} e^{2}}{4 m_{\mathrm{e}} m_{\mathrm{p}} \epsilon_{0} c^{2}}\left[\frac{3\left(\widehat{\vec{S}}_{\mathrm{p}} \cdot \vec{r}\right)\left(\widehat{\vec{S}}_{\mathrm{e}} \cdot \vec{r}\right)-\left(\widehat{\vec{S}}_{\mathrm{p}} \cdot \widehat{\vec{S}}_{\mathrm{e}}\right) r^{2}}{4 \pi r^{5}}+\frac{2\left(\widehat{\vec{S}}_{\mathrm{p}} \cdot \widehat{\vec{S}}_{\mathrm{e}}\right)}{3} \delta^{3}(\vec{r})\right]
$$

The good states are not immediately self-evident, so the four unperturbed ground states will just be taken to be the ones which the electron and proton spins combine into the triplet or singlet states of chapter 5.5.6:

$$
\text { triplet: } \quad \psi_{100}|11\rangle \quad \psi_{100}|10\rangle \quad \psi_{100}|1-1\rangle \quad \text { singlet: } \quad \psi_{100}|00\rangle
$$

or $\psi_{100}\left|s_{\text {net }} m_{\text {net }}\right\rangle$ for short, where $s_{\text {net }}$ and $m_{\text {net }}$ are the quantum numbers of net spin and its $z$-component. The next step is to evaluate the four by four matrix of Hamiltonian perturbation coefficients

$$
\left.\left\langle\underline{m}_{\text {net }} \underline{\underline{S}}_{\text {net }}\right| \psi_{100}\left|H_{1, \text { spin-spin }} \psi_{100}\right| s_{\text {net }} m_{\text {net }}\right\rangle
$$

using these states.
Now the first term in the spin-spin Hamiltonian does not produce a contribution to the perturbation coefficients. The reason is that the inner product of the perturbation coefficients written in spherical coordinates involves an integration over the surfaces of constant $r$. The ground state eigenfunction $\psi_{100}$ is constant on these surfaces. So there will be terms like $3 \widehat{S}_{\mathrm{p}, x} \widehat{S}_{\mathrm{e}, y} x y$ in the integration, and those are zero because $x$ is just as much negative as positive on these spherical surfaces, (as is $y$ ). There will also be terms like $3 \widehat{S}_{\mathrm{p}, x} \widehat{S}_{\mathrm{e}, x} x^{2}-\widehat{S}_{\mathrm{p}, x} \widehat{S}_{\mathrm{e}, x} r^{2}$ in the integration. These will be zero too because by symmetry the averages of $x^{2}, y^{2}$, and $z^{2}$ are equal on the spherical surfaces, each equal to one third the average of $r^{2}$.

So only the second term in the Hamiltonian survives, and the Hamiltonian perturbation coefficients become

$$
\left.\frac{g_{\mathrm{p}} g_{\mathrm{e}} e^{2}}{6 m_{\mathrm{e}} m_{\mathrm{p}} \epsilon_{0} c^{2}}\left\langle\underline{m}_{\text {net }}{\underline{s_{n e t}}}\right| \psi_{100}\left|\left(\widehat{\vec{S}}_{\mathrm{p}} \cdot \widehat{\vec{S}}_{\mathrm{e}}\right) \delta^{3}(\vec{r}) \psi_{100}\right| s_{\text {net }} m_{\text {net }}\right\rangle
$$

The spatial integration in this inner product merely picks out the value $\psi_{100}^{2}(0)=1 / \pi a_{0}^{3}$ at the origin, as delta functions do. That leaves the sum over the spin states. According to addendum \{A.10\},
triplet: $\quad \hat{\vec{S}}_{\mathrm{p}} \cdot \hat{\vec{S}}_{\mathrm{e}}\left|1 m_{\text {net }}\right\rangle=\frac{1}{4} \hbar^{2}\left|1 m_{\text {net }}\right\rangle \quad$ singlet: $\quad \hat{\vec{S}}_{\mathrm{p}} \cdot \hat{\vec{S}}_{\mathrm{e}}|00\rangle=-\frac{3}{4} \hbar^{2}|00\rangle$
Since the triplet and singlet spin states are orthonormal, only the Hamiltonian perturbation coefficients for which $\underline{s}_{\text {net }}=s_{\text {net }}$ and $\underline{m}_{\text {net }}=m_{\text {net }}$ survive, and these then give the leading order changes in the energy.

Plugging it all in and rewriting in terms of the Bohr energy and fine structure constant, the energy changes are:

$$
\begin{equation*}
\text { triplet: } E_{1, \text { spin-spin }}=\frac{1}{3} g_{\mathrm{p}} g_{\mathrm{e}} \frac{m_{\mathrm{e}}}{m_{\mathrm{p}}} \alpha^{2}\left|E_{1}\right| \quad \text { singlet: } E_{1, \text { spin-spin }}=-g_{\mathrm{p}} g_{\mathrm{e}} \frac{m_{\mathrm{e}}}{m_{\mathrm{p}}} \alpha^{2}\left|E_{1}\right| \tag{A.256}
\end{equation*}
$$

The energy of the triplet states is raised and that of the singlet state is lowered. Therefore, in the true ground state, the electron and proton spins combine into the singlet state. If they somehow get kicked into a triplet state, they will eventually transition back to the ground state, say after 10 million years or so, and release a photon. Since the difference between the two energies is so tiny on account of the very small values of both $\alpha^{2}$ and $m_{\mathrm{e}} / m_{\mathrm{p}}$, this will be a very low energy photon. Its wave length is as long as 0.21 m , producing the 21 cm hydrogen line.

## A. 40 Deuteron wave function

This addendum examines the form of the wave function of the deuteron. It assumes that the deuteron can be described as a two particle system; a proton and a neutron. In reality, both the proton and the neutron consist of three quarks. So the deuteron is really a six particle system. That will be ignored here.

Then the deuteron wave function is a function of the positions and spin angular momenta of the proton and neutron. That however can be simplified considerably. First of all, it helps if the center of gravity of the deuteron is taken as origin of the coordinate system. In that coordinate system, the individual positions of proton and neutron are no longer important. The only quantity that is important is the position vector going from neutron to proton, $\{\mathrm{A} .5\}$ :

$$
\vec{r} \equiv \vec{r}_{\mathrm{p}}-\vec{r}_{\mathrm{n}}
$$

That represents the relative position of the proton relative to the neutron.
Consider now the spin angular momenta of proton and neutron. The two have spin angular momenta of the same magnitude. The corresponding quantum number, called the "spin" for short, equals $s_{\mathrm{p}}=s_{\mathrm{n}}=\frac{1}{2}$. However, the proton and neutron can still have different spin angular momentum along whatever is chosen to be the $z$-axis. In particular, each can have a spin $S_{z}$ along the $z$-axis that is either $\frac{1}{2} \hbar$ or $-\frac{1}{2} \hbar$.

All together it means that the deuteron wave function depends nontrivially on both the nucleon spacing and the spin components in the $z$-direction:

$$
\psi=\psi\left(\vec{r}, S_{z, \mathrm{p}}, S_{z, \mathrm{n}}\right)
$$

The square magnitude of this wave function gives the probability density to find the nucleons at a given spacing $\vec{r}$ and with given spin values along the $z$-axis.

It is solidly established by experiments that the wave function of the deuteron has net nuclear spin $j_{\mathrm{N}}=1$ and even parity. The question to be examined now is what that means for the orbital angular momentum and the spins of the proton and neutron. To answer that, the wave function needs to be written in terms of states that have definite combined orbital angular momentum and definite combined spin.

The conditions for a state to have definite orbital angular momentum were discussed in chapter 4.2. The angular dependence of the state must be given by a spherical harmonic $Y_{l}^{m}(\theta, \phi)$. Here $\theta$ and $\phi$ are the angles that the vector $\vec{r}$ makes with the axes of the chosen spherical coordinate system. The azimuthal quantum number $l$ describes the magnitude of the orbital angular momentum. In particular, the magnitude of the orbital momentum is $\sqrt{l(l+1)} \hbar$. The magnetic quantum number $m$ describes the component of the orbital angular momentum along the chosen $z$-axis. In particular, that component equals $m \hbar$. Both $l \geqslant 0$ and $|m| \leqslant l$ must be integers.

As far as the combined spin angular momentum is concerned, the possibilities were discussed in chapter 5.5.6 and in more detail in chapter 12. First, the proton and neutron spins can cancel each other perfectly, producing a state of zero net spin. This state is called the "singlet" state. Zero net spin has a corresponding quantum number $s=0$. And since the component of the angular momentum along any chosen $z$-axis can only be zero, so is the spin magnetic quantum number $m_{s}=0$.

The second possibility is that the proton and neutron align their spins in parallel, crudely speaking. More precisely, the combined spin has a magnitude given by quantum number $s=\frac{1}{2}+\frac{1}{2}=1$. The combined spin angular momentum along the chosen $z$ direction is $m_{s} \hbar$ where $m_{s}$ can be $-1,0$, or 1 .

The wave function of the deuteron can be written as a combination of the above states of orbital and spin angular momentum. It then takes the generic
form:

$$
\begin{equation*}
\psi=\sum_{n l m s m_{s}} c_{n l m s m_{s}} R_{n}(|\vec{r}|) Y_{l}^{m}(\theta, \phi)\left|s m_{s}\right\rangle \tag{A.257}
\end{equation*}
$$

Here the $c_{n l m s m_{s}}$ are constants. The functions $R_{n}$ are not of particular interest here; any complete set of orthonormal radial functions will do. Note that the individual terms in the sum above are not supposed to be energy eigenfunctions. They are merely chosen states of definite orbital and spin angular momentum. The ket $\left|s m_{s}\right\rangle$ is a way of indicating the combined spin state of the two nucleons. It is defined in terms of the separate spins of the proton and neutron in chapter 5.5.6 (5.26).

The above expression for the wave function is quite generally valid for a system of two fermions. But it can be made much more specific based on the mentioned known properties of the deuteron.

The simplest is the fact that the parity of the deuteron is even. Spherical harmonics have odd parity if $l$ is odd, and even if $l$ is even, \{D.14\}. So there cannot be any odd values of $l$ in the sum above. In other words, the constants $c_{n l m s m_{s}}$ must be zero for odd $l$.

Physically, that means that the spatial wave function is symmetric with respect to replacing $\vec{r}$ by $-\vec{r}$. It may be noted that this spatial symmetry and the corresponding even parity are exactly what is expected theoretically. The reasons were explored earlier in $\{$ A. 8$\}$ and $\{\mathrm{A} .9\}$. The wave function for any given spin state should not change sign, and odd parity cannot meet that requirement. However, it should be noted that the arguments in $\{\mathrm{A} .8\}$ and $\{A .9\}$ are not valid if the potential includes terms of second or higher order in the momentum. Some more advanced potentials that have been written down include such terms.

The spatial symmetry also means that the wave function is symmetric with respect to swapping the two nucleons. That is because $\vec{r}$ is the vector from neutron to proton, so swapping the two inverts the sign of $\vec{r}$. This does assume that the small difference in mass between the neutron and proton is ignored. Otherwise the swap would change the center of gravity. Recall that the (part of the) wave function considered here is relative to the center of gravity. In any case, the hypothetical wave functions for a bound state of two protons or one of two neutrons would be exactly symmetric under exchange of the positions of the two identical particles.

The condition that the nuclear spin $j_{\mathrm{N}}=1$ is a bit more complex. First a brief review is needed into how angular momenta combine in quantum mechanics. (For a more complete description, see chapter 12.) A state with definite quantum numbers $l$ and $s$ has in general quantum uncertainty in the net nuclear spin $j_{\mathrm{N}}$. But the values of $j_{\mathrm{N}}$ cannot be completely arbitrary. The only values that can have nonzero probability are in the range

$$
|l-s| \leqslant j_{\mathrm{N}} \leqslant l+s
$$

The key is now that unless a state $l, s$ has a nonzero probability for $j_{\mathrm{N}}=1$, it cannot appear in the deuteron wave function at all. To verify that, take an inner product of the state with the representation (A.257) of the deuteron wave function. In the left hand side, you get zero because the deuteron wave function has $j_{\mathrm{N}}=1$ and states of different $j_{\mathrm{N}}$ are orthogonal. In the right hand side, all terms except one drop out because the states in the sum are orthonormal. The one remaining term is the coefficient of the considered state. Then this coefficient must be zero since the left hand side is.

Using the above criterion, consider which states cannot appear in the deuteron wave function. First of all, states with $s=0$ are according to the inequalities above states of nuclear spin $j_{\mathrm{N}}=l$. That cannot be 1 , since $l$ had to be even because of parity. So states with $s=0$ cannot appear in the deuteron wave function. It follows that the deuteron wave function has a combined nucleon $\operatorname{spin} s=1$ without quantum uncertainty.

Secondly, states with $l \geqslant 4$ have $j_{\mathrm{N}}$ at least equal to 3 according to the above inequalities. So these states cannot appear. That leaves only states with $l=0$ or 2 and $s=1$ as possibilities.

Now states with $l=0$ and $s=1$ are states with $j_{\mathrm{N}}=1$. Any such state can appear in the deuteron wave function. To what amount remains unknown. That would only be answerable if an exact solution to the proton-neutron deuteron would be available. But surely, based on arguments like those in $\{A .8\}$ and $\{\mathrm{A} .9\}$, it is to be expected that there is a significant $l=0$ component.

States with $l=2$ and $s=1$ are also a possibility. But they cannot appear in arbitrary combinations. Any such state has multiple possible values for $j_{\mathrm{N}}$ in the range from 1 to 3 . That uncertainty must be eliminated before the states are acceptable for the deuteron wave function. It turns out that pure $j_{\mathrm{N}}=1$ states can be obtained by taking specific combinations of states. In particular, groups of states that vary only in the quantum numbers $m$ and $m_{s}$ can be combined into states with $j_{\mathrm{N}}=1$. (For the curious, the specific combinations needed can be read off in figure 12.6).

The bottom line is that the deuteron wave function can have uncertainty in the orbital angular momentum. In particular, both orbital angular momentum numbers $l=0$ and $l=2$ can and do have a nonzero probability.

## A. 41 Deuteron model

A very simple model can be used to give some context to the data of the deuteron. This addendum describes that model. Then it discusses the various major problems of the model. Some possible fixes for these problems are indicated.

In all cases it is assumed that the deuteron is modelled as a two-particle system, a proton and a neutron. Furthermore, the proton and neutron are
assumed to have the same properties in the deuteron as they have in free space. These assumptions are not really true. For one, the proton and neutron are not elementary particles but combinations of quarks. However, ignoring that is a reasonable starting point in trying to understand the deuteron.

## A.41.1 The model

The deuteron contains two nucleons, a proton and a neutron. The simple model assumes that the potential energy of the deuteron only depends on the distance $r$ between the nucleons. More specifically, it assumes that the potential energy has some constant value $-V_{0}$ up to some spacing $r=d_{0}$. And it assumes that the potential is zero for spacings larger than $d_{0}$. Figure A. 24 shows the idea.

This model is analytically solvable. First, the deuteron involves the motion of two particles, the proton and the neutron. However, the problem may be simplified to that of an imaginary single "reduced mass" encircling the center of gravity of the deuteron, addendum $\{\mathrm{A} .5\}$.

The reduced mass in the simplified problem is half the mass of the proton or neutron. (That ignores the tiny difference in mass between the proton and neutron.) The potential for the reduced mass is $-V_{0}$ if the reduced mass is within a distance $d_{0}$ of the center of gravity and zero beyond that. A potential of this type is commonly called a [spherical] [square] well potential. Figure A. 24 shows the potential in green.

Figure A.24: Crude deuteron model. The potential is in green. The relative probability of finding the nucleons at a given spacing is in black.

The solution for the reduced mass problem may be worked out following addendum $\{$ A. 6$\}$. Note that the model involves two unknown parameters, the potential $V_{0}$ and the distance $d_{0}$. Two pieces of experimental information need to be used to fix values for these parameters.

First of all, the binding energy should match the experimental 2.2247 MeV . Also, the root-mean square radial position of the nucleons away from the center of the nucleus should be about 1.955 fm, [J.P. McTavish 1982 J. Phys. G 8 911; J.L. Friar et al 1984 Phys. Rev. C 30 1084]. (Based on electron scattering experiments, physicists are confident that the root-mean-square radial position
of the charge from the center of the deuteron is 2.14 fm . However, this "charge radius" is larger than the root mean square radial position of the nucleons. The main reason is that the proton has a finite size. For example, even in the hypothetical case that the distance of the two nucleons from the center of gravity would be zero, there would still be a positive charge radius; the one of the proton. The proton by itself has a significant charge radius, 0.88 fm .) The distance $r$ of the reduced mass from the origin should match the distance between the nucleons; in other words it should be twice the 1.955 fm radius.

| $d_{0}$ | $V_{0, \min }$ | $V_{0}$ | $\langle V\rangle$ | $\langle T\rangle$ | $E$ | $r_{\mathrm{rms}} / 2$ | $\langle T\rangle_{\min }$ | $A_{\mathrm{S}}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| fm | MeV | MeV | MeV | MeV | MeV | fm | MeV | $1 / \sqrt{\mathrm{fm}}$ |
| 1.2 | 71.1 | 88.5 | -21.0 | 18.8 | -2.22 | 1.77 | 7.6 | 0.79 |
| 2.1 | 23.2 | 33.7 | -12.5 | 10.3 | -2.22 | 1.95 | 6.2 | 0.88 |
| 3.0 | 11.4 | 19.2 | -9.2 | 7.0 | -2.22 | 2.15 | 5.1 | 0.98 |
| 1.8 | 31.6 | 43.0 | -13.7 | 11.7 | -2.02 | 1.96 | 6.1 | 0.82 |
| 2.1 | 23.2 | 33.7 | -12.5 | 10.3 | -2.22 | 1.95 | 6.2 | 0.88 |
| 2.4 | 17.8 | 27.7 | -11.7 | 9.3 | -2.42 | 1.95 | 6.1 | 0.94 |

Table A.4: Deuteron model data. The top half of the table allows some deviation from the experimental nucleon root-mean-square radial position. The bottom half allows some deviation from the experimental energy.

Table A. 4 shows that these two experimental constraints are met when the distance $d_{0}$ is 2.1 fm and the potential $V_{0}$ about 35 MeV . The fact that the distance $d_{0}$ matches the charge radius is just a coincidence.

There is some justification for this model. For one, it is well established that the nuclear force very quickly becomes negligible beyond some typical spacing between the nucleons. The above potential reflects that. Based on better models, (in particular the so-called OPEP potential), the typical range of the nuclear force is roughly 1.5 fm . The potential cut-off $d_{0}$ in the model is at 2.1 fm . Obviously that is in the ballpark, though it seems a bit big. (For a full-potential/zero-potential cut-off.)

The fact that both the model and exact potentials vanish at large nucleon spacings also reflects in the wave function. It means that the rate of decay of the wave function at large nucleon spacings is correctly represented. The rate of decay depends only on the binding energy $E$.

To be more precise, the model wave function is, $\{$ A. 6$\}$,

$$
\psi=\frac{A_{\mathrm{S}}}{\sqrt{4 \pi}} \frac{e^{-\sqrt{2 m_{\mathrm{red}}|E| r / \hbar}}}{r} \quad \text { for } \quad r>d_{0}
$$

where $A_{\mathrm{S}}$ is some constant. Unlike the model, the experimental wave function has some angular variation. However, if this variation is averaged away, the experimental wave function decays just like the model for distances much larger than 1.5 fm . In addition, the model matches the experimental value for the constant $A_{\mathrm{S}}, 0.88$, table A. 4 .

To be fair, this good agreement does not actually support the details of the potential as much as it may seem. As the difference between $-V_{0}$ and the expectation potential $\langle V\rangle$ in table A. 4 shows, the nucleons are more likely to be found beyond the spacing $d_{0}$ than below it. And the root mean square separation of the nucleons depends mostly on the wave function at large values of $r$. As a consequence, if the model gets $A_{S}$ right, then the root mean square separation of the nucleons cannot be much wrong either. That is true regardless of what exactly the potential for $r<d_{0}$ is. Still, the model does get the right value.

Another point in favor of the model is that the kinetic energy cannot be all wrong. In particular, the Heisenberg uncertainty relationship implies that the kinetic energy of the deuteron must be at least 6.2 MeV . The second-last column in the table shows the minimum kinetic energy that is possible for the root-mean-square radial nucleon position in the previous column. It follows that unavoidably the kinetic energy is significantly larger than the binding energy. That reflects the fact that the deuteron is only weakly bound. (For comparison, for the proton-electron hydrogen atom the kinetic energy and binding energy are equal.)

The model also supports the fact that there is only a single bound state for the deuteron. The second column in the table gives the smallest value of $V_{0}$ for which there is a bound state at all. Clearly, the estimated values of $V_{0}$ are comfortably above this minimum. But for a second bound state to exist, the value of $V_{0}$ needs to exceed the value in the second column by a factor 4 . Obviously, the estimated values get nowhere close to that.

A final redeeming feature of the model is that the deduced potential $V_{0}$ is reasonable. In particular, 35 MeV is a typical potential for a nucleon inside a heavy nucleus. It is used as a ballpark in the computation of so-called alpha decay of nuclei, [31, p. 83, 252].

## A.41.2 The repulsive core

While the model of the deuteron described in the previous subsection has several redeeming features, it also has some major problems. The problem to be addressed in this subsection is that the nuclear force becomes repulsive when the nucleons try to get too close together. The model does not reflect such a "repulsive core" at all.

A simple fix is to declare nucleon spacings below a certain value $d_{\text {min }}$ to be off-limits. Typically, half a femtometer is used for $d_{\text {min }}$. The potential is taken
to be infinite, rather than $-V_{0}$, for spacings below $d_{\text {min }}$. That prevents the nucleons from getting closer than half a femtometer together.

| $d_{0}$ | $V_{0, \text { min }}$ | $V_{0}$ | $\langle V\rangle$ | $\langle T\rangle$ | $E$ | $r_{\mathrm{rms}} / 2$ | $\langle T\rangle_{\min }$ | $A_{\mathrm{S}}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| fm | MeV | MeV | MeV | MeV | MeV | fm | MeV | $1 / \sqrt{\mathrm{fm}}$ |
| 0.7 | 2559.9 | 2657.3 | -119.7 | 117.5 | -2.22 | 1.75 | 7.6 | 0.78 |
| 1.7 | 71.1 | 88.5 | -21.0 | 18.8 | -2.22 | 1.96 | 6.1 | 0.88 |
| 2.6 | 23.2 | 33.8 | -12.5 | 10.3 | -2.22 | 2.16 | 5.0 | 0.99 |

Table A.5: Deuteron model data with a repulsive core of 0.5 fm .

The modifications needed to the mathematics to include this repulsive core are minor. Table A. 5 summarizes the results. The value of $V_{0}$ for a second bound state would need to be about 160 MeV .

Note that the value of the potential cut-off distance $d_{0}$ has been reduced from 2.1 fm to 1.7 fm . As discussed in the previous subsection, that can be taken to be an improvement. Also, the expectation potential and kinetic energies seem much better. A much more advanced potential, the so-called Argonne $v_{18}$, gives 22 and 19.8 MeV for these expectation values.

Figure A.25: Crude deuteron model with a 0.5 fm repulsive core. Thin grey lines are the model without the repulsive core. Thin red lines are more or less comparable results from the Argonne $v_{18}$ potential.

Figure A. 25 shows the potential and probability density. The previous results without repulsive core are shown as thin grey lines for easier comparison. Note that there are very distinctive differences between the wave functions with and without repulsive core. But astonishingly, the values for the root mean square nucleon separation $r_{\text {rms }}$ are virtually identical. The value of $r_{\text {rms }}$ is not at all a good quantity to gauge the accuracy of the model.

Figure A. 25 also shows corresponding results according to the much more sophisticated Argonne $v_{18}$ model, [51]. The top red line shows the probability density for finding the nucleons at that spacing. The lower curve shows an effective spherical potential. A note of caution is needed here; the true deuteron potential has very large deviations from spherical symmetry. So the comparison of potentials is fishy. What is really plotted in figure A. 25 is the effective potential that integrated against the probability density produces the correct expectation potential energy.

It is interesting to see from figure A. 25 how small the 2.2 MeV binding energy of the deuteron really is, as compared to the minimum value of the potential energy.

## A.41.3 Spin dependence

An big problem with the model so far is that nucleon-nucleon interactions depend strongly on the nucleon spins. Such an effect also exists for the protonelectron hydrogen atom, $\{\mathrm{A} .39 .5\}$. However, there the effect is extremely small. For the deuteron, the effect of spin is dramatic.

The proton and neutron each have spin $1 / 2$. They must align these spins in parallel into a so-called triplet state of combined spin 1, chapter 5.5.6. If instead they align their spins in opposite directions in a singlet state of zero net spin, the deuteron will not bind. The model as given so far does not describe this.

One simple way to fix this up is to write two different potentials. One potential $V_{\mathrm{t}}(r)$ is taken to apply if the nucleons are in the triplet state. It can be modeled by the piecewise constant potential as discussed so far. A second potential $V_{\mathrm{s}}(r)$ is taken to apply if the nucleons are in the singlet state. A suitable form can be deduced from experiments in which nucleons are scattered off each other. This potential should not allow a bound state.

That leaves only the problem of how to write the complete potential. The complete potential should simplify to $V_{\mathrm{t}}$ for the triplet state and to $V_{\mathrm{s}}$ for the singlet state. A form that does that is

$$
\begin{equation*}
V=V_{\mathrm{t}}(r)\left[\frac{3}{4}+\frac{1}{\hbar^{2}} \widehat{\vec{S}}_{\mathrm{p}} \cdot \hat{\vec{S}}_{\mathrm{n}}\right]+V_{\mathrm{s}}(r)\left[\frac{1}{4}-\frac{1}{\hbar^{2}} \hat{\vec{S}}_{\mathrm{p}} \cdot \hat{\vec{S}}_{\mathrm{n}}\right] \tag{A.258}
\end{equation*}
$$

The reason that this works is because the dot product $\widehat{\vec{S}}_{\mathrm{p}} \cdot \widehat{\vec{S}}_{\mathrm{n}}$ between the proton and neutron spins is $\frac{1}{4} \hbar^{2}$ in the triplet state and $-\frac{3}{4} \hbar^{2}$ in the singlet state, $\{\mathrm{A} .10\}$.

## A.41.4 Noncentral force

So far it has been assumed that the potential in a given spin state only depends on the distance $r$ between the nucleons. If true, that would imply that the orbital
angular momentum of the motion of the nucleons is conserved. In terms of classical physics, the forces between the particles would be along the connecting line between the particles. That does not produce a moment that can change orbital angular momentum.

In terms of quantum mechanics, it gets phrased a little differently. A potential that only depends on the distance between the particles commutes with the orbital angular momentum operators. Then so does the Hamiltonian. And that means that the energy states can also be taken to be states of definite orbital angular momentum.

In particular, in the ground state, the proton and neutron should then be in a state of zero orbital angular momentum. Such a state is spherically symmetric. Therefore the proton charge distribution should be spherically symmetric too. All that would be just like for the electron in the hydrogen atom. See chapters $4.2,4.3,4.5$, and 7.3 , addendum $\{\mathrm{A} .39\}$, and derivations $\{\mathrm{A} .8\}$ and $\{\mathrm{A} .9\}$ for more details on these issues.

However, the fact is that the charge distribution of the deuteron is not quite spherically symmetric. Therefore, the potential cannot just depend on the distance $r$ between proton and neutron. It must also depend on the direction of the vector $\vec{r}$ from neutron to proton. In particular, it must depend on how this vector aligns with the nucleon spins. There are no other directions to compare to in the deuteron besides the spins.

The orientation of the chosen coordinate system should not make a difference for the potential energy. From a classical point of view, there are three nuclear angles that are nontrivial. The first two are the angles that the vector $\vec{r}$ from neutron to proton makes with the neutron and proton spins. The third is the angle between the two spins. These three angles, plus the distance between the neutron and proton, fully determine the geometry of the nucleus.

To check that, imagine a coordinate system with origin at the neutron. Take the $x$-axis along the connecting line to the proton. Rotate the coordinate system around the $x$-axis until the neutron spin is in the $x y$-plane. What determines the geometry in this coordinate system is the angle in the $x y$-plane between the connecting line and the neutron spin. And the two angles that fix the direction of the proton spin; the one with the connecting line and the one with the neutron spin.

In quantum mechanics, angles involving angular momentum vectors are not well defined. That is due to angular momentum uncertainty, chapter 4.2. However, dot products between vectors can be used to substitute for angles between vectors, for given lengths of the vectors. Because the spin vectors have a given length, there are four parameters that fix the geometry:

$$
r \quad \hat{\vec{S}}_{\mathrm{n}} \cdot \hat{\vec{S}}_{\mathrm{p}} \quad \hat{\vec{S}}_{\mathrm{n}} \cdot \vec{r} \quad \hat{\vec{S}}_{\mathrm{p}} \cdot \vec{r}
$$

The potential energy should depend on these four parameters. Note that the
effect of the first two parameters was already modelled in the previous subsections.

In order that orbital angular momentum is not conserved, the last two parameters should be involved. But not separately, because they change sign under a parity transformation or time reversal. It is known that to very good approximation, nuclei respect the parity and time-reversal symmetries. Terms quadratic in the last two parameters are needed. And in particular, the product of the last two parameters is needed. If you just square either parameter, you get a trivial multiple of $r^{2}$. That can be seen from writing the spins out in terms of the so-called Pauli matrices, as defined in chapter 12.

The bottom line is that the needed additional contribution to the potential is due to the product of the final two terms. This contribution is called the "tensor potential" for reasons that are not important. By convention, the tensor potential is written in the form

$$
\begin{equation*}
S_{12} V_{\mathrm{T}}(r) \quad \text { with } \quad S_{12} \equiv \frac{4}{\hbar^{2}}\left(\frac{3}{r^{2}}\left(\hat{\vec{S}}_{\mathrm{n}} \cdot \vec{r}\right)\left(\hat{\vec{S}}_{\mathrm{p}} \cdot \vec{r}\right)-\hat{\vec{S}}_{\mathrm{n}} \cdot \hat{\vec{S}}_{\mathrm{p}}\right) \tag{A.259}
\end{equation*}
$$

The choice of the symbol $S_{12}$ is another one of those confusion-prone physics conventions. One source uses the same symbol only a few pages away for a matrix element. The division by $r^{2}$ is to make $S_{12}$ independent of the distance between the nucleons. This distance is separately accounted for in the factor $V_{\mathrm{T}}$. Also the subtraction of the dot product between the spins makes the average of $S_{12}$ over all directions of $\vec{r}$ zero. That means that $\Delta V$ only describes the angular variation of the potential. The angular average must be described by other potentials such as the ones written down earlier.

It turns out that $S_{12}$ commutes with the operator of the square net nucleon spin but not with the operator of orbital angular momentum. That is consistent with the fact that the deuteron has definite net nucleon spin $s=1$ but uncertain orbital angular momentum. Its quantum number of orbital angular momentum can be $l=0$ or 2 .

It should also be noted that $S_{12}$ produces zero when applied on the singlet nucleon spin state. So the term has no effect on singlet states. These properties of $S_{12}$ may be verified by crunching it out using the properties of the Pauli spin matrices, chapter 12.10 , including that $\sigma_{i}^{2}=I$ and $\sigma_{i} \sigma_{\bar{\imath}}=-\sigma_{\bar{\imath}} \sigma_{i}=\mathrm{i} \sigma_{\overline{\bar{\imath}}}$ with $i, \bar{\imath}, \overline{\bar{\imath}}$ successive numbers in the cyclic sequence ... 1231231....

Figure A. 26 illustrates the effects of the uncertainty in orbital angular momentum on the deuteron. The data are taken from the Argonne $v_{18}$ potential, [51].

The black curve is the probability density for finding the nucleons at that spacing $r$. Most of this probability density is due to the spherically symmetric, $l=0$, part of the wave function. This contribution is shown as the grey curve labelled 0 . The contribution due to the $l=2$ state is the grey curve labelled 2 .

Figure A.26: Effects of uncertainty in orbital angular momentum.

The total probability of the $l=2$ state is only $5.8 \%$ according to the Argonne $v_{18}$ potential.

That might suggest that the effect of the $l=2$ state on the deuteron binding could be ignored. But that is untrue. If the deuteron wave function was completely spherically symmetric, the potential would given by the thin green curve labeled 0 . The binding energy from this potential is significantly less than that of the hypothetical dineutron, shown in blue. And the dineutron is not even bound. If the deuteron was in a pure $l=2$ state, the binding would be less still according to the thin green line labelled 2. However, the deuteron is in a combination of the $l=0$ and $l=2$ states. The energy of the interaction of these two states lowers the potential energy greatly. It produces the combined potential energy curve shown as the thick green line.

In terms of chapter 5.3, the lowering of the potential energy is a twilight effect. Even for an $l=2$ state probability of only $5.8 \%$, a twilight effect can be quite large. That is because it is proportional to the square root of the $5.8 \%$ probability, which is a quarter. In addition, the factor $V_{\mathrm{T}}$ in the tensor potential turns out to be quite large.

## A.41.5 Spin-orbit interaction

So far, the assumption has been that the potential of the deuteron only depends on its geometry. But scattering data suggests that the potential also depends on the motion of the nucleons. A similar effect, the "spin-orbit coupling" occurs for the proton-electron hydrogen atom, addendum \{A.39\}. However, there the effect is very small. Spin-orbit interaction is proportional to the dot product of net orbital angular momentum and net nucleon spin. In particular, it produces a term in the potential of the form

$$
V_{\mathrm{so}}(r) \widehat{\vec{L}} \cdot \widehat{\vec{S}}
$$

This term does not contribute to the uncertainty in orbital angular momentum. But it can explain how nucleon beams can get polarized with respect to spin in scattering experiments.

## A. 42 Nuclear forces

The purpose of this addendum is to examine the nature of nuclear forces somewhat closer. The forces will be modeled using the "meson exchange" idea. This idea illustrates one primary way that physicists cope with the fact that nuclei are too complex to describe exactly.

## A.42.1 Basic Yukawa potential

As pointed out in chapter 7.5.2, the fundamental forces of nature between elementary particles are due to the exchange of bosons between these particles. In those terms, nuclei consist of quarks. The exchange of gluons between these quarks produces the so-called color force. It is that force that holds nuclei together. Unfortunately, describing that mathematically is not a practical proposition. Quantum chromedynamics is prohibitively difficult.

But you will never find quarks or gluons in isolation. Quarks and their gluons are always confined inside "colorless" combinations of two or three quarks. (To be painstakingly honest, there might be more exotic colorless combinations of quarks and gluons than that. But their energy should be too high to worry about here.) What is observed physically at the time of writing, 2012, are groups of three quarks, (baryons), three antiquarks, (antibaryons), and a quark and an antiquark (mesons). An easier description of nuclear forces can be based on these groups of quarks.

In this picture, nuclei can be taken to consist of nucleons. A nucleon consists of a group of three quarks, so it is a baryon. There are two types of nucleons: protons and neutrons. A proton contains two "up" quarks, at electric charge $\frac{2}{3} e$ each, and one "down" quark, at $-\frac{1}{3} e$. That makes the net charge of a proton $\frac{2}{3} e+\frac{2}{3} e-\frac{1}{3} e$ equal to $e$. A neutron has one up quark and two down ones, making its net charge $\frac{2}{3} e-\frac{1}{3} e-\frac{1}{3} e$ equal to zero.

For both protons and neutrons, the group of three quarks is in its ground state, much like a helium atom is normally in its ground state. Like single quarks, nucleons are fermions with spin equal to $1 / 2$. (Roughly speaking, two of the three quarks in nucleons align their spins in opposite directions, causing them to cancel each other.) Nucleons have positive intrinsic parity. That means that their mere presence does not produce a change in sign in the wave function when the coordinate system is inverted, chapter 7.3. (Actually, there is some ambiguity in the assignment of intrinsic parity to particles. But a fermion and
the corresponding antifermion must have opposite parity. Taking the parity of fermions positive makes that of the corresponding antifermions negative.)

Protons and neutrons combine together into nuclei. However, the protons in nuclei repel each other because of their electric charges. So there must be some compensating force that keeps the nucleons together anyway. This force is what is called the "nuclear force." The question in this addendum is how this nuclear force can be described. Its physical cause is still the force due to the exchange of gluons between quarks. But its mathematical description is going to be different. The reason is that by definition the nuclear force is a net force on nucleons, i.e. on groups of quarks. And it is assumed to depend on the average positions, and possibly momenta, of these groups of quarks.

Note that there is some approximation involved here. Exactly speaking, the nuclear forces should depend on the positions of the individual quarks in the nucleons, not just on their average position. That is a concern when two nucleons get very close together. For one, then the distinction between the two separate groups of quarks must blur. Nucleons do repel one another strongly at very close distances, much like atoms do due to Pauli repulsion, chapter 5.10. But still their quantum uncertainty in position creates a probability for them to be very close together. Fortunately, typical energy levels in normal nuclear physics are low enough that this is not believed to be a dominating effect. Indeed, the models discussed here are known to work very well at larger nucleon spacings. For smaller nucleon spacing however, they become much more complex, and their accuracy much more uncertain. And that happens well before the nucleons start intruding significantly on each others space. Little in life is ideal, isn't it?

In a particle exchange explanation of the nuclear force, roughly speaking nucleons have to "pop up" particles that other nucleons then absorb and viceversa. The first question is what these particles would be. As already mentioned, only colorless combinations of quarks and their gluons are observed in isolation. Therefore only such colorless combinations can be expected to be able to readily bridge the gap between nucleons that are relatively far apart. The lowest energy of these colorless combinations are the easiest to pop up. And that are the pions; a pion is a meson consisting of a quark and antiquark pair in its ground state.

There are three types of pions. The $\pi^{+}$pion consists of an up quark plus an antidown quark. Antiparticles have the opposite charge from the corresponding particles, so the antidown quark has charge $\frac{1}{3} e$. That makes the net charge of the $\pi^{+}$pion $\frac{2}{3} e+\frac{1}{3} e$ equal to $e$, the same as that of the proton. The $\pi^{-}$pion consists of an antiup quark plus a down quark, producing a net charge $-\frac{2}{3} e-\frac{1}{3} e$ equal to $-e$. That is as it should be since self-evidently the $\pi^{-}$is the antiparticle of the $\pi^{+}$. The $\pi^{0}$ pion is a quantum superposition of an up-antiup pair and a down-antidown pair and is electrically neutral.

Pions are bosons of zero spin and negative intrinsic parity. The negative parity is due to the antiquark, and zero spin is due to the fact that in pions the
quark and antiquark align their spins in opposite directions in a singlet state, chapter 5.5.6.

These pions are the most important particles that protons and neutrons exchange. The first question is then of course where they come from. How is it possible that pions just appear out of nothing? Well, it is possible due to a mixture of special relativity and the uncertainty inherent in quantum mechanics.

The creation of particles out of energy is allowed by special relativity. As discussed in chapter 1.1.2, special relativity gives the energy $E$ of a particle as:

$$
E=\sqrt{\vec{p}^{2} c^{2}+\left(m c^{2}\right)^{2}}
$$

Here $c$ is the speed of light, $\vec{p}$ the momentum of the particle, and $m$ its mass (at rest). According to this expression, a particle at rest represents an amount of energy equal to $m c^{2}$. This is the rest mass energy. The charged $\pi^{+}$and $\pi^{-}$ pions have a rest mass energy of about 140 MeV , and the neutral $\pi^{0} 135 \mathrm{MeV}$. So to create an actual pion requires at least 135 MeV of energy.

Quantum mechanics replaces the momentum $\vec{p}$ in the energy above by the operator $\hbar \nabla / \mathrm{i}$ in order to find the Hamiltonian. Then it applies that Hamiltonian to a pion wave function $\varphi_{\pi}$. But the square root in the above expression is a problem. Fortunately, for spinless bosons like pions an acceptable solution is easy: just square the energy. Or rather, apply the Hamiltonian twice. That produces the relativistic so-called Klein-Gordon eigenvalue problem

$$
\begin{equation*}
-\hbar^{2} c^{2} \nabla^{2} \varphi_{\pi}+\left(m_{\pi} c^{2}\right)^{2} \varphi_{\pi}=E^{2} \varphi_{\pi} \tag{A.260}
\end{equation*}
$$

Now consider first a single nucleon located at the origin. Supposedly this nucleon can pop up a pion. But where would the nucleon get the 135 MeV or more of energy? Surely, if there was a probability of actually finding a 135 MeV pion well away from the nucleon, it would violate energy conservation. But remarkably, despite the positive pion rest mass energy, the Klein-Gordon equation has a simple solution where the total pion energy $E$ appears to be zero:

$$
\varphi_{\pi}=C \frac{e^{-r / R}}{r} \quad R \equiv \frac{\hbar c}{m_{\pi} c^{2}} \approx 1.4 \mathrm{fm}
$$

Here $r$ is the distance from the nucleon and $C$ an arbitrary constant. In effect, this solution has a big negative kinetic energy. You might say that a zero-energy pion "tunnels out" of the nucleon, chapter 7.12.2.

To check the above solution, just plug it in the Klein-Gordon equation (A.260) with $E=0$, using the expression (N.5) for the Laplacian $\nabla^{2}$ found in the notations. But to be true, this substitution is somewhat misleading. A more careful analysis shows that the left hand side in the Klein-Gordon equation does have a nonzero spike at $r=0,\{\mathrm{D} \cdot 2.2\}$. But there the pion will experience an interaction energy with the nucleon.

Now assume that the nucleon does indeed manage to create a pion field around itself. A field that acts as a potential $\varphi$ that can produce forces on other nucleons. That would be much like a charged particle creates an electrostatic potential that can produce forces on other charged particles. Then it seems a plausible guess that the pion potential $\varphi$ will vary with position just like the zero-energy wave function $\varphi_{\pi}$ above. Look at electromagnetics. The photon of electromagnetics has zero rest mass. And for zero rest mass, the zero-energy wave function above becomes the correct $C / r$ Coulomb potential of electromagnetics.

Actually, despite the fact that it works for electromagnetics, the zero-energy wave function above does not quite give the right form for a pion potential. But it does give the general idea. The correct potential is discussed in the next subsections. This subsection will stick with the form above as qualitatively OK.

Now consider a second nucleon. This nucleon will of course also create a pion potential. That is just like if it was all by itself. But in addition, it will interact with the pion potential created by the first nucleon. So there will be an energy of interaction between the nucleons. Taking another cue from electromagnetics, this energy should presumably be proportional to the potential that the first nucleon creates at the position of the second nucleon.

That idea then gives the interaction energy between two nucleons as

$$
\begin{equation*}
V_{\text {Yukawa }}=-C_{\mathrm{Y}} \frac{e^{-r / R}}{r} \quad R \equiv \frac{\hbar c}{m_{\pi} c^{2}} \approx 1.4 \mathrm{fm} \tag{A.261}
\end{equation*}
$$

Here $r$ is the distance between the two nucleons, and $C_{\mathrm{Y}}$ is some positive constant that must be determined experimentally. The above interaction energy is called the "Yukawa potential" after the Japanese physicist who first derived it. It is really a potential energy, rather than a potential. (At least in the terminology of this book for fields. In physics, pretty much everything is called a potential.)

The Yukawa potential is attractive. This is in contrast to the Coulomb potential, which is repulsive between like charges. The best physical explanation for the difference may be the analysis in $\{\mathrm{A} .22\}$, in particular $\{\mathrm{A} .22 .5\}$. (There are many other "explanations" that derive the difference using an electromagnetic Hamiltonian or Lagrangian that already has the difference build in. But a derivation is not an explanation.)

Note the exponential in the Yukawa potential. It will make the potential negligibly small as soon as the distance $r$ between the nucleons is significantly greater than $R$. With $\hbar c$ about 197 MeV fm and the average pion rest mass energy about $138 \mathrm{MeV}, R$ is about 1.4 fm (femtometer). So unless the nucleons are within a distance not much greater than 1.4 fm from each other, they do not experience a nuclear force from each other. Yukawa had derived the typical range of the nuclear force.

Actually, at the time that Yukawa did his work, the pion was unknown. But the range of the nuclear force was fairly well established. So Yukawa really predicted the existence, as well as the mass of the pion, a then unknown particle! After a long and frustrating search, this particle was eventually discovered in cosmic rays.

The Yukawa potential also explained why heavy nuclei are unstable. Suppose that you keep stuffing nucleons, and in particular protons, into a nucleus. Because of the exponential in the Yukawa potential, the nuclear force is very short range. It is largely gone beyond distances of a couple of fm . So a proton gets pulled into the nucleus only by the nucleons in its immediate vicinity. But the Coulomb repulsion between protons does not have the exponential decay. So the same proton gets pushed out of the nucleus by protons from all over the nucleus. If the nucleus is big enough, the pushers simply have to win because of their much larger numbers.

Putting a lot of neutrons in the nucleus can help, because they produce nucleon attraction and no Coulomb repulsion. But neutrons by themselves are unstable. Put too many neutrons in a nucleus, and they will turn into protons by beta decay. Obviously, that defeats the purpose. As a result, beyond a certain size, the nucleus is going to fall apart whatever you do.

You can see why Yukawa would end up with the Nobel prize in physics.

## A.42.2 OPEP potential

The Yukawa potential energy (A.261) described in the previous section is not quite right yet. It does not give the true nuclear force between two nucleons produced by pion exchange.

In a more careful analysis, the potential energy depends critically on the properties of the exchanged particle. See the next subsection for an explanation of that. For a pion, the relevant properties are that it has zero spin and negative parity. Taking that into account produces the so-called "one-pion exchange potential" energy or "OPEP" for short:

$$
\begin{align*}
V_{\mathrm{OPEP}} & \sim \frac{g_{\pi}^{2}}{12}\left(\frac{m_{\pi}}{m_{\mathrm{p}}}\right)^{2} m_{\pi} c^{2} \vec{\tau}_{1} \cdot \vec{\tau}_{2}\left[\vec{\sigma}_{1} \cdot \vec{\sigma}_{2}+S_{12} V_{\mathrm{T}}\right] \frac{e^{-r / R}}{r / R}  \tag{A.262}\\
S_{12} & \equiv \frac{3}{r^{2}}\left(\vec{\sigma}_{1} \cdot \vec{r}\right)\left(\vec{\sigma}_{2} \cdot \vec{r}\right)-\vec{\sigma}_{1} \cdot \vec{\sigma}_{2} \quad V_{\mathrm{T}} \equiv 1+3 \frac{R}{r}+3 \frac{R^{2}}{r^{2}}
\end{align*}
$$

Here $r$ is again the distance between nucleons 1 and 2, equal to the length of the vector $\vec{r}$ connecting the two nucleons, $R$ is again the typical range of the nuclear force, $m_{\pi}$ again the pion mass, while $m_{\mathrm{p}}$ is the nucleon mass:
$r \equiv|\vec{r}| \equiv\left|\vec{r}_{2}-\vec{r}_{1}\right| \quad R \equiv \frac{\hbar c}{m_{\pi} c^{2}} \approx 1.4 \mathrm{fm} \quad m_{\pi} c^{2} \approx 138 \mathrm{MeV} \quad m_{\mathrm{p}} c^{2} \approx 938 \mathrm{MeV}$

Also $g_{\pi}^{2} \approx 15$ is an empirical constant, [36, p. 135], [5, p. 85]. Further $\vec{\sigma}_{1}$ and $\vec{\sigma}_{2}$ are the nucleon spins $\widehat{\vec{S}}_{1}$ and $\widehat{\vec{S}}_{2}$, nondimensionalized by dividing by $\frac{1}{2} \hbar$.

Finally the dot product $\vec{\tau}_{1} \cdot \vec{\tau}_{2}$ involves the so-called "isospin" of the nucleons. Isospin will be discussed in chapter 14.18. There it will be explained that it has nothing to do with spin. Instead isospin is related to nucleon type. In particular, if both nucleons involved are protons, or if both are neutrons, then $\vec{\tau}_{1} \cdot \vec{\tau}_{2}=1$.

If one nucleon is a proton and the other a neutron, like in the deuteron, the value of $\vec{\tau}_{1} \cdot \vec{\tau}_{2}$ can vary. But in any case, it is related to the symmetry of the spatial and spin states. In particular, compare also chapter 5.5.6 and \{A.10\},

$$
\begin{aligned}
\text { symmetric spatially: } & \vec{\sigma}_{1} \cdot \vec{\sigma}_{2}=\left\{\begin{aligned}
-3 \text { (singlet) } & \Longrightarrow \vec{\tau}_{1} \cdot \vec{\tau}_{2}=1 \\
1 \text { (triplet) } & \Longrightarrow \vec{\tau}_{1} \cdot \vec{\tau}_{2}=-3
\end{aligned}\right. \\
\text { antisymmetric spatially: } & \vec{\sigma}_{1} \cdot \vec{\sigma}_{2}=\left\{\begin{aligned}
-3 \text { (singlet) } & \Longrightarrow \quad \vec{\tau}_{1} \cdot \vec{\tau}_{2}=-3 \\
1 \text { (triplet) } & \Longrightarrow \\
\vec{\tau}_{1} \cdot \vec{\tau}_{2}= & 1
\end{aligned}\right.
\end{aligned}
$$

For the deuteron, as well as for the hypothetical diproton and dineutron, the spatial state is symmetric under nucleon exchange. That is as you would expect for a ground state, $\{A .8\}$ and $\{A .9\}$. It then follows from the above values that the first, $\vec{\sigma}_{1} \cdot \vec{\sigma}_{2}$, term in the square brackets in the OPEP (A.262) produces a negative, attractive, potential for these nuclei. That is true regardless whether the spin state is singlet or triplet.

The second, $S_{12} V_{\mathrm{T}}$, term in the OPEP is called a tensor potential, \{A.41.4\}. This potential can create uncertainty in orbital angular momentum. As discussed in \{A.41.4\}, having a tensor potential is an essential part in getting the deuteron bound. But the tensor potential is zero for the singlet spin state. And the spin state must be the singlet one for the diproton and dineutron, to meet the antisymmetrization requirement for the two identical nucleons. So the diproton and dineutron are not bound.

The deuteron however can be in the triplet spin state. In that case the tensor potential is not zero. To be sure, the tensor potential does average out to zero over all directions of $\vec{r}$. But that does not prevent attractive niches to be found. And note how big the multiplying factor $V_{\mathrm{T}}$ is for $R$ about 1.4 fm and nucleon spacings $r$ down to say 2 fm . The tensor potential is big.

Of course, that also depends on $S_{12}$. But $S_{12}$ is not small either. For example, if $\vec{r}$ is in the $x$-direction, then $S_{12}$ times a triplet state is three times the opposite triplet state minus the original one.

## A.42.3 Explanation of the OPEP potential

The purpose of this subsection is to explain the OPEP potential between nucleons as given in the previous subsection physically.

Note that the objective is not to give a rigorous derivation of the OPEP potential using advanced quantum field theory. Physicists presumably already
got the OPEP right. They better, because it is a standard part of current nuclear potentials. The explanations here will be based on simple physical assumptions. They follow the derivation of the Koulomb potential in $\{\mathrm{A} .22 .1\}$. That derivation was classical, although a simple quantum field version can be found in $\{\mathrm{A} .22 .3\}$. Note that the original Yukawa derivation was classical too. It was still worth a Nobel prize.

The arguments here are loosely based on [16, p. 282-288]. However, often the assumptions made in that reference seem quite arbitrary. To avoid that, the exposition below makes much more liberal use of quantum ideas. After all, in final analysis the classical field is just a reflection of underlying quantum mechanics. Hopefully the quantum arguments will show much more compellingly that things just have to be the way they are.

First of all, like in the first subsection it will be assumed that every nucleon can generate a pion potential. Other nucleons can observe that potential and interact with it, producing forces between the nucleons involved.

The net pion potential produced by all the nucleons will be called $\varphi$. It will be assumed that the energy in the observable pion field is given in terms of $\varphi$ as

$$
E_{\varphi}=\frac{\epsilon_{1}}{2} \int\left|\frac{1}{c} \frac{\partial \varphi}{\partial t}\right|^{2}+|\nabla \varphi|^{2}+\left|\frac{m_{\pi} c^{2}}{\hbar c} \varphi\right|^{2} \mathrm{~d}^{3} \vec{r}
$$

Here $\epsilon_{1}$ is some empirical constant, $m_{\pi}$ the pion mass, and the integral is over all space. There should be some expression for the energy in the observable field, and the integral above is what the Klein-Gordon equation for free pions preserves, $\{\mathrm{D} .32\}$. So it seems the likely expression. Also, the above integral gives the correct energy in an electrostatic field, chapter 13.2 (13.11), taking into account that the photon has no mass.
(Do note that there are some qualifications to the statement that the above integral gives the correct energy in an electrostatic field. The electromagnetic field is quite tricky because, unlike the pion, the photon wave function is a relativistic four-vector. See $\{$ A. 22$\}$ for more. But at the very least, the integral above gives the correct expression for the effective energy in the electrostatic field.)

Finally it will be assumed that there is an interaction energy between the observable pion field and the nucleons. But the precise expression for that interaction energy is not yet obvious. Only a generic expression can reasonably be postulated at this stage. In particular, it will be postulated that the interaction energy of the pion field with an arbitrary nucleon numbered $i$ takes the form:

$$
E_{\varphi i}=-\int \varphi f_{i} \mathrm{~d}^{3} \vec{r}
$$

The minus sign is inserted since the interaction will presumably lower the energy. If it did not, there should be no pion field at all in the ground state. The factor $f_{i}$ will be called the interaction factor of nucleon $i$.

It still needs to be figured out what is the appropriate form of this interaction factor. But it will be assumed that it involves the wave function $\Psi_{i}$ of nucleon $i$ in some way. In particular, in regions where the wave function is zero, $f_{i}$ will be zero too. That means that where there is no probability of finding the nucleon, there is no interaction of the nucleon with the field either. In other words, the interaction is "local," rather than long range; it occurs at the location of the nucleon. One motivation for this assumption is that long-range interactions are just bound to produce problems with special relativity.

It will further be assumed that the wave function of each nucleon $i$ is slighly spread out around some nominal position $\vec{r}_{i}$. After all, if you want a potential in terms of nucleon positions, then nucleons should at least approximately have positions. One immediate consequence is then that the interaction factor $f_{i}$ is zero except close to the nominal position $\vec{r}_{i}$ of the nucleon.

The ground state is the state in which the combined pion field and interaction energy is minimal. To find the properties of that state requires variational calculus. This is worked out in considerable detail in $\{$ A. 22.1$\}$ and $\{$ A. 2$\}$. (While those derivations do not include the $m_{\pi}$ term, its inclusion is trivial.) The analysis shows that the observable potential must satisfy

$$
\begin{equation*}
-\nabla^{2} \varphi+\left(\frac{m_{\pi} c^{2}}{\hbar c}\right)^{2} \varphi=\frac{1}{\epsilon_{1}} \sum_{i} f_{i} \tag{A.263}
\end{equation*}
$$

As noted above, the interaction factors $f_{i}$ in the right hand side are zero away from the nucleons. And that means that away from the nucleons the potential satisfies the Klein-Gordon eigenvalue problem with zero energy. That was a good guess, in the first subsection! But now the complete potential can be figured out, given the interaction factors $f_{i}$.

The variational analysis further shows that the energy of interaction between a nucleon numbered $i$ and one numbered $j$ is:

$$
\begin{equation*}
V_{i j}=-\int \varphi_{i}(\vec{r}) f_{j}(\vec{r}) \mathrm{d}^{3} \vec{r} \tag{A.264}
\end{equation*}
$$

Here $\varphi_{i}$ is the potential caused by nucleon $i$. In other words, $\varphi_{i}$ is the solution of (A.263) if only a single interaction factor $f_{i}$ in the sum in the right hand side is included.

The big question remains, what exactly is the interaction factor $f_{i}$ between the pion field and a nucleon $i$ ? The first guess would be that the interaction energy at a given position is proportional to the probability of finding the nucleon at that position. In short,

$$
f_{i, \mathrm{fg}}=g\left|\Psi_{i}\right|^{2} \quad ?
$$

where "fg" stands for "first-guess" and $g$ is some constant. This reflects that the probability of finding the nucleon is given by its square wave function $\left|\Psi_{i}\right|^{2}$. The above interaction factor is essentially what you would have in electrostatics.

There $g$ would be the electric charge, so for pions you could call it the "mesic charge." (Note that the square wave function integrates to 1 so the integrated interaction factor above is $g$.)

Given the above first-guess interaction factor, according to (A.263) a nucleon $i$ would create a first-guess potential, $\{D .2 .2\}$,

$$
\begin{equation*}
\varphi_{i, \mathrm{fg}}=\frac{g}{4 \pi \epsilon_{1}} \frac{e^{-r / R}}{r} \quad(\text { except vanishingly close to the nucleon } i) \tag{A.265}
\end{equation*}
$$

Here $r$ is the distance from the nucleon. If you assume for simplicity that the nucleon is at the origin, $r$ is the distance from the origin.

The above potential is spherically symmetric; it is the same in all directions. (That is true even if the nucleon wave function is not spherically symmetric. The wave function is only nonzero very close to $\vec{r}_{i}$, so it looks like a single point away from the immediate vicinity of the nucleon.)

The interaction energy with a second nucleon $j$ may now be found using (A.264). In particular, because the wave function of nucleon $j$ is only nonzero very close to its nominal position $\vec{r}_{j}$, you can approximate $\varphi_{i}(\vec{r})$ in (A.264) as $\varphi_{i}\left(\vec{r}_{j}\right)$. Then you can take it out of the integral. So the interaction energy is proportional to $\varphi_{i}\left(\vec{r}_{j}\right)$. That is the potential caused by nucleon $i$ evaluated at the position of nucleon $j$. That was another good guess, in the first subsection! More precisely, you get

$$
V_{i j, \mathrm{fg}}=-\frac{g^{2}}{4 \pi \epsilon_{1}} \frac{e^{-r_{i j} / R}}{r_{i j}}
$$

where $r_{i j}=\left|\vec{r}_{j}-\vec{r}_{i}\right|$ is the distance between the nucleons. This first guess potential energy is the Yukawa potential of the first subsection.

The Yukawa potential would be appropriate for a field of spinless pions with positive intrinsic parity. And except for the sign problem mentioned in the first subsection, it also gives the correct Coulomb potential energy in electrostatics.

Unfortunately, as noted in the first subsection, the pion has negative intrinsic parity, not positive. And that is a problem. Imagine for a second that a nucleon pops up a pion. The nucleon has positive parity. However, the pion that pops up has negative intrinsic parity. And parity is preserved, chapter 7.3. If the intrinsic parity of the pion is negative, its orbital parity must be negative too to maintain a positive combined system parity, chapter 7.4.2. Negative orbital parity means that the pion wave function $\varphi_{\pi}$ must have opposite values at $\vec{r}$ and $-\vec{r}$. But as mentioned, the first-guess potential is spherically symmetric; the values at $\vec{r}$ and $-\vec{r}$ are the same.
(Note that this argument blurs the distinction between a pion wave function $\varphi_{\pi}$ and an observable pion potential $\varphi$. But you would expect them to be closely related, $\{\mathrm{A} .22 .3\}$. In particularly, reasonably speaking you would expect that spherically symmetric wave functions correspond to spherically symmetric observable potentials, as well as vice-versa.)
(You might also, correctly, object to the inaccurate picture that the nucleon pops up a pion. The ground state of the nucleon-pions system is a state of definite energy. Energy states are stationary, chapter 7.1.4. However, in energy states the complete nucleon-pions system should have definite angular momentum and parity, chapter 7.3. That is just like nuclei in energy states have definite angular momentum and parity, chapter 14.1. The term in the nucleon-pions system wave function in which there is just the nucleon, with no pions, already sets the angular momentum and parity. A different term in the system wave function, in particular one in which there is a pion in a state of definite angular momentum and parity, cannot have different angular momentum or parity. Otherwise angular momentum and parity would have uncertainty.)

So how to fix this? Suppose that you differentiate the first-guess potential (A.265) with respect to, say, $x$. The differentiation will bring in a factor $x$ in the potential,

$$
\frac{\partial \varphi_{i, \mathrm{fg}}}{\partial x}=\frac{\partial \varphi_{i, \mathrm{fg}}}{\partial r} \frac{x}{r}
$$

And that factor $x$ will produce an opposite sign at $-\vec{r}$ compared to $\vec{r}$. That means that the parity is now negative as it should be.

According to (A.263), the first guess potential satisfies

$$
-\nabla^{2} \varphi_{i, \mathrm{fg}}+\left(\frac{m_{\pi} c^{2}}{\hbar c}\right)^{2} \varphi_{i, \mathrm{fg}}=\frac{1}{\epsilon_{1}} g\left|\Psi_{i}\right|^{2}
$$

Differentiating both sides with respect to $x$, you get for its $x$-derivative, the second-guess potential $\varphi_{i, \text { sg }}$ :

$$
-\nabla^{2} \varphi_{i, \mathrm{sg}}+\left(\frac{m_{\pi} c^{2}}{\hbar c}\right)^{2} \varphi_{i, \mathrm{sg}}=\frac{1}{\epsilon_{1}} \sum_{i} g \frac{\partial}{\partial x}\left|\Psi_{i}\right|^{2} \quad \varphi_{i, \mathrm{sg}}=\frac{\partial \varphi_{i, \mathrm{fg}}}{\partial x}
$$

So apparently, if you put a $x$-derivative on the square nucleon wave function in the first-guess interaction factor $f_{i, \mathrm{fg}}$ you get a pion potential consistent with parity conservation.

There are a couple of new problems. First of all, this potential now has orbital angular momentum. If you check out the spherical harmonics in table 4.3, you see that a spherically symmetric wave function has no orbital angular momentum. But the factor $x$ produces a wave function of the form

$$
c(r) Y_{1}^{1}-c(r) Y_{1}^{-1}
$$

where $c(r)$ is some spherically symmetric function. The first term above has angular momentum $\hbar$ in the $z$-direction. The second term has angular momentum $-\hbar$ in the $z$-direction. So there is uncertainty in angular momentum, but it is not zero. The azimuthal quantum number of square orbital angular momentum, call it $l_{\pi}$, is 1 with no uncertainty.

So where does this angular momentum come from? Angular momentum should be preserved. The pion itself has no spin. So its orbital angular momentum will have to come from the half unit of nucleon spin. Indeed it is possible for half a unit of nucleon spin, $s_{i}=\frac{1}{2}$, and one unit of pion orbital angular momentum, $l_{\pi}=1$, to combine into still only half a unit of net angular momentum $j=\frac{1}{2}$, 7.4.2.

But consider also the angular momentum in the $z$-direction. If the pion is given $\hbar$ in the $z$-direction, then that must come from the fact that the nucleon spin changes from $\frac{1}{2} \hbar$ in the $z$-direction to $-\frac{1}{2} \hbar$. Conversely, if the pion has $-\hbar$, then the nucleon must change from $-\frac{1}{2} \hbar$ to $\frac{1}{2} \hbar$. Either way, the nucleon spin in the $z$-direction must flip over.

In quantum terms, how does that happen? Consider the scaled nucleon $z \operatorname{spin}$ operator $\sigma_{z}$ for a second. If you apply this operator on the "spin-up" state with $z$ spin $\frac{1}{2} \hbar$, you get a multiple of the same state back. (Actually, because of the scaling, you get the exact same state back.) The spin-up state is an eigenstate of the operator $\sigma_{z}$ as it should. But the spin-up state is not an eigenstate of the operators $\sigma_{x}$ and $\sigma_{y}$. These operators do not commute with $\sigma_{z}$. So if you apply $\sigma_{x}$ or $\sigma_{y}$ on the spin-up state, you will also get some of the $-\frac{1}{2} \hbar$ spin-down state. In fact, if you look a bit closer at angular momentum, chapter 12.10, you see that you get only a spin-down state. So both $\sigma_{x}$ and $\sigma_{y}$ do exactly what is needed; they flip spin-up over to spin-down. Similarly, they flip spin-down over to spin-up.

The second problem has to do with the original notion of differentiating the spherically symmetric potential with respect to $x$. Why not $y$ or $z$ or some oblique direction? The pion field should not depend on how you have oriented your mathematical axes system. But the $x$-derivative does depend on it. A similar problem exists of course with arbitrarily choosing one of the operators $\sigma_{x}$ or $\sigma_{y}$ above.

Now dot products are the same regardless of how the coordinate system is oriented. That then suggests how both problems above can be solved at the same time. In the first-guess interaction factor, add the dot product between the scaled nucleon spin $\vec{\sigma}_{i}$ and the spatial differentiation operator $\nabla_{i}$. That gives the third-guess interaction factor as

$$
f_{i, \mathrm{tg}}=g R \vec{\sigma}_{i} \cdot \nabla_{i}\left|\Psi_{i}\right|^{2}=g R\left[\sigma_{x} \frac{\partial}{\partial x_{i}}+\sigma_{y} \frac{\partial}{\partial y_{i}}+\sigma_{z} \frac{\partial}{\partial z_{i}}\right]\left|\Psi_{i}\right|^{2}
$$

The factor $R$ has been added to keep the units of the first guess intact.
Time for a reality check. Consider a nucleon in the spin-up state. If the "mesic charge" $g$ would be zero, there would be no pion field. There would just be this bare nucleon with half a unit of spin-up and positive parity. Next assume that $g$ is not zero, but still small. Then the bare nucleon term should still dictate the spin and intrinsic parity. There will now also be terms with pions in the complete system wave function, but they must obey the same spin and
parity. You can work out the detailed effect of the third guess interaction factor above using table 4.3 and chapter 12.10 . If you do, you see that it associates the spin-up nucleon with a state

$$
\sqrt{4 \pi} \frac{\partial \varphi_{i, \mathrm{fg}}}{\partial r}\left(\sqrt{\frac{1}{3}} Y_{1}^{0} \uparrow-\sqrt{\frac{2}{3}} Y_{1}^{1} \downarrow\right)
$$

where $Y_{1}^{0}$ and $Y_{1}^{1}$, table 4.3, describe the spatial pion potential and $\uparrow$ and $\downarrow$ nucleon spin-up, respectively spin-down. Loosely associating the pion potential with a pion wave function, you can check from the Clebsch-Gordon tables 12.5 that the state in parentheses obeys the spin and parity of the original bare nucleon.

So the third guess seems pretty good. But there is one more thing. Recall that there are three different pions, with different charges, So you would expect that there are really three different functions $f_{i}$, one for each pion field. Alternatively, the function $f_{i}$ should be three-dimensional vector. But what sort of vector?

Note that charge is preserved. If a proton pops up a positively charged $\pi^{+}$pion, it must itself change into a uncharged neutron. And if a neighboring neutron absorbs that $\pi^{+}$, it acquires its positive charge and turns into a proton. The same thing happens when a neutron emits a negatively charged $\pi^{-}$that a proton absorbs. Whenever a charged particle is exchanged between a proton and a neutron, both change type. (Charged particles cannot be exchanged between nucleons of the same type because there are no nucleons with negative charge or with two units of positive charge.)

So, it is necessary to describe change of nucleon type. Physicists do that in a very weird way; they pattern the mathematics on that of spin, chapter 14.18. First a completely abstract " 123 " coordinate system is introduced. If a nucleon is a proton, then it is said that the nucleon has a component $\frac{1}{2}$ along the abstract 3 -axis. If a nucleon is a neutron, it is said that it has a component $-\frac{1}{2}$ along the 3 -axis.

Compare that with spin. If a nucleon is spin-up, it has a spin component $\frac{1}{2} \hbar$ along the physical $z$-axis. If it is spin-down, it has a spin component $-\frac{1}{2} \hbar$ along the $z$-axis. The idea is very similar.

Now recall from above that the operators $\sigma_{x}$ and $\sigma_{y}$ flip over the spin in the $z$-direction. In 123 -space, physicist define abstract operators $\tau_{1}$ and $\tau_{2}$ that do a similar thing: they flip over the value along the 3 -axis. And that means that these operators change protons into neutrons or vice-versa. So they do exactly what is needed in exchanges of charged pions. Physicist also define an operator $\tau_{3}$, analogous to $\sigma_{z}$, which does not change the 3 -component.

Of course, all this may seem an extremely round-about way of doing something simple: define operators that flip over nucleon type. And normally it really would be. But if it is assumed that nuclear forces are charge-independent, (which is a reasonable approximation), things change. In that case it turns out
that the physics must remain the same under rotations of this abstract 123coordinate system. And that requirement can again be met by forming a dot product, this time between $\vec{\tau}=\left(\tau_{1}, \tau_{2}, \tau_{3}\right)$ vectors.

That idea then gives the final expression for the functions $f_{i}$ :

$$
\vec{f}_{i}=g R \vec{\tau}_{i} \quad \vec{\sigma}_{i} \cdot \nabla_{i}\left|\Psi_{i}\right|^{2}=g R \vec{\tau}_{i}\left[\sigma_{x} \frac{\partial}{\partial x_{i}}+\sigma_{y} \frac{\partial}{\partial y_{i}}+\sigma_{z} \frac{\partial}{\partial z_{i}}\right]\left|\Psi_{i}\right|^{2}
$$

Note that $\vec{f}_{i}$ is now a three-dimensional vector because $\vec{\tau}_{i}$ is. In the final potential, $\vec{\tau}_{i}$ gets into a dot product with $\vec{\tau}_{j}$ of the other nucleon. That makes the complete potential the same regardless of rotation of the abstract 123-coordinate system as it should.

Now it is just a matter of working out the final potential. Do one thing at a time. Recall first the effect of the $x$-derivative on the nucleon wave function. It produces a potential that is the $x$-derivative of the spherically symmetric first-guess potential (A.265). That works out to

$$
\frac{g R}{4 \pi \epsilon_{1}} \frac{\mathrm{~d} e^{-r / R} / r}{\mathrm{~d} r} \frac{\partial r}{\partial x}=-\frac{g R}{4 \pi \epsilon_{1}}\left[\frac{1}{R r^{2}}+\frac{1}{r^{3}}\right] e^{-r / R} x
$$

Of course, there ares similar expressions for the derivatives in the other two directions. So the potential produced by nucleon $i$ at the origin is

$$
\varphi_{i}(\vec{r})=-\frac{g R}{4 \pi \epsilon_{1}} \vec{\tau}_{i}\left[\frac{1}{R r^{2}}+\frac{1}{r^{3}}\right] e^{-r / R} \vec{r} \cdot \vec{\sigma}_{i}
$$

Now the interaction potential with another nucleon follows from (A.264). But here you need to be careful. The integral will involve terms like

$$
\text { [some constant] } \int \varphi_{i}(\vec{r}) \frac{\partial\left|\Psi_{j}\right|^{2}}{\partial x} \mathrm{~d}^{3} \vec{r}
$$

In this case, you cannot just approximate $\vec{r}$ in $\varphi_{i}(\vec{r})$ as the nominal position $\vec{r}_{j}$ of nucleon $j$. That is not accurate. Since the $x$-derivative works on a very concentrated wave function, it will produce large negative and positive values, and errors will accumulate. The solution is to perform an integration by parts in the $x$-direction. That puts the derivative on the potential instead of the wave function and adds a minus sign. Then you can evaluate this negative derivative of the potential at the nominal position of nucleon $\vec{r}_{j}$.

Differentating the potential is a bit of a mess, but straightforward. Then the potential becomes

$$
V_{i j} \sim \frac{g^{2}}{12 \pi \epsilon_{1} R} \vec{\tau}_{i} \cdot \vec{\tau}_{j}\left[\vec{\sigma}_{i} \cdot \vec{\sigma}_{j}+S_{i j} V_{\mathrm{T}}\right] \frac{e^{-r / R}}{r / R}
$$

If you define the constant $g_{\pi}$ appropriately, this gives the OPEP potential (A.262).

## A．42．4 Multiple pion exchange and such

Unfortunately，the nuclear force is not just a matter of the exchange of single pions．While the OPEP works very well at nucleon distances above 3 fm ，at shorter ranges other processes become important．

The most important range is the one of the primary nucleon attractions． Conventionally，this range is ballparked as nucleon distances in the range $1<$ $\mathrm{r}<2 \mathrm{fm},[5, \mathrm{p} .91]$ ，$\llbracket 3 \rrbracket$ ．（References vary about the actual range however，［31， p．111］，［36，pp．177］．）In this range，two－pion exchanges dominate．In such exchanges two pions appear during the course of the interaction．Since this requires double the uncertainty in energy，the typical range is correspondingly smaller than for one－pion exchanges．

Two－pion exchanges are much more difficult to crunch out than one－pion ones．In addition，it turns out that straightforward two－pion exchanges are not enough，【3】．The interactions also have to include various so－called＂reso－ nances．＂

Resonances are extremely short－lived excited states of baryons and mesons． They decay through the strong force，which typically takes on the order of $10^{-23} \mathrm{~s}$ ．A particle moving near the speed of light will only travel a distance of the order of a femtometer during such a time．Therefore resonances are not observed directly．Instead they are deduced from experiments in which particles are scattered off each other．Excited states of nucleons can be deduced from preferred scattering of particular frequencies．More or less bound states of pions can be deduced from collision dynamics effects．Collisions involving three particles are quite different if two of the three particles stick together， even briefly，than if all three go off in separate directions．

The lowest energy excited state for nucleons is a set of resonances called the ＂delta particles，＂$\Delta^{++}, \Delta^{+}, \Delta^{0}$ ，and $\Delta^{-}$．In the deltas，the three constituent quarks of the nucleons align their spins in the same direction for a net spin of $\frac{3}{2}$ ．The state further has enough antisymmetry to allow three quarks to be equal．That explains the nucleon charge $2 e$ of the $\Delta^{++}$，consisting of three up quarks at $\frac{2}{3} e$ each，and the charge $-e$ of the $\Delta^{-}$，consisting of three down quarks at $-\frac{1}{3} e$ each．The delta resonances are often indicated by $\Delta(1232)$ ，where the quantity between parentheses is the nominal rest mass energy in MeV ．That allows excited states of higher energy to be accommodated．If the excited states allow no more than two quarks to be equal，like the normal nucleons，they are indicated by $N$ instead of $\Delta$ ．In those terms，the normal proton and neutron are $N(939)$ states．（The rest mass energies are nominal because resonances have a tremendous uncertainty in energy．That is to be expected from their short life time on account of the energy－time uncertainty relationship．The＂width＂of the delta energy is over 100 MeV ．）

Pion resonances of interest involve the 775 MeV rho（ $\rho$ ），and the 783 MeV omega $(\omega)$ resonances．Both of these states have spin 1 and odd parity．The

550 MeV eta $(\eta)$ particle is also of importance．This particle has spin 0 and odd parity like the pions．The eta is not really a resonance，based on its relatively long $0.510^{-18} \mathrm{~s}$ life time．

Older references like［36］picture the resonances as correlated multi－pion states．However，quantum chromedynamics has been associating actual particles with them．Take the rho，for example．In［36］it is pictured as a two－pion correlated state．（A true bound state of two 140 MeV pions should have an energy less than 280 MeV ，not 775 MeV ．）However，quantum chromedynamics identifies a rho as a single excited pion with a 775 MeV rest mass．It does decay almost instantly into two pions．The omega，pictured as a three－pion correlated state，is according to quantum chromedynamics a quantum superposition of half an up－antiup and half a down－antidown quark pair，not unlike the neutral rho． It usually decays into three pions．Quantum chromedynamics describes the $\eta$ as a meson having a strange－antistrange quark component．

The rho and omega resonances appear to be important for the nucleon re－ pulsions at short range．And 3 and 4 pion exchanges have about the same range as the $\omega$ ．So if the omega is included，as it normally is，it seems that multi－pion exchanges should be included too．Crunching out complete multi－pion pion ex－ changes，with the additional complications of the mentioned resonances，is a formidable task．

One－meson exchanges are much easier to analyze than multi－meson ones． Therefore physicists may model the multi－pion processes as the exchange of one combined boson，rather than of multiple pions．That produces so－called＂one－ boson exchange potentials，＂or＂OBEP＂s for short．They work surprisingly well．

The precise Yukawa potential that is produced depends on the spin and parity of the exchanged boson，［36，pp．176ff］，【3】．The pion has zero spin and negative parity．Such a particle is often called＂pseudoscalar．＂Scalar means that its wave function at each point is a just a number．However，normal numbers，like say a mass，do not change sign if the directions of the axes are inverted．The eta is a $0^{-}$pseudoscalar like the pion．It produces a similar potential as the OPEP．

However，the rho and omega are $1^{-}$bosons．Such bosons are often called ＂＂vector particles．＂Their wave function at each point is a three－dimension－ al vector，$\{$ A．20\}. And normal vectors do change sign if the directions of the axes are inverted，so the rho and omega are not pseudovectors．Vector bosons generate a repulsive potential，among various other effects．That can take care of the needed repulsive short range forces quite nicely．

Unfortunately，to describe the attractive forces in the intermediate range， OBEP models need a roughly $600 \mathrm{MeV} 0^{+}$＂scalar＂boson．In fact，many OBEP models use both a 500 MeV and a 700 MeV scalar boson．The existence of such scalar resonances has never been accepted．While an older reference like ［36，pp．172］may point to a perceived very wide resonance at 700 MeV ，how
convincing can a 700 MeV resonance with a width of at least 600 MeV be? This lack of physical justification does detract from the OBEP potentials.

And of course, they are approximations in any case. There are important issues like multi-nucleon interactions and electromagnetic properties that probably only a comprehensive description of the actual exchange processes can correctly describe, $\llbracket 3 \rrbracket$. Despite much work, nuclear potentials remain an active research area. One author already thinks in terms of millennia, [32].

## A. 43 Classical vibrating drop

The simplest collective description for a nucleus models it as a vibrating drop of a macroscopic liquid. To represent the nuclear Coulomb repulsions the liquid can be assumed to be positively charged. This section gives a condensed derivation of small vibrations of such a liquid drop according to classical mechanics. It will be a pretty elaborate affair, condensed or not.

## A.43.1 Basic definitions

The drop is assumed to be a sphere of radius $R_{0}$ when it is not vibrating. For a nucleus, $R_{0}$ can be identified as the nuclear radius,

$$
R_{0}=R_{A} A^{1 / 3}
$$

When vibrating, the radial position of the surface will be indicated by $R$. This radial position will depend on the spherical angular coordinates $\theta$ and $\phi$, figure N.3, and time.

The mass density, (mass per unit volume), of the liquid will be indicated by $\rho_{m}$. Ignoring the difference between proton and neutron mass, for a nucleus the mass density can be identified as

$$
\rho_{m}=\frac{A m_{\mathrm{p}}}{\frac{4}{3} \pi R_{0}^{3}}
$$

The mass density is assumed constant throughout the drop. This implies that the liquid is assumed to be incompressible, meaning that the volume of any chunk of liquid is unchangeable.

The charge density is defined analogously to the mass density:

$$
\rho_{c}=\frac{Z e}{\frac{4}{3} \pi R_{0}^{3}}
$$

It too is assumed constant.
The surface tension $\sigma$ can be identified as

$$
\sigma=\frac{C_{s} A^{2 / 3}}{4 \pi R_{0}^{2}}=\frac{C_{s}}{4 \pi R_{A}^{2}}
$$

## A.43.2 Kinetic energy

The possible frequencies of vibration can be figured out from the kinetic and potential energy of the droplet. The kinetic energy is easiest to find and will be done first.

As noted, the liquid will be assumed to be incompressible. To see what that means for the motion, consider an arbitrary chunk of liquid. An elementary element of surface area $\mathrm{d} S$ of that chunk gobbles up an amount of volume while it moves given by $\vec{v} \cdot \vec{n} \mathrm{~d} S$, where $v$ is the liquid velocity and $\vec{n}$ is a unit vector normal to the surface. But for a given chunk of an incompressible liquid, the total volume cannot change. Therefore:

$$
\int_{S} \vec{v} \cdot \vec{n} \mathrm{~d} S=0
$$

Using the Gauss-Ostrogradsky, or divergence theorem, this means that $\nabla \cdot \vec{v}$ must integrate to zero over the interior of the chunk of liquid. And if it must integrate to zero for whatever you take the chunk to be, it must be zero uniformly:

$$
\nabla \cdot \vec{v}=0
$$

This is the famous "continuity equation" for incompressible flow. But it is really no different from Maxwell's continuity equation for the flow of charges if the charge density remains constant, chapter 13.2.

To describe the dynamics of the drop, the independent variables will be taken to be time and the unperturbed positions $\vec{r}_{0}$ of the infinitesimal volume elements $d^{3} \vec{r}$ of liquid. The velocity field inside the drop is governed by Newton's second law. On a unit volume basis, this law takes the form

$$
\rho_{m} \frac{\partial \vec{v}}{\partial t}=-\rho_{c} \nabla \varphi-\nabla p
$$

where $\varphi$ is the electrostatic potential and $p$ is the pressure. It will be assumed that the motion is slow enough that electrostatics may be used for the electromagnetic force. As far as the pressure force is concerned, it is one of the insights obtained in classical fluid mechanics that a constant pressure acting equally from all directions on a volume element of liquid does not produce a net force. To get a net force on an element of liquid, the pressure force on the front of the element pushing it back must be different from the one on the rear pushing it forward. So there must be variations in pressure to get a net force on elements of liquid. Using that idea, it can be shown that for an infinitesimal element of liquid, the net force per unit volume is minus the gradient of pressure. For a real classical liquid, there may also be viscous internal forces in addition to pressure forces. However, viscosity is a macroscopic effect that is not relevant to the nuclear quantum system of interest here. (That changes in a two-liquid description, [40, p. 187].)

Note that the gradients of the potential and pressure should normally be evaluated with respect to the perturbed position coordinates $\vec{r}$. But if the amplitude of vibrations is infinitesimally small, it is justified to evaluate $\nabla$ using the unperturbed position coordinates $\vec{r}_{0}$ instead. Similarly, $\nabla$ in the continuity equation can be taken to be with respect to the unperturbed coordinates.

If you take the divergence of Newton's equation. i.e. multiply with $\nabla \cdot$, the left hand side vanishes because of continuity, and so the sum of potential and pressure satisfies the so-called "Laplace equation:"

$$
\nabla^{2}\left(\rho_{c} \varphi+p\right)=0
$$

The solution can be derived in spherical coordinates $r_{0}, \theta_{0}$, and $\phi_{0}$ using similar, but simpler, techniques as used to solve the hydrogen atom. The solution takes the form

$$
\rho_{c} \varphi+p=\sum_{l, m} c_{l m}(t) \frac{r_{0}^{l}}{R_{0}^{l}} \bar{Y}_{l}^{m}\left(\theta_{0}, \phi_{0}\right)
$$

where the $c_{l m}$ are small unknown coefficients and the $\bar{Y}_{l}^{m}$ are real spherical harmonics. The precise form of the $\bar{Y}_{l}^{m}$ is not of importance in the analysis.

Plugging the solution for the pressure into Newton's second law shows that the velocity can be written as

$$
\vec{v}=\sum_{l, m} v_{l m}(t) R_{0} \nabla\left(\frac{r_{0}^{l}}{R_{0}^{l}} \bar{Y}_{l}^{m}\left(\theta_{0}, \phi_{0}\right)\right)
$$

where the coefficients $v_{l m}$ are multiples of time integrals of the $c_{l m}$. What multiples is irrelevant as the potential and pressure will no longer be used.
(You might wonder about the integration constant in the time integration. It is assumed that the droplet was initially spherical and at rest before some surface perturbation put it into motion. If the drop was initially rotating, the analysis here would need to be modified. More generally, if the droplet was not at rest initially, it must be assumed that the initial velocity is "irrotational," meaning that $\nabla \times \vec{v}=0$.)

Since the velocity is the time-derivative of position, the positions of the fluid elements are

$$
\vec{r}=\vec{r}_{0}+\sum_{l, m} r_{l m}(t) R_{0} \nabla \frac{r_{0}^{l}}{R_{0}^{l}} \bar{Y}_{l}^{m}\left(\theta_{0}, \phi_{0}\right)
$$

where $\vec{r}_{0}$ is the unperturbed position of the fluid element and the coefficients of velocity are related to those of position by

$$
v_{l m}=\dot{r}_{l m}
$$

What will be important in the coming derivations is the radial displacement of the liquid surface away from the spherical shape. It follows from taking the
radial component of the displacement evaluated at the surface $r_{0}=R_{0}$. That produces

$$
\begin{equation*}
R\left(\theta_{0}, \phi_{0}\right)=R_{0}+\delta\left(\theta_{0}, \phi_{0}\right) \quad \delta=\sum_{l, m} r_{l m}(t) l \bar{Y}_{l}^{m}\left(\theta_{0}, \phi_{0}\right) \tag{A.266}
\end{equation*}
$$

To be sure, in the analysis $\delta$ will be defined to be the radial surface displacement as a function of the physical angles $\theta$ and $\phi$. However, the difference between physical and unperturbed angles can be ignored because the perturbations are assumed to be infinitesimal.

The kinetic energy is defined by

$$
T=\int \frac{1}{2} \rho_{m} \vec{v} \cdot \vec{v} \mathrm{~d}^{3} \vec{r}_{0}
$$

Putting in the expression for the velocity field in terms of the $r_{l m}$ position coefficients gives

$$
T=\int \frac{1}{2} \rho_{m} \sum_{l, m} \dot{r}_{l m} R_{0}\left(\nabla \frac{r_{0}^{l}}{R_{0}^{l}} \bar{Y}_{l}^{m}\right) \cdot \sum_{l, \underline{m}} \dot{r}_{\underline{l m}} R_{0}\left(\nabla \frac{r_{0}^{\underline{l}}}{R_{0}^{l}} \bar{Y}_{\underline{l}}^{\underline{m}}\right) \mathrm{d}^{3} \vec{r}_{0}
$$

To simplify this, a theorem is useful. If any two functions $F$ and $G$ are solutions of the Laplace equation, then the integral of their gradients over the volume of a sphere can be simplified to an integral over the surface of that sphere:

$$
\begin{equation*}
\int_{V}(\nabla F) \cdot(\nabla G) \mathrm{d}^{3} \vec{r}_{0}=\int_{V} \nabla(F \cdot \nabla G) \mathrm{d}^{3} \vec{r}_{0}=\int_{S} F \frac{\partial G}{\partial r_{0}} \mathrm{~d} S_{0} \tag{A.267}
\end{equation*}
$$

The first equality is true because the first term obtained in differentiating out the product $F \cdot \nabla G$ is the left hand side, while the second term is zero because $G$ satisfies the Laplace equation. The second equality is the divergence theorem applied to the sphere. Further, the surface element of a sphere is in spherical coordinates:

$$
\mathrm{d} S_{0}=R_{0}^{2} \sin \theta_{0} \mathrm{~d} \theta_{0} \mathrm{~d} \phi_{0}
$$

Applying these results to the integral for the kinetic energy, noting that $r_{0}$ $=R_{0}$ on the surface of the droplet, gives

$$
T=\frac{1}{2} \rho_{m} \sum_{l, m} \sum_{l, \underline{m}} \dot{r}_{l m} \dot{r}_{\underline{l} \underline{m}} \underline{l} R_{0}^{3} \iint \bar{Y}_{l}^{m} \bar{Y}_{\underline{l}}^{\underline{m}} \sin \theta_{0} \mathrm{~d} \theta_{0} \mathrm{~d} \phi_{0}
$$

Now the spherical harmonics are orthonormal on the unit sphere; that means that the final integral is zero unless $l=\underline{l}$ and $m=\underline{m}$, and in that case the integral is one. Therefore, the final expression for the kinetic energy becomes

$$
\begin{equation*}
T=\frac{1}{2} \rho_{m} R_{0}^{3} \sum_{l, m} l \dot{r}_{l m}^{2} \tag{A.268}
\end{equation*}
$$

## A.43.3 Energy due to surface tension

From here on, the analysis will return to physical coordinates rather than unperturbed ones.

The potential energy due to surface tension is simply the surface tension times the surface of the deformed droplet. To evaluate that, first an expression for the surface area of the droplet is needed.

The surface can be described using the spherical angular coordinates $\theta$ and $\phi$ as $r=R(\theta, \phi)$. An infinitesimal coordinate element $\mathrm{d} \theta \mathrm{d} \phi$ corresponds to a physical surface element that is approximately a parallelogram. Specifically, the sides of that parallelogram are

$$
\mathrm{d} \vec{r}_{1}=\frac{\partial \vec{r}_{\text {surface }}}{\partial \theta} \mathrm{d} \theta \quad \mathrm{~d} \vec{r}_{2}=\frac{\partial \vec{r}_{\text {surface }}}{\partial \phi} \mathrm{d} \phi
$$

To get the surface area $\mathrm{d} S$, take a vectorial product of these two vectors and then the length of that. To work it out, note that in terms of the orthogonal unit vectors of a spherical coordinate system,

$$
\vec{r}_{\text {surface }}=\hat{\imath}_{r} R \quad \frac{\partial \hat{\imath}_{r}}{\partial \theta}=\hat{\imath}_{\theta} \quad \frac{\partial \hat{\imath}_{r}}{\partial \phi}=\sin \theta \hat{\imath}_{\phi}
$$

That way, the surface area works out to be

$$
S=\iint \sqrt{1+\left(\frac{1}{R} \frac{\partial R}{\partial \theta}\right)^{2}+\left(\frac{1}{R \sin \theta} \frac{\partial R}{\partial \phi}\right)^{2}} R^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi
$$

Multiply by the surface tension $\sigma$ and you have the potential energy due to surface tension.

Of course, this expression is too complicated to work with. What needs to be done, first of all, is to write the surface in the form

$$
R=R_{0}+\delta
$$

where $\delta$ is the small deviation away from the radius $R_{0}$ of a perfect spherical drop. This can be substituted into the integral, and the integrand can then be expanded into a Taylor series in terms of $\delta$. That gives the potential energy $V_{s}$ $=\sigma S$ as

$$
\begin{aligned}
V_{s}= & \sigma \iint R_{0}^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi+\sigma \iint 2 R_{0} \delta \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi+\sigma \iint \delta^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \\
& +\sigma \iint \frac{1}{2}\left[\left(\frac{1}{R_{0}} \frac{\partial \delta}{\partial \theta}\right)^{2}+\left(\frac{1}{R_{0} \sin \theta} \frac{\partial \delta}{\partial \phi}\right)^{2}\right] R_{0}^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi
\end{aligned}
$$

where the final integral comes from expanding the square root and where terms of order of magnitude $\delta^{3}$ or less have been ignored. The first integral in the
result can be ignored; it is the potential energy of the undeformed droplet, and only differences in potential energy are important. However, the second integral is one problem, and the final one another.

The second integral is first. Its problem is that if you plug in a valid approximate expression for $\delta$, you are still not going to get a valid approximate result for the integral. The radial deformation $\delta$ is both negative and positive over the surface of the cylinder, and if you integrate, the positive parts integrate away against the negative parts, and what you have left is mainly the errors.

Why is $\delta$ both positive and negative? Because the volume of the liquid must stay the same, and if $\delta$ was all positive, the volume would increase. The condition that the volume must remain the same means that

$$
\frac{4 \pi}{3} R_{0}^{2}=\iiint r^{2} \sin \theta \mathrm{~d} r \mathrm{~d} \theta \mathrm{~d} \phi=\iint \frac{1}{3} R^{3} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi
$$

the first because of the expression for volume in spherical coordinates and the second from integrating out $r$. Writing again $R=R_{0}+\delta$ and expanding in a Taylor series gives after rearranging

$$
-\iint R_{0}^{2} \delta \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi=\iint R_{0} \delta^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi
$$

where the integral of $\delta^{3}$ has been ignored. Now the integral in the left hand side is essentially the one needed in the potential energy. According to this equation, it can be replaced by the integral in the right hand side. And that one can be accurately evaluated using an approximate expression for $\delta$ : since the integrand is all positive, there is no cancellation that leaves only the errors. Put more precisely, if the used expression for $\delta$ has an error of order $\delta^{2}$, direct evaluation of the integral in the left hand side gives an unacceptable error of order $\delta^{2}$, but evaluation of the integral in the right hand side gives an acceptable error of order $\delta^{3}$.

If this is used in the expression for the potential energy, it produces

$$
\begin{aligned}
V_{s}= & V_{s, 0}-\sigma \iint \delta^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \\
& +\sigma \iint \frac{1}{2}\left[\left(\frac{1}{R_{0}} \frac{\partial \delta}{\partial \theta}\right)^{2}+\left(\frac{1}{R_{0} \sin \theta} \frac{\partial \delta}{\partial \phi}\right)^{2}\right] R_{0}^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi
\end{aligned}
$$

Now $\delta$ can be written in terms of the spherical harmonics defined in the previous subsection as

$$
\delta=\sum_{l, m} \delta_{l m} \bar{Y}_{l}^{m}
$$

where the $\delta_{l m}$ are time dependent coefficients still to be found. If this is substituted into the expression for the potential, the first integral is similar to the one
encountered in the previous subsection; it is given by the orthonormality of the spherical harmonics. However, the final term involves an integral of the form

$$
I=\iint\left[\frac{\partial \bar{Y}_{l}^{m}}{\partial \theta} \frac{\partial \bar{Y}_{\underline{l}}^{\underline{m}}}{\partial \theta}+\frac{1}{\sin ^{2} \theta} \frac{\partial \bar{Y}_{l}^{m}}{\partial \phi} \frac{\partial \bar{Y}_{\underline{l}}^{\underline{\underline{m}}}}{\partial \phi}\right] \sin \theta \mathrm{d} \theta \mathrm{~d} \phi
$$

This integral can be simplified by using the same theorem (A.267) used earlier for the kinetic energy. Just take $F=r^{l} \bar{Y}_{l}^{m}$ and $G=r^{l} \bar{Y}_{l}^{\underline{m}}$ and integrate over a sphere of unit radius. The theorem then produces an equality between a volume integral and a surface one. The surface integral can be evaluated using the orthonormality of the spherical harmonics. The volume integral can be integrated explicitly in the radial direction to produce a multiple of $I$ above and a second term that can once more be evaluated using the orthonormality of the spherical harmonics. It is then seen that $I=0$ unless $l=\underline{l}$ and $m=\underline{m}$ and then $I=l(l+1)$.

Putting it all together, the potential energy due to surface tension becomes

$$
\begin{equation*}
V_{s}=V_{s, 0}+\sum_{l, m} \frac{1}{2}(l-1)(l+2) \sigma \delta_{l m}^{2} \tag{A.269}
\end{equation*}
$$

## A.43.4 Energy due to Coulomb repulsion

The potential energy due to the Coulomb forces is tricky. You need to make sure that the derivation is accurate enough. What is needed is the change in potential energy when the radial position of the surface of the droplet changes from the spherical value $r=R_{0}$ to the slightly perturbed value $r=R_{0}+\delta$. The change in potential energy must be accurate to the order of magnitude of $\delta^{2}$.

Trying to write a six-dimensional integral for the Coulomb energy would be a mess. Instead, assume that the surface perturbation is applied in small increments, as a perturbation $\delta^{\prime}$ that is gradually increased from zero to $\delta$. Imagine that you start with the perfect sphere and cumulatively add thin layers of charged liquid $\mathrm{d} \delta^{\prime}$ until the full surface perturbation $\delta$ is achieved. (With adding negative amounts $\mathrm{d} \delta^{\prime}$ understood as removing charged liquid. At each stage, just as much liquid is removed as added, so that the total volume of liquid stays the same.) The change in potential energy due to addition of an infinitesimal amount of charge equals the amount of charge times the surface potential at the point where it is added.

The surface radius perturbation and its differential change can be written in terms of spherical harmonics:

$$
\delta^{\prime}=\sum_{l, m} \delta_{l m}^{\prime} \bar{Y}_{l}^{m} \quad \mathrm{~d} \delta^{\prime}=\sum_{l, m} \mathrm{~d} \delta_{l m}^{\prime} \bar{Y}_{l}^{m}
$$

The amount of charge added per unit solid angle $\mathrm{d} \Omega=\sin \theta \mathrm{d} \theta \mathrm{d} \phi$ will be called $\gamma^{\prime}$. It is given in terms of the charge density $\rho_{c}$ and $\delta^{\prime}$ as

$$
\gamma^{\prime}=\rho_{c}\left(\frac{1}{3}\left(R_{0}+\delta^{\prime}\right)^{3}-\frac{1}{3} R_{0}^{3}\right)
$$

To first approximation, the incremental amount of charge laid down per unit solid angle is

$$
\mathrm{d} \gamma^{\prime} \sim \rho_{c} R_{0}^{2} \mathrm{~d} \delta^{\prime}
$$

However, if $\mathrm{d} \gamma$ is written in terms of spherical harmonics,

$$
\mathrm{d} \gamma^{\prime}=\sum_{l, m} \mathrm{~d} \gamma_{l m}^{\prime} \bar{Y}_{l}^{m} \quad \mathrm{~d} \gamma_{l m}^{\prime} \sim \rho_{c} R_{0}^{2} \mathrm{~d} \delta_{l m}^{\prime}
$$

then the coefficient $\mathrm{d} \gamma_{00}^{\prime}$ is zero exactly, because the net volume, and hence the net charge, remains unchanged during the build-up process. (The spherical harmonic $Y_{0}^{0}$ is independent of angular position and gives the average; the average charge added must be zero if the net charge does not change.) The coefficient $\mathrm{d} \delta_{00}^{\prime}$ is zero to good approximation, but not exactly.

Now the surface potential is needed for the deformed drop. There are two contributions to this potential: the potential of the original spherical drop and the potential of the layer $\delta^{\prime}$ of liquid that has been laid down, (the removed liquid here counting as negative charge having been laid down.) For the spherical drop, to the needed accuracy

$$
V_{0, \text { surface }} \sim \frac{Z e}{4 \pi \epsilon_{0}\left(R_{0}+\delta^{\prime}\right)} \sim \frac{Z e}{4 \pi \epsilon_{0} R_{0}}-\frac{Z e}{4 \pi \epsilon_{0} R_{0}^{2}} \delta^{\prime}
$$

For the surface potential of the laid-down layer, fortunately only a leading order approximation is needed. That means that the thickness of the layer can be ignored. That turns it into a spherical shell of negligible thickness at $r=$ $R_{0}$. The potential inside the shell can always be written in the form

$$
V_{1, \text { inside }}=\sum_{l, m} V_{l m} \frac{r^{l}}{R_{0}^{l}} \bar{Y}_{l}^{m}
$$

though the coefficients $V_{l m}$ are still unknown. The potential outside the shell takes the form

$$
V_{1, \text { outside }}=\sum_{l, m} V_{l m} \frac{R_{0}^{l+1}}{r^{l+1}} \bar{Y}_{l}^{m}
$$

where the coefficients $V_{l m}$ are approximately the same as those inside the shell because the shell is too thin for the potential to vary significantly across it.

However, the electric field strength does vary significantly from one side of the shell to the other, and it is that variation that determines the coefficients $V_{l m}$. First, integrate Maxwell's first equation over a small surface element of the shell. Since the shell has thickness $\delta^{\prime}$, you get

$$
\rho_{c} \delta^{\prime} \mathrm{d} S=\left(\mathcal{E}_{r, \text { immediately outside }}-\mathcal{E}_{r, \text { immediately inside }}\right) \mathrm{d} S
$$

where $\mathrm{d} S$ is the area of the shell element. Note that $\mathcal{E}_{r}=-\partial V_{1} / \partial r$, and substitute in the inside and outside expressions for $V_{1}$ above, differentiated with respect to $r$ and evaluated at $r=R_{0}$. That gives the $V_{l m}$ and then

$$
V_{1, \text { surface }}=\sum_{l, m} \frac{\rho_{c} R_{0}}{(2 l+1) \epsilon_{0}} \delta_{l m}^{\prime} \bar{Y}_{l}^{m} \quad \rho_{c}=\frac{Z e}{\frac{4}{3} \pi R_{0}^{3}}
$$

Multiplying the two surface potentials by the amount of charge laid down gives the incremental change in Coulomb potential of the drop as

$$
\mathrm{d} V_{c}=\left[\frac{Z e}{4 \pi \epsilon_{0} R_{0}}-\frac{Z e}{4 \pi \epsilon_{0} R_{0}^{2}} \delta^{\prime}+\sum_{l, m} \frac{3 Z e}{(2 l+1) 4 \pi \epsilon_{0} R_{0}^{2}} \delta_{l, m}^{\prime} \bar{Y}_{l}^{m}\right] \mathrm{d} \gamma^{\prime} \sin \theta \mathrm{d} \theta \mathrm{~d} \phi
$$

Substituting in $\delta^{\prime}=\sum_{l, m} \delta_{l m}^{\prime} \bar{Y}_{l}^{m}$ and $\mathrm{d} \gamma^{\prime}=\sum_{l, m} \mathrm{~d} \gamma_{l m}^{\prime} \bar{Y}_{\underline{l}}^{\underline{m}}$, the integrals can be evaluated using the orthonormality of the spherical harmonics. In particular, the first term of the surface potential integrates away since it is independent of angular position, therefore proportional to $\bar{Y}_{0}^{0}$, and $\mathrm{d} \gamma_{00}^{\prime}$ is zero. For the other terms, it is accurate enough to set $\mathrm{d} \gamma_{l m}^{\prime}=\rho_{c} R_{0}^{2} \mathrm{~d} \delta_{l m}^{\prime}$ and then $\delta^{\prime}$ can be integrated from zero to $\delta$ to give the Coulomb potential of the fully deformed sphere:

$$
\begin{equation*}
V_{c}=V_{c, 0}-\sum_{l, m} \frac{l-1}{2 l+1} \frac{Z e}{4 \pi \epsilon_{0}} \rho_{c} \delta_{l m}^{2} \tag{A.270}
\end{equation*}
$$

## A.43.5 Frequency of vibration

Having found the kinetic energy, (A.268), and the potential energy, (A.269) plus (A.270), the motion of the drop can be determined.

A rigorous analysis would so using a Lagrangian analysis, $\{A .1\}$. It would use the coefficients $r_{l m}$ as generalized coordinates, getting rid of the $\delta_{l m}$ in the potential energy terms using (A.266). But this is a bit of an overkill, since the only thing that the Lagrangian analysis really does is show that each coefficient $r_{l m}$ evolves completely independent of the rest.

If you are willing to take that for granted, just assume $r_{l m}=\varepsilon \sin (\omega t-\varphi)$ with $\varepsilon$ and $\varphi$ unimportant constants, and then equate the maximum kinetic energy to the maximum potential energy to get $\omega$. The result is

$$
\omega^{2}=\frac{(l-1) l(l+2)}{3} \frac{C_{s}}{R_{A}^{2} m_{\mathrm{p}}} \frac{1}{A}-\frac{2(l-1) l}{2 l+1} \frac{e^{2}}{4 \pi \epsilon_{0} R_{A}^{3} m_{\mathrm{p}}} \frac{Z^{2}}{A^{2}}
$$

Note that this is zero if $l=0$. There cannot be any vibration of a type $\delta=$ $\delta_{00} Y_{0}^{0}$ because that would be a uniform radial expansion or compression of the drop, and its volume must remain constant. The frequency is also zero for $l=$ 1. In that case, the potential energy does not change according to the derived expressions. If kinetic energy cannot be converted into potential energy, the
droplet must keep moving. Indeed, solutions for $l=1$ describe that the droplet is translating at a constant speed without deformation. Vibrations occur for $l$ $\geqslant 2$, and the most important ones are the ones with the lowest frequency, which means $l=2$.

## A. 44 Relativistic neutrinos

It is certainly dubious to describe beta decay nonrelativistically. Neutrinos are highly relativistic particles with almost zero rest mass. So [16, p. 258] rightly states that it is absurd to treat them nonrelativistically. Then he immediately proceeds to do it anyway. (But he confirms the results later using a proper analysis.)

One big problem is that relativistically, spin and orbital angular momentum become mixed-up. That problem was encountered earlier for the photon, which is an even more relativistic particle. Chapter 7.4.3 needed some contortions to talk around that problem.

But note that while the problem for the neutrino is qualitatively similar, the details are quite different. While the photon is a boson, the neutrino is a fermion. Fermions, unlike bosons, are described by the Dirac equation, chapter 12.12 versus $\{\mathrm{A} .21\}$.

To understand the Dirac equation requires some linear algebra, in particular matrices. But to understand the discussion here, the information in the notations section should be plenty.

Consider first the Dirac Hamiltonian eigenvalue problem for the electron and its antiparticle, the positron, in empty space. It is simplest thought of as a system of two equations:

$$
\begin{equation*}
m c^{2} \vec{\psi}^{-}+c \widehat{\vec{p}} \cdot \vec{\sigma} \vec{\psi}^{+}=E \vec{\psi}^{-} \quad-m c^{2} \vec{\psi}^{+}+c \widehat{\vec{p}} \cdot \vec{\sigma} \vec{\psi}^{-}=E \vec{\psi}^{+} \tag{A.271}
\end{equation*}
$$

Here $c$ is the speed of light and $m$ the rest mass of the electron or positron. So $m c^{2}$ is the rest mass energy according to Einstein's famous relation. Further $\widehat{\vec{p}}$ is the linear momentum operator. And $\vec{\sigma}$ is the spin angular momentum operator, except for a scale factor. More precisely, $\vec{\sigma}=\widehat{\vec{S}} / \frac{1}{2} \hbar$. The three components of $\vec{\sigma}$ are the famous "Pauli spin matrices."

In the nonrelativistic limit, $\vec{\psi}^{-}$becomes the wave function of an electron. Recall from chapter 5.5.1 that this wave function can be thought of as a vector with two components; the first component corresponds to the spin-up state and the second to the spin-down state. Similarly $\vec{\psi}^{+}$becomes the wave function of a positron.

The nonrelativistic limit means mathematically that the rest mass energies $m c^{2}$ are much larger than the kinetic energies. Or more simply, it is the limit $c \rightarrow \infty$. Under those conditions, by approximation,

$$
m c^{2} \vec{\psi}^{-} \approx E \vec{\psi}^{-} \quad-m c^{2} \vec{\psi}^{+} \approx E \vec{\psi}^{+}
$$

So in the nonrelativistic limit the energy of the electron is approximately the rest mass energy, as it should be. Note however that the value of $E$ for a positron is negative. That should not be taken to mean that the rest mass energy of a positron is negative. It is the same as the one of an electron, positive. The positron is an antiparticle, and the value of $E$ of an antiparticle picks up an extra minus sign because these particles move backward in time. Quantum mechanics relates $E$ to the time derivative as $E \rightarrow \mathrm{i} \hbar \partial / \partial t$, as seen in the Schrödinger equation, so a sign change in $E$ is equivalent to a reversal in time.

If you improve the accuracy of the nonrelativistic approximations a bit using some mathematical manipulation, the energy will also include the classical kinetic energy. To see how that works, (without using more proper matrix eigenvalue methods), premultiply the second equation in (A.271) by $\widehat{\vec{p}} \cdot \vec{\sigma} / 2 m c$ and add it to the first. In doing so, note that $(\widehat{\vec{p}} \cdot \vec{\sigma})^{2}$ is simply $\widehat{p}^{2}$. That can be verified by multiplying out the Pauli matrices given in chapter 12.10. In particular,

$$
(\widehat{\vec{p}} \cdot \vec{\sigma})(\widehat{\vec{p}} \cdot \vec{\sigma})=\sum_{i=1}^{3} \sum_{j=1}^{3} \widehat{p}_{i} \sigma_{i} \widehat{p}_{j} \sigma_{j}=\sum_{i=1}^{3} \widehat{p}_{i} \widehat{p}_{i} \quad \text { since } \quad\left\{\begin{array}{l}
\sigma_{i} \sigma_{i}=1 \text { for all } i \\
\sigma_{i} \sigma_{j}+\sigma_{j} \sigma_{i}=0 \text { if } i \neq j
\end{array}\right.
$$

Taking that into account, you get

$$
\left(m c^{2}+\frac{\widehat{p}^{2}}{2 m}\right) \vec{\psi}^{-}+\frac{c \widehat{\vec{p}} \cdot \vec{\sigma}}{2} \vec{\psi}^{+}=E\left(\vec{\psi}^{-}+\frac{c \widehat{\vec{p}} \cdot \vec{\sigma}}{2 m c^{2}} \vec{\psi}^{+}\right)
$$

This expression can be rewritten as

$$
\left(m c^{2}+\frac{\widehat{p}^{2}}{2 m}\right)\left(\vec{\psi}^{-}+\frac{c \widehat{\vec{p}} \cdot \vec{\sigma}}{2 m c^{2}} \vec{\psi}^{+}\right)=E\left(\vec{\psi}^{-}+\frac{c \widehat{\vec{p}} \cdot \vec{\sigma}}{2 m c^{2}} \vec{\psi}^{+}\right)
$$

(If you multiply this out, you get an additional term, but it is negligibly small compared to the rest.) Now note that this is an eigenvalue problem for an electron whose wave function has picked up a little bit of $\vec{\psi}^{+}$. You might say that the slightly relativistic electron picks up a bit of a nonrelativistic positron wave function. Also its energy has picked up an additional term $\widehat{p}^{2} / 2 m$, the classical kinetic energy.

Derivation $\{\mathrm{D} .81\}$ shows how take this further, and do it rigorously using proper linear algebra procedures.

But this addendum is not really interested in the nonrelativistic limit. Instead it is interested in the ultrarelativistic limit, where it is the rest mass that is negligible compared to the kinetic energy. And for zero rest mass, the Dirac eigenvalue problem (A.271) becomes

$$
\begin{equation*}
c \widehat{\vec{p}} \cdot \vec{\sigma} \vec{\psi}^{+}=E \vec{\psi}^{-} \quad c \widehat{\vec{p}} \cdot \vec{\sigma} \vec{\psi}^{-}=E \vec{\psi}^{+} \tag{A.272}
\end{equation*}
$$

To make some sense out of this, define two new partial wave functions as

$$
\vec{\psi}_{\mathrm{R}}=\frac{\vec{\psi}^{-}+\vec{\psi}^{+}}{2} \quad \vec{\psi}_{\mathrm{L}}=\frac{\vec{\psi}^{-}-\vec{\psi}^{+}}{2}
$$

By taking sums and differences of the ultrarelativistic equations above, you then get

$$
\begin{equation*}
c \widehat{\vec{p}} \cdot \vec{\sigma} \vec{\psi}_{\mathrm{R}}=E \vec{\psi}_{\mathrm{R}} \quad-c \widehat{\vec{p}} \cdot \vec{\sigma} \vec{\psi}_{\mathrm{L}}=E \overrightarrow{\psi_{\mathrm{L}}} \tag{A.273}
\end{equation*}
$$

The mathematician Weyl first noted how remarkable these equations really are. The equations for the two partial wave functions are not coupled! Partial wave function $\vec{\psi}_{\mathrm{L}}$ is not in the equation for $\vec{\psi}_{\mathrm{R}}$ and $\vec{\psi}_{\mathrm{R}}$ is not in the one for $\vec{\psi}_{\mathrm{L}}$. So it seems like each equation might describe a particle whose wave function is a simple two-dimensional vector. In other words, each equation could describe a particle without a partner. Note incidentally that the second equation is the negative $E$ version of the first. So presumably the second equation could merely describe the antiparticle of the particle of the first equation.

Reasonably speaking, these particles should be electrically neutral. After all, their wave functions are equal combinations of $\vec{\psi}^{-}$, the equivalent of the negatively charged nonrelativistic electron in this system, and $\vec{\psi}^{+}$, the equivalent of the positively charged nonrelativistic positron. So these particles should be neutral as well as massless. In short, they should be neutrinos.

There are a couple of problems however. The Dirac equation includes both the electron and the positron, the time-reversed electron. If you write an equation for a particle that does not inherently include a time-reversed partner, are you violating time-reversal symmetry?

The other problem is what happens if you look at nature in the mirror. Or rather, what you really want to do is "inversion:" swap the positive direction of all three axes in a Cartesian coordinate system. This has the effect of creating a mirror image of nature, since the coordinate system is now left-handed instead of right-handed. And its effects are mathematically easier to describe.

First consider what happens to the original Dirac equation (A.271). The linear momentum operator $\widehat{\vec{p}}$ introduces a minus sign under inversion. That is because this operator is proportional to the gradient operator $\nabla$, and every Cartesian coordinate in $\nabla$ changes sign. However, the spin operators $\vec{\sigma}$ are like orbital angular momentum, $\vec{r} \times \widehat{\vec{p}}$, so they introduce two minus signs, which means no sign change.
(These arguments as presented look at the dot product purely algebraically. If you consider the gradient as a vector, there is an additional sign change since the unit vectors change direction. But the same holds for the $\vec{\sigma}$ vector in the dot product, so there is no difference in the final answer.)

At face value then, the $\widehat{\vec{p}} \cdot \vec{\sigma}$ terms in the Dirac system change sign. That would mean that nature does not behave in the same way when seen in the mirror; the Dirac equation is not the same. And that is definitely wrong; it is
very accurately established that electromagnetic systems involving electrons do behave in exactly the same way when seen in the mirror.

Fortunately there is a loophole to save the mathematics of the Dirac equation. It can be assumed that either the electron or the positron has negative "intrinsic" parity. In other words it can be assumed that either nonrelativistic wave function changes sign under inversion. You can check that if either $\vec{\psi}^{-}$or $\vec{\psi}^{+}$changes sign under inversion, then the Dirac system stays the same under inversion. Which one of the two changes sign is not important, since the sign of the wave function does not make a difference for the physics. It is convention to assume that the antiparticles of fermions have the negative intrinsic parity. In that case, you do not need to worry about intrinsic parity if you have no antiparticles present.

But now reconsider the Hamiltonian eigenvalue problem (A.273) for the neutrinos. The trick no longer works! If you can have one of these particles by itself, not tied to a partner, the physics is no longer the same when seen in the mirror.

There is an important consequence to that. If nature is the same when seen in the mirror, there is a conserved mathematical quantity called "parity." That is just like there is a conserved quantity called angular momentum because nature behaves in the same way when you look at it in a rotated coordinate system, chapter 7.3. What it boils down to is that Weyl was saying that parity might not be conserved in nature.

At the time, Pauli lambasted Weyl for daring to suggest something so obviously stupid like that. However, Pauli lived long enough to learn in 1956 that experiments showed that indeed neutrinos do not conserve parity. (Weyl had already died.)

The fact that the Weyl Hamiltonians do not conserve parity can be described more abstractly. Let $\Pi$ be the "parity operator" that expresses what happens to a wave function when the axes are inverted. The above discussion can then be summarized abstractly as

$$
\Pi(c \widehat{\vec{p}} \cdot \vec{\sigma}) \vec{\psi}=-(c \widehat{\vec{p}} \cdot \vec{\sigma}) \Pi \vec{\psi}
$$

In words, when you invert axes, the $\widehat{\vec{p}} \cdot \vec{\sigma}$ operator introduces a minus sign. Also the wave function $\vec{\psi}$ changes into its mirror image. Now the expression in parentheses is the first Weyl Hamiltonian, or minus the second. So the expression above can be read that if you interchange the order of the parity operator and either Hamiltonian, it introduces a minus sign. It is said that the parity operator and the Hamiltonian do not commute: the order in which they are applied makes a difference.

It is quite generally true that if an operator does not commute with the Hamiltonian, the corresponding quantity is not preserved. See for example chapter 4.5.1, 7.1.4 and \{A.19\}. So you might ask whether orbital angular momentum is preserved by the Weyl Hamiltonian. If you grind out the commutator
of an orbital angular momentum component with the Weyl Hamiltonian using the rules of chapters 4.5.4 and 5.5.3, you find that you get something nonzero. So orbital angular momentum is not conserved by the Weyl neutrinos. That was no big surprise to physicists, because the Dirac equation does not conserve orbital angular momentum either. Similarly, if you work out the commutator of a component of spin, you find that spin is not preserved either.

However, if you add the two operators, you get the net angular momentum, orbital plus spin. That operator does commute with the Weyl Hamiltonians. So the Weyl Hamiltonians do conserve net angular momentum, like the Dirac equation does. That is very fortunate, because without doubt Pauli would have had a fit if Weyl had suggested that nature does not conserve net angular momentum.

But relativity does mix up orbital angular momentum with spin. Often this book describes particles as being in states of specific orbital angular momentum with specific values of the spin. For example, that is how the nonrelativistic hydrogen atom was described, chapter 4.3. Such a description is not really justified for particles at relativistic speeds. Fortunately the electron in a hydrogen atom has a kinetic energy much less than its rest mass energy. Things are much worse in beta decay, where the neutrino is emitted at almost the speed of light.

You might ask what else the Weyl Hamiltonians commute with. It can be seen that they commute with the linear momentum operators: different linear momentum operators commute because basically they are just derivatives, and spin commutes with nonspin. Different spin components do not commute, but everything commutes with itself. Since the Hamiltonian only involves the spin component in the direction of the linear momentum, (because of the dot product), the Hamiltonian commutes with the spin in that direction.

It is instructive to form a mental picture of these neutrinos. According to the above, the neutrinos can be in states with definite linear momentum and with definite spin in the direction of that linear momentum. In those states the neutrinos move in a specific direction and also rotate around an axis in the same direction. You can think of it macroscopically as screws; screws too rotate around their axis of motion while they move in or out of their hole.

Now there are two kinds of screws. Normal, "right-handed," screws move into the hole if you rotate them clockwise with a screwdriver. Some special applications use "left-handed" screws, which are machined so that they move into the hole when you rotate them counter-clockwise. (One of the screws that keep the pedals on a bicycle is normally a left-handed screw, to prevent you from loosening it up when pedaling.)

Experiments show that all antineutrinos observed in a normal lab setting act like right-handed screws. Neutrinos act like left-handed screws. Since a right-handed screw turns into a left-handed screw when seen in a mirror, nature is not the same when seen in a mirror. If, say, a beta decay is observed in a mirror, the antineutrino that comes out is left-handed, rather than right-handed

## as it should.

(Using arguments like in $\{\mathrm{D} .70\}$, it can be seen that $\vec{\psi}_{\mathrm{R}}$ above is righthanded and $\vec{\psi}_{\mathrm{L}}$ left handed, [53, p. 95].)

Note that theoretical physicists do not know about screws. So they came up with a different way to express that antineutrinos are right-handed like normal screws, while neutrinos are left-handed. They call the component of spin in the direction of motion, scaled so that its values are $\pm 1$, the "helicity." So according to theoretical physicists, antineutrinos as seen in a lab have helicity 1 , while neutrinos have helicity -1 .

It is ironic that Pauli in turn did not live long enough to learn that Weyl's neutrinos were wrong on at least one major count. Around 1998, experiments found that neutrinos and antineutrinos are not massless as was long thought. Their mass is extremely tiny, (far too tiny to be accurately measured by experimental methods available at the time of writing), but it is not zero.

Fundamentally, it makes a big difference, because then their speed must be less than the speed of light. Hypothetically, an observer can then move with a speed faster than some antineutrino produced in a lab. The antineutrino then seems to go backward for that observer. Since the spin is still in the same direction, the observer sees a left-handed antineutrino, not a right-handed one. So the handedness, or helicity, of antineutrinos, and similarly neutrinos, is not fundamental. A process like the beta decay of an nucleus moving at a speed extremely close to the speed of light could produce a left-handed antineutrino trailing the nucleus. But since this does not happen for a nucleus at rest, nature is still not the same when seen in the mirror.

At the time of writing, the precise nature of neutrinos is not yet fully understood. Usually, it is assumed that neutrinos are distinct from antineutrinos. Neutrinos for which that is true are called Dirac neutrinos. However, so-called Majorana neutrinos would be their own antiparticles; neutrinos and antineutrinos would simply differ in the spin state.

## A. 45 Fermi theory

This note needs more work, but as far as I know is basically OK. Unfortunately, a derivation of electron capture for zero spin transitions is not included.

This note derives the Fermi theory of beta decay. In particular, it gives the ballparks that were used to create figure 14.54. It also describes the Fermi integral plotted in figure 14.52, as well as Fermi's (second) golden rule. There is also a final subsection on electron capture, A.45.7.

When beta decay was first observed, it was believed that the nucleus simply ejected an electron. However, problems quickly arose with energy and momentum conservation. To solve them, Pauli proposed in 1931 that in addition to the electron, also a neutral particle was emitted. Fermi called it the "neutrino," for
"small neutral one." Following ideas of Pauli in 1933, Fermi in 1934 developed a comprehensive theory of beta decay. The theory justifies the various claims made about allowed and forbidden beta decays. It also allows predictions of the decay rate and the probability that the electron and antineutrino will come out with given kinetic energies. This note gives a summary. The ballparks as described in this note are the ones used to produce figure 14.54 .

A large amount of work has gone into improving the accuracy of the Fermi theory, but it is outside the scope of this note. To get an idea of what has been done, you might start with [23] and work backwards. One point to keep in mind is that the derivations below are based on expanding the electron and neutrino wave functions into plane waves, waves of definite linear momentum. For a more thorough treatment, it may be a better idea to expand into spherical waves, because nuclear states have definite angular momentum. That idea is worked out in more detail in the note on gamma decay, $\{\mathrm{A} .25\}$. That is news to the author. But it was supposed to be there, I think.

## A.45.1 Form of the wave function

A classical quantum treatment will not do for beta decay. To see why, note that in a classical treatment the wave function state before the decay is taken to be of the form

$$
\psi_{1}\left(\vec{r}_{1}, S_{z, 1}, \vec{r}_{2}, S_{z, 2}, \ldots, \vec{r}_{A}, S_{z, A}\right)
$$

where 1 through $A$ number the nucleons. However, the decay creates an electron and a antineutrino out of nothing. Therefore, after the decay the classical wave function is of the form

$$
\psi_{2}\left(\vec{r}_{1}, S_{z, 1}, \vec{r}_{2}, S_{z, 2}, \ldots, \vec{r}_{A}, S_{z, A}, \vec{r}_{e}, S_{z, e}, \vec{r}_{\bar{\nu}}, S_{z, \bar{\nu}}\right)
$$

There is no way to describe how $\psi_{1}$ could evolve into $\psi_{2}$. You cannot just scribble in two more arguments into a function somewhere half way during the evolution. That would be voodoo mathematics. And there is also a problem with one nucleon turning from a neutron into a proton. You should really cross out the argument corresponding to the old neutron, and write in an argument for the new proton.

You might think that maybe the electron and antineutrino were always there to begin with. But that has some major problems. A lone neutron falls apart into a proton, an electron and an antineutrino. So supposedly the neutron would consist of a proton, an electron, and an antineutrino. But to confine light particles like electrons and neutrinos to the size of a nucleon would produce huge kinetic energies. According to the Heisenberg uncertainty relation $p \sim \hbar / \Delta x$, where the energy for relativistic particles is about $p c$, so the kinetic energy of a light particle confined to a 1 fm range is about 200 MeV . What conceivable force could be strong enough to hold electrons and neutrinos that hot? And how
come the effects of this mysterious force never show up in the atomic electrons that can be very accurately observed? How come that electrons come out in beta decays with only a few MeV , rather than 200 MeV ?

Further, a high-energy antineutrino can react with a proton to create a neutron and a positron. That neutron is supposed to consist of a proton, an electron, and an antineutrino. So, following the same reasoning as before, the original proton before the reaction would consist of a positron, an electron, and a proton. That proton in turn would supposedly also consist of a positron, an electron, and an proton. So the original proton consists of a positron, an electron, a positron, an electron, and a proton. And so on until a proton consists of a proton and infinitely many electron / positron pairs. Not just one electron with very high kinetic energy would need to be confined inside a nucleon, but an infinite number of them, and positrons to boot. And all these electrons and positrons would somehow have to be prevented from annihilating each other.

It just does not work. There is plenty of solid evidence that neutrons and protons each contain three quarks, not other nucleons along with electrons, positrons, and neutrinos. The electron and antineutrino are created out of pure energy during beta decay, as allowed by Einstein's famous relativistic expression $E=m c^{2}$. A relativistic quantum treatment is therefore necessary.

In particular, it is necessary to deal mathematically with the appearance of the electron and an antineutrino out of nothing. To do so, a more general, more abstract way must be used to describe the states that nature can be in. Consider a decay that produces an electron and an antineutrino of specific momenta $\vec{p}_{e}$, respectively $\vec{p}_{\bar{\nu}}$. The final state is written as

$$
\begin{equation*}
\psi_{2}=\psi_{2, \text { nuc }}\left|1 e, \vec{p}_{e}\right\rangle\left|1 \bar{\nu}, \vec{p}_{\bar{\nu}}\right\rangle \tag{A.274}
\end{equation*}
$$

where $\psi_{2, \text { nuc }}$ is the nuclear part of the final wave function. The electron ket $\left|1 e, \vec{p}_{e}\right\rangle$ is a "Fock-space ket," and should be read as "one electron in the state with angular momentum $\vec{p}_{e}$." The antineutrino ket should be read as "one antineutrino in the state with angular momentum $\vec{p}_{\bar{\nu}}$."

Similarly, the state before the decay is written as

$$
\begin{equation*}
\psi_{1}=\psi_{1, \text { nuc }}\left|0 e, \vec{p}_{e}\right\rangle\left|0 \bar{\nu}, \vec{p}_{\bar{\nu}}\right\rangle \tag{A.275}
\end{equation*}
$$

where $\left|0 e, \vec{p}_{e}\right\rangle$ means "zero electrons in the state with angular momentum $\vec{p}_{e}$," and similar for the antineutrino ket. Written in this way, the initial and final wave functions are no longer inconsistent. What is different is not the form of the wave function, but merely how many electrons and antineutrinos are in the states with momentum $\vec{p}_{e}$, respectively $\vec{p}_{\bar{\nu}}$. Before the decay, the "occupation numbers" of these states are zero electrons and zero antineutrinos. After the decay, the occupation numbers are one electron and one neutrino. It is not that the initial state does not have occupation numbers for these states, (which would make $\psi_{1}$ and $\psi_{2}$ inconsistent), but merely that these occupation numbers have the value zero, (which does not).
(You could also add kets for different momentum states that the final electron and antineutrino are not in after the decay. But states that have zero electrons and neutrinos both before and after the considered decay are physically irrelevant and can be left away.)

That leaves the nuclear part of the wave function. You could use Fock-space kets to deal with the disappearance of a neutron and appearance of a proton during the decay. However, there is a neater way. The total number of nucleons remains the same during the decay. The only thing that happens is that a nucleon changes type from a neutron into a proton. The mathematical trick is therefore to take the particles to be nucleons, instead of protons and neutrons. If you give each nucleon a "nucleon type" property, then the only thing that happens during the decay is that the nucleon type of one of the nucleons flips over from neutron to proton. No nucleons are created or destroyed. Nucleon type is typically indicated by the symbol $T_{3}$ and is defined to be $\frac{1}{2}$ if the nucleon is a proton and $-\frac{1}{2}$ if the nucleon is a neutron. (Some older references may define it the other way around.) The general form of the nuclear wave function therefore becomes

$$
\Psi_{N}\left(\vec{r}_{1}, S_{z, 1}, T_{3,1}, \vec{r}_{2}, S_{z, 2}, T_{3,2}, \ldots, \vec{r}_{A}, S_{z, A}, T_{3, A} ; t\right)
$$

During the decay, the $T_{3}$ value of one nucleon will change from $-\frac{1}{2}$ to $\frac{1}{2}$.
Of course, the name "nucleon type" for $T_{3}$ is not really acceptable, because it is understandable. In the old days, the names "isobaric spin" or "isotopic spin" were used, because nucleon type has absolutely nothing to do with spin. However, it was felt that these nonsensical names could cause some smart outsiders to suspect that the quantity being talked about was not really spin. Therefore the modern term "isospin" was introduced. This term contains nothing to give the secret away that it is not spin at all.

## A.45.2 Source of the decay

Next the source of the decay must be identified. Ultimately that must be the Hamiltonian, because the Hamiltonian describes the time evolution of systems according to the Schrödinger equation.

In a specific beta decay process, two states are involved. A state $\psi_{1}$ describes the nucleus before the decay, and a state $\psi_{2}$ describes the combination of nucleus, electron, and antineutrino after the decay. That makes the system into a socalled "two state system." The unsteady evolution of such systems was discussed in chapter 7.6 and $\{\mathrm{D} .38\}$. The key to the solution were the "Hamiltonian coefficients." The first one is:

$$
E_{1} \equiv H_{11} \equiv\left\langle\psi_{1} \mid H \psi_{1}\right\rangle
$$

where $H$ is the (relativistic) Hamiltonian. The value of $H_{11}$ is the expectation value of the energy $E_{1}$ when nature is in the state $\psi_{1}$. Assuming that the
nucleus is initially at rest, the relativistic energy is just the rest mass energy of the nucleus. It is given in terms of its mass by Einstein's famous relation $E_{1}=$ $m_{\mathrm{N} 1} c^{2}$.

The Hamiltonian coefficient for the final state is similarly

$$
E_{2} \equiv H_{22} \equiv\left\langle\psi_{2} \mid H \psi_{2}\right\rangle
$$

Using the form given in the previous section for the final wave function, that becomes

$$
\left.E_{2}=\left\langle 1 \bar{\nu}, \vec{p}_{\bar{\nu}}\right|\left\langle 1 e, \vec{p}_{e}\right| \psi_{2, \text { nuc }}\left|H \psi_{2, \text { nuc }}\right| 1 e, \vec{p}_{e}\right\rangle\left|1 \bar{\nu}, \vec{p}_{\bar{\nu}}\right\rangle
$$

It is the expectation value of energy after the decay. It consists of the sum of the rest mass energies of final nucleus, electron, and antineutrino, as well as their kinetic energies.

The Hamiltonian coefficient that describes the interaction between the two states is crucial, because it is the one that causes the decay. It is

$$
H_{21} \equiv\left\langle\psi_{2} \mid H \psi_{1}\right\rangle
$$

Using the form for the wave functions given in the previous section:

$$
\left.H_{21}=\left\langle 1 \bar{\nu}, \vec{p}_{\bar{\nu}}\right|\left\langle 1 e, \vec{p}_{e}\right| \psi_{2, \text { nuc }}\left|H \psi_{1, \text { nuc }}\right| 0 e, \vec{p}_{e}\right\rangle\left|0 \bar{\nu}, \vec{p}_{\bar{\nu}}\right\rangle
$$

If $H_{21}$ is zero, no decay will occur. And most of the Hamiltonian does not produce a contribution to $H_{21}$. But there is a small part of the Hamiltonian, call it $H^{\prime}$, that does produce a nonzero interaction. That part is due to the weak force.

Unfortunately, Fermi had no clue what $H^{\prime}$ was. He assumed that beta decay would not be that much different from the better understood decay of excited atomic states in atoms. Gamma decay is the direct equivalent of atomic decay for excited nuclei. Beta decay is definitely different, but maybe not that different. In atomic decay an electromagnetic photon is created, rather than an electron and antineutrino. Still the general idea seemed similar.

In atomic decay $H^{\prime}$ is essentially proportional to the product of the charge of the excited electron, times the spatial eigenstate of the photon, times a "photon creation" operator $\widehat{a}^{\dagger}$ :

$$
H^{\prime} \propto e \psi_{\text {photon }}(\vec{r}) \widehat{a}^{\dagger}
$$

In words, it says that the interaction of the electron with the electromagnetic field can create photons. The magnitude of that effect is proportional to the amplitude of the photon at the location of the electron, and also to the electric charge of the electron. The electric charge acts as a "coupling constant" that links electrons and photons together. If the electron was uncharged, it would not be able to create photons. So it would not be able to create an electric field. Further, the fact that the coupling between the electron and the photon occurs
at the location of the electron eliminates some problems that relativity has with action at a distance.

There is another term in $H^{\prime}$ that involves an annihilation operator $\widehat{a}$ instead of a creation operator. An annihilation operator destroys photons. However, that does not produce a contribution to $H_{21}$; if you try to annihilate the nonexisting photon in the initial wave function, you get a zero wave function. On the other hand for the earlier term, the creation operator is essential. It turns the initial state with no photon into a state with one photon. States with different numbers of particles are orthogonal, so the Hamiltonian coefficient $H_{12}$ would be zero without the creation operator. Looked at the other way around, the presence of the creation operator in the Hamiltonian ensures that the final state must have one more photon for the decay to occur. (See addendum \{A.15\} for more details on electromagnetic interactions, including a more precise description of $H^{\prime}$. See also \{A.25\}.)

Fermi assumed that the general ideas of atomic decay would also hold for beta decay of nuclei. Electron and antineutrino creation operators in the Hamiltonian would turn the zero-electron and zero-antineutrino kets into one-electron and one-antineutrino ones. Then the inner products of the kets are equal to one pairwise. Therefore both the creation operators and the kets drop out of the final expression. In that way the Hamiltonian coefficient simplifies to

$$
H_{21}=\left\langle\psi_{2, \text { nuc }}\right| \sum_{i=1}^{A} g h_{i} \psi_{e, \vec{p}_{e}}\left(\vec{r}_{i}\right) \psi_{\vec{\nu}, \vec{p}_{\bar{\nu}}}\left(\vec{r}_{i}\right)\left|\psi_{1, \text { nuc }}\right\rangle
$$

where the index $i$ is the nucleon number and $g h_{i}$ is the remaining still unknown part of the Hamiltonian. In indicating this unknown part by $g h_{i}$, the assumption is that it will be possible to write it as some generic dimensional constant $g$ times some simple nondimensional operator $h_{i}$ acting on nucleon number $i$.

To write expressions for the wave functions of the electron and antineutrino, you face the complication that unbound states in infinite space are not normalizable. That produced mathematical complications for momentum eigenstates in chapter 7.9.2, and similar difficulties resurface here. To simplify things, the mathematical trick is to assume that the decaying nucleus is not in infinite space, but in an extremely large "periodic box." The assumption is that nature repeats itself spatially; a particle that exits the box through one side reenters it through the opposite side. Space "wraps around" if you want, and opposite sides of the box are assumed to be physically the same location. It is like on the surface of the earth: if you move along the straightest-possible path on the surface of the earth, you travel around the earth along a big circle and return to the same point that you started out at. Still, on a local scale, the surface on the earth looks flat. The idea is that the empty space around the decaying nucleus has a similar property, in each of the three Cartesian dimensions. This trick is also commonly used in solid mechanics, chapter 10.

In a periodic box, the wave function of the antineutrino is

$$
\psi_{\bar{\nu}, \vec{p}_{\overline{\mathcal{V}}}}=\frac{1}{\sqrt{\mathcal{V}}} e^{\mathrm{i} \vec{p}_{\bar{\nu}} \cdot \vec{r} / \hbar}=\frac{1}{\sqrt{\mathcal{V}}} e^{\mathrm{i}\left(p_{x, \bar{\nu}} x+p_{y, \bar{\nu}} y+p_{z, \bar{v}}\right) / \hbar}
$$

where $\mathcal{V}$ is the volume of the periodic box. It is easy to check that this wave function is indeed normalized. Also, it is seen that it is indeed an eigenfunction of the $x$-momentum operator $\hbar \partial / \mathrm{i} \partial x$ with eigenvalue $p_{x}$, and similar for the $y$ and $z$-momentum operators.

The wave function of the electron will be written in a similar way:

$$
\psi_{e, \vec{p}_{e}}(\vec{r})=\frac{1}{\sqrt{\mathcal{V}}} e^{\mathrm{i} \vec{p}_{e} \cdot \vec{r} / \hbar}=\frac{1}{\sqrt{\mathcal{V}}} e^{\mathrm{i}\left(p_{x, e} x+p_{y, e} y+p_{z, e} z\right) / \hbar}
$$

This however has an additional problem. It works fine far from the nucleus, where the momentum of the electron is by definition the constant vector $\vec{p}_{e}$. However, near the nucleus the Coulomb field of the nucleus, and to some extent that of the atomic electrons, affects the kinetic energy of the electron, and hence its momentum. Therefore, the energy eigenfunction that has momentum $\vec{p}$ far from the nucleus differs significantly from the above exponential closer to the nucleus. And this wave function must be evaluated at nucleon positions inside the nucleus! The problem is particularly large when the momentum $\vec{p}_{e}$ is low, because then the electron has little kinetic energy and the Coulomb potential is relatively speaking more important. The problem gets even worse for lowenergy positron emission, because a positively-charged positron is repelled by the positive nucleus and must tunnel through to reach it.

The usual way to deal with the problem is to stick with the exponential electron wave function for now, and fix up the problem later in the final results. The fix-up will be achieved by throwing in an additional fudge factor. While "Fermi fudge factor" alliterates nicely, it does not sound very respectful, so physicists call the factor the "Fermi function."

The bottom line is that for now

$$
\begin{equation*}
H_{21}=\frac{g}{\sqrt{\mathcal{V}}}\left\langle\psi_{2, \text { nuc }} \mid \sum_{i=1}^{A} h_{i} e^{\mathrm{i}\left(\vec{p}_{e}+\vec{p}_{\bar{\nu}}\right) \cdot \vec{r}_{i} / \hbar} \psi_{1, \text { nuc }}\right\rangle \tag{A.276}
\end{equation*}
$$

That leaves the still unknown operator $g h_{i}$. The constant $g$ is simply defined so that the operator $h_{i}$ has a magnitude that is of order one. That means that $\left\langle\psi_{2, \text { nuc }} \mid h_{i} \psi_{1, \text { nuc }}\right\rangle$ should never be greater than about one, though it could be much less if $\psi_{2 \text { nuc }}$ and $h_{i} \psi_{1, \text { nuc }}$ turn out to be almost orthogonal. It is found that $g$ has a rough value of about $100 \mathrm{eV} \mathrm{fm}^{3}$, depending a bit on whether it is a Fermi or Gamow-Teller decay. Figure 14.54 simply used $100 \mathrm{MeV} \mathrm{fm}{ }^{3}$.

## A.45.3 Allowed or forbidden

The question of allowed and forbidden decays is directly related to the Hamiltonian coefficient $H_{21}$, (A.276), derived in the previous subsection, that causes the decay.

First note that the emitted electron and antineutrino have quite small momentum values, on a nuclear scale. In particular, in their combined wave function

$$
\frac{1}{\mathcal{V}} e^{\mathrm{i}\left(\vec{p}_{e}+\vec{p}_{\vec{v}}\right) \cdot \vec{r}_{i} / \hbar}
$$

the argument of the exponential is small. Typically, its magnitude is only a few percent, It is therefore possible to approximate the exponential by one, or more generally by a Taylor series:

$$
e^{\mathrm{i}\left(\vec{p}_{e}+\vec{p}_{\bar{\nu}}\right) \cdot \vec{r}_{i} / \hbar} \approx 1+\frac{\mathrm{i}\left(\vec{p}_{e}+\vec{p}_{\bar{\nu}}\right) \cdot \vec{r}_{i}}{\hbar}+\frac{1}{2!}\left(\frac{\mathrm{i}\left(\vec{p}_{e}+\vec{p}_{\bar{\nu}}\right) \cdot \vec{r}_{i}}{\hbar}\right)^{2}+\ldots
$$

Since the first term in the Taylor series is by far the largest, you would expect that the value of $H_{21}$, (A.276), can be well approximated by replacing the exponential by 1 , giving:

$$
H_{21}^{0}=\frac{g}{\sqrt{\mathcal{V}}}\left\langle\psi_{2, \text { nuc }} \mid \sum_{i=1}^{A} h_{i} \psi_{1, \text { nuc }}\right\rangle
$$

However, clearly this approximation does not work if the value of $H_{21}^{0}$ is zero for some reason:

> If the simplified coefficient $H_{21}^{0}$ is nonzero, the decay is allowed. If it is zero, the decay is forbidden.

If the decay is forbidden, higher order terms in the Taylor series will have to be used to come up with a nonzero value for $H_{21}$. Since these higher order terms are much smaller, and $H_{21}$ drives the decay, a forbidden decay will proceed much slower than an allowed one.

Why would a decay not be allowed? In other words why would $\psi_{2, \text { nuc }}$ and $h_{i} \psi_{1, \text { nuc }}$ be exactly orthogonal? If you took two random wave functions for $\psi_{2, \text { nuc }}$ and $\psi_{1, \text { nuc }}$, they definitely would not be. But $\psi_{2, \text { nuc }}$ and $\psi_{1, \text { nuc }}$ are not random wave functions. They satisfy a significant amount of symmetry constraints.

One very important one is symmetry with respect to coordinate system orientation. An inner product of two wave functions is independent of the angular orientation of the coordinate system in which you evaluate it. Therefore, you can average the inner product over all directions of the coordinate system. However, the angular variation of a wave function is related to its angular momentum; see chapter 7.3 and its note. In particular, if you average a wave function of definite angular momentum over all coordinate system orientations, you get zero unless
the angular momentum is zero. So, if it was just $\psi_{1, \text { nuc }}$ in the inner product in $H_{21}^{0}$, the inner product would be zero unless the initial nucleus had zero spin. However, the final state is also in the inner product, and being at the other side of it, its angular variation acts to counteract that of the initial nucleus. Therefore, $H_{21}^{0}$ will be zero unless the initial angular momentum is exactly balanced by the net final angular momentum. And that is angular momentum conservation. The decay has to satisfy it.

Note that the linear momenta of the electron and antineutrino have become ignored in $H_{21}^{0}$. Therefore, their orbital angular momentum is approximated to be zero too. Under these condition $H_{21}^{0}$ is zero unless the angular momentum of the final nucleus plus the spin angular momentum of electron and antineutrino equals the angular momentum of the original nucleus. Since the electron and antineutrino can have up to one unit of combined spin, the nuclear spin cannot change more than one unit. That is the first selection rule for allowed decays given in chapter 14.19.6.

Another important constraint is symmetry under the parity transformation $\vec{r} \rightarrow-\vec{r}$. This transformation too does not affect inner products, so you can average the values before and after the transform. However, a wave function that has odd parity changes sign under the transform and averages to zero. So the inner product in $H_{21}^{0}$ is zero if the total integrand has odd parity. For a nonzero value, the integrand must have even parity, and that means that the parity of the initial nucleus must equal the combined parity of the final nucleus electron, and antineutrino.

Since the electron and antineutrino come out without orbital angular momentum, they have even parity. So the nuclear parity must remain unchanged under the transition. (To be sure, this is not absolutely justified. Nuclear wave functions actually have a tiny uncertainty in parity because the weak force does not conserve parity, chapter 14.19.8. This effect is usually too small to be observed and will be ignored here.)

So what if either one of these selection rules is violated? In that case, maybe the second term in the Taylor series for the electron and antineutrino wave functions produces something nonzero that can drive the decay. For that to be true,

$$
H_{21}^{1}=\frac{g}{\sqrt{\mathcal{V}}}\left\langle\psi_{2, \text { nuc }} \left\lvert\, \sum_{i=1}^{A} h_{i} \frac{\mathrm{i}\left(\vec{p}_{e}+\vec{p}_{\bar{\nu}}\right) \cdot \vec{r}_{i}}{\hbar} \psi_{1, \text { nuc }}\right.\right\rangle
$$

has to be nonzero. If it is, the decay is a first-forbidden one. Now the spherical harmonics $Y_{1}^{m}$ of orbital angular momentum are of the generic form, $\{\mathrm{D} .14\}$

$$
r Y_{1}^{m}=\sum_{j} c_{j} r_{j}
$$

with the $c_{j}$ some constants. Therefore, the factor $\vec{r}_{i}$ in $H_{21}^{1}$ brings in angular variation corresponding to one unit of angular momentum. That means that
the total spin can now change by up to one unit, and therefore the nuclear spin by up to two units. That is indeed the selection rule for first forbidden decays.

And note that because $\vec{r}_{i}$ changes sign when every $\vec{r}$ is replaced by $-\vec{r}$, the initial and final nuclear parities must now be opposite for $H_{21}^{1}$ not to be zero. That is indeed the parity selection rule for first-forbidden decays.

The higher order forbidden decays go the same way. For an $\ell$ th-forbidden decay,

$$
\begin{equation*}
H_{21}^{\ell}=\frac{g}{\ell!\sqrt{\mathcal{V}}}\left\langle\psi_{2, \text { nuc }} \left\lvert\, \sum_{i=1}^{A} h_{i}\left(\frac{\mathrm{i}\left(\vec{p}_{e}+\vec{p}_{\bar{\nu}}\right) \cdot \vec{r}_{i}}{\hbar}\right)^{\ell} \psi_{1, \text { nuc }}\right.\right\rangle \tag{A.277}
\end{equation*}
$$

must be the first nonzero inner product. Note that an $\ell$ th-forbidden decay has a coefficient $H_{21}$ proportional to a factor of order $(p R / \hbar)^{\ell}$, with $R$ the nuclear radius. Since the decay rate turns out to be proportional to $\left|H_{21}\right|^{2}$, an $\ell$ thforbidden decay is slowed down by a factor of order $(p R / \hbar)^{2 \ell}$, making highly forbidden decays extremely slow.

## A.45.4 The nuclear operator

This subsection will have a closer look at the nuclear operator $h_{i}$. While the discussion will be kept simple, having some idea about the nature of this operator can be useful. It can help to understand why some decays have relatively low decay rates that are not explained by just looking at the electron and antineutrino wave functions, and the nuclear spins and parities. The discussion will mainly focus on allowed decays.

Although Fermi did not know what $h_{i}$ was, Pauli had already established the possible generic forms for it allowed by relativity. It could take the form of a scalar (S), a vector (V), an axial vector (A, a vector like angular momentum, one that inverts when the physics is seen in a mirror), a pseudoscalar ( P , a scalar like the scalar triple product of vectors that changes sign when the physics is seen in the mirror), or a tensor ( T , a multiple-index object like a matrix that transforms in specific ways.) Fermi simply assumed the interaction was of the vector, V , type in analogy with the decay of excited atoms.

Fermi ignored the spin of the electron and antineutrino. However, Gamow \& Teller soon established that to allow for decays where the two come out with spin, (Gamow-Teller decays), ghi also should have terms with axial, A, and/ or tensor, T, character. Work of Fierz combined with experimental evidence showed that the Hamiltonian could not have both S and V , nor both A and T terms. Additional evidence narrowed $h_{i}$ down to STP combinations or VA ones.

Finally, it was established in 1953 that the correct one was the STP combination, because experimental evidence on RaE, (some physicists cannot spell bismuth-210), showed that P was present. Unfortunately, it did not. For one, the conclusion depended to an insane degree on the accuracy of a correction term.

However, in 1955 it was established that it was STP anyway, because experimental evidence on helium-6 clearly showed that the Gamow-Teller part of the decay was tensor. The question was therefore solved satisfactorily. It was STP, or maybe just ST. Experimental evidence had redeemed itself.

However, in 1958, a quarter century after Fermi, it was found that beta decay violated parity conservation, chapter 14.19.8, and theoretically that was not really consistent with STP. So experimentalists had another look at their evidence and quickly came back with good news: "The helium-6 evidence does not show Gamow-Teller is tensor after all."

The final answer is that $g h_{i}$ is VA. Since so much of our knowledge about nuclei depends on experimental data, it may be worthwhile to keep this cautionary tale, taken from the Stanford Encyclopedia of Philosophy, in mind.

It may next be noted that $g h_{i}$ will need to include a isospin creation operator to be able to turn a neutron into a proton. In Fermi decays, $h_{i}$ is assumed to be just that operator. The constant of proportionality $g$, usually called the coupling constant $g_{\mathrm{F}}$, describes the strength of the weak interaction. That is much like the unit electric charge $e$ describes the strength of the electromagnetic interaction between charged particles and photons. In Fermi decays it is found that $g_{\mathrm{F}}$ is about $88 \mathrm{eV} \mathrm{fm}^{3}$. Note that this is quite small compared to the MeV scale of nuclear forces. If you ballpark relative strengths of forces, [31, p. 285] the nuclear force is strongest, the electromagnetic force about hundred times smaller, the weak force another thousand times smaller than that, and finally gravity is another $10^{34}$ times smaller than that. The decay rates turn out to be proportional to the square of the interaction, magnifying the relative differences.

In Gamow-Teller decays, $h_{i}$ is assumed to consist of products of isospin creation operators times spin creation or annihilation operators. The latter operators allow the spin of the neutron that converts to the proton to flip over. Suitable spin creation and annihilation operators are given by the so-called "Pauli spin matrices," chapter 12.10 When they act on a nucleon, they produce states with the spin in an orthogonal direction flipped over. That allows the net spin of the nucleus to change by one unit. The appropriate constant of proportionality $g_{G T}$ is found to be a bit larger than the Fermi one.

The relevant operators then become, [5],

$$
h_{i}=\tau_{1} \pm \mathrm{i} \tau_{2} \quad h_{i}=\left(\tau_{1} \pm \mathrm{i} \tau_{2}\right) \sum_{j=1}^{3} \sigma_{j}
$$

for Fermi and Gamow-Teller decays respectively. Here the three $\sigma_{j}$ are the Pauli spin matrices of chapter 12.10. The $\tau_{i}$ are the equivalents of the Pauli spin matrices for isospin; in the combinations shown above they turn neutrons into protons, or vice-versa. Please excuse: using the clarity now made possible by modern physical terminology, they create, respectively annihilate, isospin. The upper sign is relevant for beta-minus decay and the lower for beta-plus
decay. The Gamow-Teller operator absorbs the spin part of the electron and antineutrino wave functions, in particular the averaging over the directions of their spin.

So how do these nuclear operators affect the decay rate? That is best understood by going back to the more physical shell-model picture. In beta minus decay, a neutron is turned into a proton. That proton usually occupies a different spatial state in the proton shells than the original neutron in the neutron shells. And different spatial states are supposedly orthogonal, so the inner product $\left\langle\psi_{2, \text { nuc }} \mid h_{i} \psi_{1, \text { nuc }}\right\rangle$ will usually be pretty small, if the decay is allowed at all. There is one big exception, though: mirror nuclei. In a decay between mirror nuclei, a nucleus with a neutron number $N_{1}=Z_{1} \pm 1$ decays into one with neutron number $N_{2}=Z_{2} \mp 1$. In that case, the nucleon that changes type remains in the same spatial orbit. Therefore, the Fermi inner product equals one, and the Gamow Teller one is maximal too. Allowed decays of this type are called "superallowed." The simplest example is the beta decay of a free neutron.

If you allow for beta decay to excited states, more superallowed decays are possible. States that differ merely in nucleon type are called isobaric analog states, or isospin multiplets, chapter 14.18. There are about twenty such superallowed decays in which the initial and final nuclei both have spin zero and positive parity. These twenty are particularly interesting theoretically, because only Fermi decays are possible for them. And the Fermi inner product is $\sqrt{2}$. (The reason that it is $\sqrt{2}$ instead of 1 like for mirror nuclei can be seen from thinking of isospin as if it is just normal spin. Mirror nuclei have an odd number of nucleons, so the net nuclear isospin is half integer. In particular the net isospin will be $\frac{1}{2}$ in the ground state. However, nuclei with zero spin have an even number of nucleons, hence integer net isospin. The isospin of the twenty decays is one; it cannot be zero because at least one nucleus must have a nonzero net nucleon type $T_{3, \text { net }}$. The net nucleon type is only zero if the number of protons is the same as the number of neutrons. It is then seen from (12.9) and (12.10) in chapter 12 that the isospin creation or annihilation operators will produce a factor $\sqrt{2}$.)

These decays therefore allow the value of the Fermi coupling constant $g_{\mathrm{F}}$ to be determined from the decay rates. It turns out to be about $88 \mathrm{eV} \mathrm{fm}{ }^{3}$, regardless of the particular decay used to compute it. That seems to suggest that the interaction with neighboring nucleons in a nucleus does not affect the Fermi decay process. Indeed, if the value of $g_{\mathrm{F}}$ is used to analyze the decay rates of the mirror nuclei, including the free neutron that has no neighbors, the data show no such effect. The hypothesis that neighboring nucleons do not affect the Fermi decay process is known as the "conserved vector current hypothesis." What name could be clearer than that? Unlike Fermi decays, Gamow-Teller decays are somewhat affected by the presence of neighboring nuclei.

Besides the spin and parity rules already mentioned, Fermi decays must satisfy the approximate selection rule that the magnitude of isospin must be
unchanged. They can be slowed down by several orders of magnitude if that rule is violated.

Gamow-Teller decays are much less confined than Fermi ones because of the presence of the electron spin operator. As the shell model shows, nucleon spins are uncertain in energy eigenstates. Therefore, the nuclear symmetry constraints are a lot less restrictive.

## A.45.5 Fermi's golden rule

The previous four subsections have focussed on finding the Hamiltonian coefficients of the decay from a state $\psi_{1}$ to a state $\psi_{2}$. Most of the attention was on the coefficient $H_{21}^{\ell}$ that drives the decay. The next step is solution of the Schrödinger equation to find the evolution of the decay process.

The quantum amplitude of the pre-decay state $\psi_{1}$ will be indicated by $\bar{a}$ and the quantum amplitude of the final decayed state $\psi_{2}$ by $\bar{b}$. The Schrödinger equation implies that $\bar{b}$ increases from zero according to

$$
\mathrm{i} \hbar \dot{\bar{b}}=H_{21}^{\ell} e^{\mathrm{i}\left(E_{2}-E_{1}\right) t / \hbar} \bar{a}
$$

(To use this expression, the quantum amplitudes must include an additional phase factor, but it is of no consequence for the probability of the states. See chapter 7.6 and $\{D .38\}$ for details.)

Now picture the following. At the initial time there are a large number of pre-decay nuclei, all with $\bar{a}=1$. All these nuclei then evolve according to the Schrödinger equation, above, over a time interval $t_{c}$ that is short enough that $\bar{a}$ stays close to one. (Because the perturbation of the nucleus by the weak force is small, the magnitudes of the coefficients only change slowly on the relevant time scale.) In that case, $\bar{a}$ can be dropped from the equation and its solution is then seen to be

$$
\bar{b}=-H_{21}^{\ell} \frac{e^{\mathrm{i}\left(E_{2}-E_{1}\right) t_{c} / \hbar}-1}{\left(E_{2}-E_{1}\right)}
$$

Half of the exponential can be factored out to produce a real ratio:

$$
\bar{b}=-H_{21}^{\ell} e^{\mathrm{i} \frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar} \frac{\mathrm{i}}{\hbar} \frac{\sin \left(\frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar\right)}{\frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar} t_{c}
$$

Then at the final time $t_{c}$, assume that the state of all the nuclei is "measured." The macroscopic surroundings of the nuclei establishes whether or not electron and antineutrino pairs have come out. The probability that a give nucleus has emitted such a pair is given by the square magnitude $|\bar{b}|^{2}$ of the amplitude of the decayed state. Therefore, a fraction $|\bar{b}|^{2}$ of the nuclei will be found to have decayed and $1-|\bar{b}|^{2}$ will be found to be still in the pre-decay state $\psi_{1}$. After this "measurement," the entire process then repeats for the remaining $1-|\bar{b}|^{2}$ nuclei that did not decay.

The bottom line is however that a fraction $|\bar{b}|^{2}$ did. Therefore, the ratio $|\bar{b}|^{2} / t_{c}$ gives the specific decay rate, the relative amount of nuclei that decay per unit time. Plugging in the above expression for $\bar{b}$ gives:

$$
\begin{equation*}
\lambda_{\text {single final state }}=\frac{\left|H_{21}^{\ell}\right|^{2} \sin ^{2}\left(\frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar\right)}{\hbar^{2}} t_{c} \tag{A.278}
\end{equation*}
$$

To get the total decay rate, you must still sum over all possible final states. Most importantly, you need to sum the specific decay rates together for all possible electron and antineutrino momenta.

And there may be more. If the final nuclear state has spin you also need to sum over all values of the magnetic quantum number of the final state. (The amount of nuclear decay should not depend on the angular orientation of the initial nucleus in empty space. However, if you expand the electron and neutrino wave functions into spherical waves, you need to average over the possible initial magnetic quantum numbers. It may also be noted that the total coefficient $\left|H_{21}^{\ell}\right|$ for the decay $1 \rightarrow 2$ will not be the same as the one for $2 \rightarrow 1$ : you average over the initial magnetic quantum number, but sum over the final one.) If there are different excitation levels of the final nucleus that can be decayed to, you also need to sum over these. And if there is more than one type of decay process going on at the same time, they too need to be added together.

However, all these details are of little importance in finding a ballpark for the dominant decay process. The real remaining problem is summing over the electron and antineutrino momentum states. The total ballparked decay rate must be found from

$$
\lambda=\sum_{\text {all } \vec{p}_{e}, \vec{p}_{\bar{\nu}}} \frac{\left|H_{21}^{\ell}\right|^{2}}{\hbar^{2}} \frac{\sin ^{2}\left(\frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar\right)}{\left(\frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar\right)^{2}} t_{c}
$$

Based on energy conservation, you would expect that decays should only occur when the total energy $E_{2}$ of the nucleus, electron and antineutrino after the decay is exactly equal to the energy $E_{1}$ of the nucleus before the decay. However, the summation above shows that that is not quite true. For a final state that has $E_{2}$ exactly equal to $E_{1}$, the last fraction in the summation is seen to be unity, using l'Hospital. For a final state with an energy $E_{2}$ of, for example, $E_{1}+\hbar / t_{c}$, the ratio is quite comparable. Therefore decay to such a state proceeds at a comparable rate as to a state that conserves energy exactly. There is "slop" in energy conservation.

How can energy not be conserved? The reason is that neither the initial state nor the final state is an energy eigenstate, strictly speaking. Energy eigenstates are stationary states. The very fact that decay occurs assures that these states are not really energy eigenstates. They have a small amount of uncertainty
in energy. The nonzero value of the Hamiltonian coefficient $H_{21}^{\ell}$ assures that, chapter 5.3, and there may be more decay processes adding to the uncertainty in energy. If there is some uncertainty in energy, then $E_{2}=E_{1}$ is not an exact relationship.

To narrow this effect down more precisely, the fraction is plotted in figure 7.7. The spikes in the figure indicate the energies $E_{2}$ of the possible final states. Now the energy states are almost infinitely densely spaced, if the periodic box in which the decay is assumed to occur is big enough. And the box must be assumed very big anyway, to simulate decay in infinite space. Therefore, the summation can be replaced by integration, as follows:

$$
\lambda=\int_{\text {all } E_{2}} \frac{\left|H_{21}^{\ell}\right|^{2} \sin ^{2}\left(\frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar\right)}{\hbar^{2}} \frac{\mathrm{~d} N}{\left(\frac{1}{2}\left(E_{2}-E_{1}\right) t_{c} / \hbar\right)^{2}} t_{c} \frac{\mathrm{~d} E_{2}}{} \mathrm{~d} E_{2}
$$

where $\mathrm{d} N / \mathrm{d} E_{2}$ is the number of final states per unit energy range, often called the density of states $\rho\left(E_{2}\right)$.

Now assume that the complete problem is cut into bite-size pieces for each of which $\left|H_{21}^{\ell}\right|$ is about constant. It can then be taken out of the integral. Also, the range of energy in figure 7.7 over which the fraction is appreciable, the energy slop, is very small on a normal nuclear energy scale: beta decay is a slow process, so the initial and final states do remain energy eigenstates to a very good approximation. Energy conservation is almost exactly satisfied. Because of that, the density of states $\mathrm{d} N / \mathrm{d} E_{2}$ will be almost constant over the range where the integrand is nonzero. It can therefore be taken out of the integral too. What is left can be integrated analytically, [41, 18.36]. That gives:

$$
\lambda=\frac{\left|H_{21}^{\ell}\right|^{2}}{\hbar^{2}} t_{c} \frac{\mathrm{~d} N}{\mathrm{~d} E} \frac{2 \pi \hbar}{t_{c}}
$$

That is "Fermi's (second) golden rule." It describes how energy slop increases the total decay rate. It is not specific to beta decay but also applies to other forms of decay to a continuum of states. Note that it no longer depends on the artificial length $t_{c}$ of the time interval over which the system was supposed to evolve without "measurement." That is good news, since that time interval was obviously poorly defined.

Because of the assumptions involved, like dividing the problem into bite-size pieces, the above expression is not very intuitive to apply. It can be rephrased into a more intuitive form that does not depend on such an assumption. The obtained decay rate is exactly the same as if in an energy slop range

$$
\Delta E_{\text {slop }}=\frac{2 \pi \hbar}{t_{c}}
$$

all states contribute just as much to the decay as one that satisfies energy conservation exactly, while no states contribute outside of that range.
(Note that if you ballpark $t_{c}$ as the half-life, then even a half-life as short as $10^{-15} \mathrm{~s}$ gives an energy slop of a few eV , almost impossible to measure. And any nuclear decay with a half life of $10^{-15} \mathrm{~s}$ should surely produce an amount of energy equal to very many MeV . Outside the mathematics of the Fermi theory, the energy slop is imperceptible under normal conditions.)

The good news is that phrased this way, it indicates the relevant physics much more clearly than the earlier purely mathematical expression for Fermi's golden rule. The bad news is that it suffers esthetically from still involving the poorly defined time $t$, instead of already having shoved $t$ under the mat. Therefore, it is more appealing to write things in terms of the energy slop altogether:

$$
\begin{equation*}
\lambda_{\text {single final state }}=\frac{2 \pi}{\hbar \varepsilon}\left|H_{21}^{\ell}\right|^{2} \quad \Delta E_{\text {slop }} \equiv \varepsilon \quad \varepsilon t_{c} \sim 2 \pi \hbar \tag{A.279}
\end{equation*}
$$

Here $\varepsilon$ is the amount that energy conservation seems to be violated, and is related to a typical time $t_{c}$ between collisions by the energy-time uncertainty relationship shown.

It may be noted that the golden rule does not apply if the evolution is not to a continuum of states. It also does not apply if the slop range $\varepsilon$ is so large that $\mathrm{d} N / \mathrm{d} E$ is not constant over it. And it does not apply for systems that evolve without being perturbed over times long enough that the decay probability becomes significant before the system is "measured." (If $\bar{b}$ becomes appreciable, $\bar{a}$ can no longer be close to one since the probabilities $|\bar{a}|^{2}$ and $|\bar{b}|^{2}$ must add to one.) "Measurements," or rather interactions with the larger environment, are called "collisions." Fermi's golden rule applies to so-called "collision-dominated" conditions. Typically examples where the conditions are not collision dominated are in NMR and atomic decays under intense laser light.

Mathematically, the conditions for Fermi's golden rule can be written as

$$
\begin{equation*}
\left|H_{21}\right| \ll \varepsilon \ll E \quad \varepsilon \equiv \frac{2 \pi \hbar}{t_{c}} \tag{A.280}
\end{equation*}
$$

The first inequality means that the perturbation causing the decay must be weak enough that there is only a small chance of decay before a collision occurs. The second inequality means that there must be enough time between collisions that an apparent energy conservation from initial to final state applies. Roughly speaking, collisions must be sufficiently frequent on the time scale of the decay process, but rare on the quantum time scale $\hbar / E$.

It should also be noted that the rule was derived by Dirac, not Fermi. The way Fermi got his name on it was that he was the one who named it a "golden rule." Fermi had a flair for finding memorable names. God knows how he ended up being a physicist.

## A.45.6 Mopping up

The previous subsections derived the basics for the rate of beta decay. The purpose of this section is to pull it all together and get some actual ballpark estimates for beta decay.

First consider the possible values for the momenta $\vec{p}_{e}$ and $\vec{p}_{\bar{\nu}}$ of the electron and antineutrino. Their wave functions were approximately of the form

$$
\psi_{\vec{p}}=\frac{1}{\sqrt{\mathcal{V}}} e^{\mathrm{i}\left(p_{x} x+p_{y} y+p_{z} z\right) / \hbar}
$$

where $\mathcal{V}=\ell^{3}$ is the volume of the periodic box in which the decay is assumed to occur.

In a periodic box the wave function must be the same at opposite sides of the box. For example, the exponential factor $e^{\mathrm{i} p_{x} x / \hbar}$ is 1 at $x=0$, and it must be 1 again at $x=\ell$. That requires $p_{x} \ell / \hbar$ to be a whole multiple of $2 \pi$. Therefore $p_{x}$ must be a whole multiple of $2 \pi \hbar / \ell$. Successive possible $p_{x}$ values are therefore spaced the finite amount $2 \pi \hbar / \ell$ apart. And so are successive $p_{y}$ and $p_{z}$ values.

Figure A.27: Possible momentum states for a particle confined to a periodic box. The states are shown as points in momentum space. States that have momentum less than some example maximum value are in red.

Graphically this can by visualized by plotting the possible momentum values as points in a three-dimensional $p_{x}, p_{y}, p_{z}$ axis system. That is done in figure
A.27. Each point correspond to one possible momentum state. Each point is the center of its own little cube with sides $2 \pi \hbar / \ell$. The "volume" (in this three-dimensional momentum plot, not physical volume) of that little cube is $(2 \pi \hbar / \ell)^{3}$. Since $\ell^{3}$ is the physical volume $\mathcal{V}$ of the periodic box, the "volume" in momentum space taken up by each momentum state is $(2 \pi \hbar)^{3} / \mathcal{V}$

That allows the number of different momentum states to be computed. In particular, consider how many states have magnitude of momentum $\left|\vec{p}^{\prime}\right|$ less than some maximum value $p$. For some example value of $p$, these are the red states in figure A.27. Note that they form a sphere of radius $p$. That sphere has a "volume" equal to $\frac{4}{3} \pi p^{3}$. Since each state takes up a "volume" $(2 \pi \hbar)^{2} / \mathcal{V}$, the number of states $N$ is given by the number of such "volumes" in the sphere:

$$
N_{\left|\vec{p}^{\prime}\right| \leqslant p}=\frac{\frac{4}{3} \pi p^{3}}{(2 \pi \hbar)^{3} / \mathcal{V}}
$$

The number of electron states that have momentum in a range from $p_{e}$ to $p_{e}+\mathrm{d} p_{e}$ can be found by taking a differential of the expression above:

$$
\mathrm{d} N_{e}=\frac{\mathcal{V} p_{e}^{2}}{2 \pi^{2} \hbar^{3}} \mathrm{~d} p_{e}
$$

(Here the range $\mathrm{d} p_{e}$ is assumed small, but not so small that the fact that the number of states is discrete would show up.) Each momentum state still needs to be multiplied by the number of corresponding antineutrino states to find the number of states of the complete system.

Now the kinetic energy of the antineutrino $T_{\bar{\nu}}$ is fixed in terms of that of the electron and the energy release of the decay $Q$ by:

$$
T_{\bar{\nu}}=Q-T_{e}
$$

Here the kinetic energy of the final nucleus is ignored. The heavy final nucleus is unselfish enough to assure that momentum conservation is satisfied for whatever the momenta of the electron and antineutrino are, without demanding a noticeable share of the energy for itself. That is much like Mother Earth does not take any of the kinetic energy away if you shoot rockets out to space from different locations. You might write equations down for it, but the only thing they are going to tell you is that it is true as long as the speed of the nucleus does not get close to the speed of light. Beta decays do not release that much energy by far.

The electron and antineutrino kinetic energies are related to their momenta by Einstein's relativistic expression, chapter 1.1.2:

$$
\begin{equation*}
T_{e}=\sqrt{\left(m_{\mathrm{e}} c^{2}\right)^{2}+p_{e}^{2} c^{2}}-m_{\mathrm{e}} c^{2} \quad T_{\bar{\nu}}=p_{\bar{\nu}} c \tag{A.281}
\end{equation*}
$$

where $c$ is the speed of light and the extremely small rest mass of the neutrino was ignored. With the neutrino energy fixed, so is the magnitude of the neutrino
momentum:

$$
p_{\bar{\nu}}=\frac{1}{c}\left(Q-T_{e}\right)
$$

These result shows that the neutrino momentum is fixed for given electron momentum $p_{e}$. Therefore there should not be a neutrino momentum range $\mathrm{d} p_{\bar{\nu}}$ and so no neutrino states. However, Fermi's golden rule says that the theoretical energy after the decay does not need to be exactly the same as the one before it, because both energies have a bit of uncertainty. This slop in the energy conservation equation allows a range of energies

$$
\Delta E_{\text {slop }}=\Delta T_{\bar{\nu}}=\Delta p_{\bar{\nu}} c \equiv \varepsilon
$$

Therefore the total amount of neutrino states for a given electron momentum is not zero, but

$$
\Delta N_{\bar{\nu}}=\frac{\mathcal{V} p_{\bar{\nu}}^{2}}{2 \pi^{2} \hbar^{3}} \frac{1}{c} \varepsilon \quad p_{\bar{\nu}}=\frac{1}{c}\left(Q-T_{e}\right)
$$

The number of complete system states in an electron momentum range $\mathrm{d} p_{e}$ is the product of the number of electron states times the number of antineutrino states:

$$
\mathrm{d} N=\mathrm{d} N_{e} \Delta N_{\bar{\nu}}=\frac{\mathcal{V}^{2}}{4 \pi^{4} \hbar^{6} c} p_{e}^{2} p_{\bar{\nu}}^{2} \varepsilon \mathrm{~d} p_{e}
$$

Each of these states adds a contribution to the specific decay rate given by

$$
\lambda_{\text {single final state }}=\frac{2 \pi}{\hbar \varepsilon}\left|H_{21}^{\ell}\right|^{2}
$$

Therefore the total specific decay rate is

$$
\lambda=\int_{p_{e}=0}^{p_{e, \text { max }}} \frac{\mathcal{V}^{2}\left|H_{21}^{\ell}\right|^{2}}{2 \pi^{3} \hbar^{7} c} p_{e}^{2} p_{\bar{\nu}}^{2} \mathrm{~d} p_{e}
$$

where the maximum electron momentum $p_{e, \max }$ can be computed from the $Q$ value of the decay using (A.281). (For simplicity it will be assumed that $\left|H_{21}^{\ell}\right|^{2}$ has already been averaged over all directions of the electron and antineutrino momentum.)

The derived expression (A.277) for the Hamiltonian coefficient $H_{21}^{\ell}$ can be written in the form

$$
\begin{gathered}
\left|H_{21}^{\ell}\right|^{2}=\frac{g^{2}}{\mathcal{V}^{2}} \frac{1}{(\ell!)^{2}}\left(\frac{\sqrt{p_{e}^{2}+p_{\bar{\nu}}^{2}} R}{\hbar}\right)^{2 \ell} C_{N}^{\ell} \\
C_{N}^{\ell} \equiv \\
\left|\left\langle\psi_{2, \text { nuc }} \left\lvert\, \sum_{i=1}^{A} h_{i}\left(\frac{\left(\vec{p}_{e}+\vec{p}_{\bar{\nu}}\right) \cdot \vec{r}_{i}}{\sqrt{p_{e}^{2}+p_{\bar{\nu}}^{2}} R}\right)^{\ell} \psi_{1, \text { nuc }}\right.\right\rangle\right|^{2}
\end{gathered}
$$

where the overline indicates some suitable average over the directions of the electron and antineutrino momenta.

It is not easy to say much about $C_{N}^{\ell}$ in general, beyond the fact that its magnitude should not be much more than one. This book will essentially ignore $C_{N}^{\ell}$ to ballpark the decay rate, assuming that its variation will surely be much less than that of the beta decay lifetimes, which vary from milliseconds to $10^{17}$ year.

The decay rate becomes after clean up

$$
\begin{equation*}
\lambda=\frac{1}{2 \pi^{3}} \frac{g^{2} m_{\mathrm{e}}^{4} c^{2}}{\hbar^{6}} \frac{m_{\mathrm{e}} c^{2}}{\hbar} \frac{\tilde{R}^{2 \ell}}{(\ell!)^{2}} C_{N}^{\ell} \int_{\tilde{p}_{e}=0}^{\tilde{p}_{e, \text { max }}}\left(\tilde{p}_{e}^{2}+\tilde{p}_{\bar{\nu}}^{2}\right)^{\ell} \tilde{p}_{e}^{2} \tilde{p}_{\tilde{\nu}}^{2} F^{\ell} \mathrm{d} \tilde{p}_{e} \tag{A.282}
\end{equation*}
$$

where the $\tilde{p}$ indicate the electron and antineutrino momenta nondimensionalized with $m_{\mathrm{e}} c$. Also,

$$
\begin{equation*}
\tilde{Q} \equiv \frac{Q}{m_{\mathrm{e}} c^{2}} \quad \tilde{p}_{e, \max }=\sqrt{\tilde{Q}^{2}+2 \tilde{Q}} \quad \tilde{p}_{\bar{\nu}}=\tilde{Q}-\sqrt{1+\tilde{p}_{e}^{2}}+1 \quad \tilde{R} \equiv \frac{m_{\mathrm{e}} c R}{\hbar} \tag{A.283}
\end{equation*}
$$

Here $\tilde{Q}$ is the $Q$-value or kinetic energy release of the decay in units of the electron rest mass, and the next two relations follow from the expression for the relativistic kinetic energy. The variable $\tilde{R}$ a suitably nondimensionalized nuclear radius, and is small.

The factor $F^{\ell}$ that popped up out of nothing in the decay rate is thrown in to correct for the fact that the wave function of the electron is not really just an exponential. The nucleus pulls on the electron with its charge, and so changes its wave function locally significantly. The correction factor $F^{0}$ for allowed decays is called the "Fermi function" and is given by

$$
\begin{align*}
& F\left(\tilde{p}_{e}, Z_{2}, A\right)=\frac{2(1+\xi)}{\Gamma^{2}(1+2 \xi)} \frac{1}{\left(2 \tilde{p}_{e} \tilde{R}\right)^{2-2 \xi}} e^{\pi \eta}|\Gamma(\xi+\mathrm{i} \eta)|^{2}  \tag{A.284}\\
& \xi \equiv \sqrt{1-\left(\alpha Z_{2}\right)^{2}} \quad \eta \equiv \alpha Z_{2} \frac{\sqrt{1+\tilde{p}_{e}^{2}}}{\tilde{p}_{e}} \quad \alpha=\frac{e^{2}}{4 \pi \epsilon_{0} \hbar c} \approx \frac{1}{137}
\end{align*}
$$

where $\alpha$ is the fine structure constant and $\Gamma$ the gamma function. The nonrelativistic version follows for letting the speed of light go to infinity, while keeping $p_{e}=m_{\mathrm{e}} c \tilde{p}_{e}$ finite. That gives $\xi=1$ and

$$
F\left(p_{e}, Z_{2}\right)=\frac{2 \pi \eta}{1-e^{-2 \pi \eta}} \quad \eta=\frac{e^{2}}{4 \pi \epsilon_{0} \hbar} \frac{m_{\mathrm{e}}}{p_{e}}
$$

For beta-plus decay, just replace $Z_{2}$ by $-Z_{2}$, because an electron is just as much repelled by a negatively charged nucleus as a positron is by a positively charged one.

To ballpark the effect of the nuclear charge on the electron wave function, this book will use the relativistic Fermi function above whether it is an allowed decay or not.

For allowed decays, the factor in the decay rate that is governed by the $Q-$ value and nuclear charge is

$$
\begin{equation*}
f=\int_{\tilde{p}_{e}=0}^{\tilde{p}_{e, \text { max }}} \tilde{p}_{e}^{2} \tilde{p}_{\bar{\nu}}^{2} F \mathrm{~d} \tilde{p}_{e} \tag{A.285}
\end{equation*}
$$

This quantity is known as the "Fermi integral." Typical values are shown in figure 14.52 .

Note that $f$ also depends a bit on the mass number through the nuclear radius in $F$. The figure used

$$
\begin{equation*}
A=1.82+1.9 Z_{2}+0.01271 Z_{2}^{2}-0.00006 Z_{2}^{3} \tag{A.286}
\end{equation*}
$$

for beta-minus decay and

$$
\begin{equation*}
A=-1.9+1.96 Z_{2}+0.0079 Z_{2}^{2}-0.00002 Z_{2}^{3} \tag{A.287}
\end{equation*}
$$

for beta-plus decay, [23].

## A.45.7 Electron capture

Electron capture is much more simply to analyze than beta decay, because the captured electron is in a known initial state.

It will be assumed that a 1s, or K-shell, electron is captured, though L-shell capture may also contribute to the decay rate for heavy nuclei. The Hamiltonian coefficient that drives the decay is

$$
\left.H_{21}=\left\langle 1 \bar{\nu}, \vec{p}_{\bar{\nu}}\right|\langle 0 e, 1 \mathrm{~s}| \psi_{2, \text { nuc }}\left|H^{\prime} \psi_{1, \text { nuc }}\right| 1 e, 1 \mathrm{~s}\right\rangle\left|0 \bar{\nu}, \vec{p}_{\bar{\nu}}\right\rangle
$$

In this case, it is an electron annihilation term in the Hamiltonian that will produce a nonzero term. However, the result will be the pretty much same; the Hamiltonian coefficient simplifies to

$$
H_{21}=\frac{g}{\sqrt{\mathcal{V}}}\left\langle\psi_{2, \text { nuc }} \mid \sum_{i=1}^{A} g h_{i} \psi_{100}\left(\vec{r}_{i}\right) e^{\mathrm{i} \vec{p}_{\bar{\nu}} \cdot \vec{r}_{i} / \hbar} \psi_{1, \text { nuc }}\right\rangle
$$

Here $\psi_{100}$ is the hydrogen ground state wave function, but rescaled for a nucleus of charge $Z e$ instead of $e$. It does not contribute to making forbidden decays possible, because $\psi_{100}$ is spherically symmetric. In other words, the 1 s electron has no orbital angular momentum and so cannot contribute to conservation of angular momentum and parity. Therefore, $\psi_{100}$ can safely be approximated by its value at the origin, from chapter 4.3,

$$
\psi_{100}\left(\vec{r}_{i}\right) \approx \frac{1}{\sqrt{\pi a_{0}^{3}}} \quad a_{0}=\frac{4 \pi \epsilon_{0} \hbar^{2}}{m_{\mathrm{e}} e^{2} Z_{1}}=\frac{\hbar}{m_{\mathrm{e}} c \alpha Z_{1}}
$$

where $\alpha$ is the fine-structure constant
The square Hamiltonian coefficient for $\ell$ th-forbidden decays then becomes

$$
\begin{aligned}
& \left|H_{21}^{\ell}\right|^{2}=\frac{\frac{g^{2}}{\mathcal{V}} \frac{m_{\mathrm{e}}^{3} c^{3} \alpha^{3} Z^{3}}{\pi \hbar^{3}} \frac{1}{(\ell!)^{2}}\left(\frac{p_{\bar{\nu}} R}{\hbar}\right)^{2 \ell} C_{N}^{\ell}}{C_{N}^{\ell}=\equiv\left|\left\langle\psi_{2, \text { nuc }} \left\lvert\, \sum_{i=1}^{A} h_{i}\left(\frac{\vec{p}_{\bar{\nu}} \cdot \vec{r}_{i}}{p_{\bar{\nu}} R}\right)^{\ell} \psi_{1, \text { nuc }}\right.\right\rangle\right|^{2}}
\end{aligned}
$$

The decay rate for electron capture is

$$
\lambda=\frac{2 \pi}{\hbar \varepsilon}\left|H_{21}^{\ell}\right|^{2} \frac{\mathcal{V} p_{\bar{\nu}}^{2}}{2 \pi^{2} \hbar^{3}} \Delta p_{\bar{\nu}} \quad \Delta p_{\bar{\nu}}=\frac{\varepsilon}{c}
$$

where the first ratio is the decay rate of a single state, with $\varepsilon$ the energy slop implied by Fermi's golden rule.

Put it all together, including the fact that there are two K electrons, and the electron-capture decay rate becomes

$$
\begin{equation*}
\lambda=\frac{2}{\pi^{2}} \frac{g^{2} m_{\mathrm{e}}^{4} c^{2}}{\hbar^{6}} \frac{m_{\mathrm{e}} c^{2}}{\hbar}(\alpha Z)^{3} \frac{\tilde{R}^{2 \ell}}{(\ell!)^{2}} C_{N}^{\ell} \tilde{p}_{\bar{\nu}}^{2 \ell} \tilde{p}_{\bar{\nu}}^{2} \tag{A.288}
\end{equation*}
$$

where the $\tilde{p}_{\bar{\nu}}$ indicate the neutrino momentum nondimensionalized with $m_{\mathrm{e}} c$. Also,

$$
\begin{equation*}
\tilde{Q} \equiv \frac{Q}{m_{\mathrm{e}} c^{2}} \quad \tilde{p}_{\bar{\nu}}=\tilde{Q} \quad \tilde{R} \equiv \frac{m_{\mathrm{e}} c R}{\hbar} \tag{A.289}
\end{equation*}
$$

for the coefficients.

## Appendix D

## Derivations

This appendix gives various derivations. Sometimes you need to see the derivation to judge whether a result is applicable in given circumstances. And some people like to see the derivation period.

## D. 1 Generic vector identities

The rules of engagement are as follows:

- The Cartesian axes are numbered using an index $i$, with $i=1,2$, and 3 for $x, y$, and $z$ respectively.
- Also, $r_{i}$ indicates the coordinate in the $i$ direction, $x, y$, or $z$.
- Derivatives with respect to a coordinate $r_{i}$ are indicated by a simple subscript $i$.
- If the quantity being differentiated is a vector, a comma is used to separate the vector index from differentiation ones.
- Index $\bar{\imath}$ is the number immediately following $i$ in the cyclic sequence .. 123123... and $\overline{\bar{\imath}}$ is the number immediately preceding $i$.
The first identity to be derived involves the "vectorial triple product:"

$$
\begin{equation*}
\nabla \times \nabla \times \vec{v}=\nabla(\nabla \cdot \vec{v})-\nabla^{2} \vec{v} \tag{D.1}
\end{equation*}
$$

To do so, first note that the $i$-th component of $\nabla \times \vec{v}$ is given by

$$
v_{\overline{\bar{i}, \bar{\iota}}}-v_{\bar{i}, \overline{\bar{\imath}}}
$$

Repeating the rule, the $i$-th component of $\nabla \times \nabla \times \vec{v}$ is

$$
\left(v_{\bar{\imath}, i}-v_{i, \bar{\imath}}\right)_{\bar{\imath}}-\left(v_{i, \overline{\bar{\imath}}}-v_{\overline{\bar{\imath}}, i}\right)_{\overline{\bar{\imath}}}
$$

That writes out to

$$
v_{i, i i}+v_{\bar{\imath}, \bar{\imath} i}+v_{\overline{\bar{\imath}}, \overline{\bar{\imath}} i}-v_{i, i i}-v_{i, \bar{\imath}}-v_{i, \overline{\bar{u}}}
$$

since the first and fourth terms cancel each other. The first three terms can be recognized as the $i$-th component of $\nabla(\nabla \cdot \vec{v})$ and the last three as the $i$-th component of $-\nabla^{2} \vec{v}_{i}$.

A second identity to be derived involves the "scalar triple product:"

$$
\begin{equation*}
(\vec{a} \times \vec{b}) \cdot \vec{c}=\vec{a} \cdot(\vec{b} \times \vec{c}) \tag{D.2}
\end{equation*}
$$

This is easiest derived from simply writing it out. The left hand side is

$$
a_{y} b_{z} c_{x}-a_{z} b_{y} c_{x}+a_{z} b_{x} c_{y}-a_{x} b_{z} c_{y}+a_{x} b_{y} c_{z}-a_{y} b_{x} c_{z}
$$

while the right hand side is

$$
a_{x} b_{y} c_{z}-a_{x} b_{z} c_{y}+a_{y} b_{z} c_{x}-a_{y} b_{x} c_{z}+a_{z} b_{x} c_{y}-a_{z} b_{y} c_{x}
$$

Inspection shows it to be the same terms in a different order. Note that since no order changes occur, the three vectors may be noncommuting operators.

## D. 2 Some Green's functions

## D.2.1 The Poisson equation

The so-called "Poisson equation" is

$$
-\nabla^{2} u=f \quad \nabla \equiv \hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

Here $f$ is supposed to be a given function and $u$ an unknown function that is to be found.

The solution $u$ to the Poisson equation in infinite space may be found in terms of its so-called "Green's function" $G(\vec{r})$. In particular:

$$
u(\vec{r})=\int_{\operatorname{all} \underline{\underline{r}}} G(\vec{r}-\overrightarrow{\underline{r}}) f(\underline{\vec{r}}) \mathrm{d}^{3} \underline{\vec{r}} \quad G(\vec{r}-\overrightarrow{\underline{r}})=\frac{1}{4 \pi|\vec{r}-\underline{\vec{r}}|}
$$

Loosely speaking, the above integral solution chops function $f$ up into spikes $f(\underline{\vec{r}}) \mathrm{d}^{3} \underline{\vec{r}}$. A spike at a position $\underline{\vec{r}}$ then makes a contribution $G(\vec{r}-\underline{\vec{r}}) f(\underline{\vec{r}}) \mathrm{d}^{3} \underline{\vec{r}}$ to $u$ at $\vec{r}$. Integration over all such spikes gives the complete $u$.

Note that often, the Poisson equation is written without a minus sign. Then there will be a minus sign in $G$.

The objective is now to derive the above Green's function. To do so, first an intuitive derivation will be given and then a more rigorous one. (See also chapter 13.3.4 for a more physical derivation in terms of electrostatics.)

The intuitive derivation defines $G(\vec{r})$ as the solution due to a unit spike, i.e. a "delta function," located at the origin. That means that $G=G(\vec{r})$ is the solution to

$$
\nabla^{2} G=\delta^{3} \quad \text { with } \quad G(\vec{r}) \rightarrow 0 \quad \text { when } \quad \vec{r} \rightarrow \infty
$$

Here $\delta^{3}=\delta^{3}(\vec{r})$ is the three-dimensional delta function, defined as an infinite spike at the origin that integrates to 1 .

By itself the above definition is of course meaningless: infinity is not a valid number. To give it meaning, it is necessary to define an approximate delta function, one that is merely a large spike rather than an infinite one. This approximate delta function $\delta_{\varepsilon}^{3}=\delta_{\varepsilon}^{3}(\vec{r})$ must still integrate to 1 and will be required to be zero beyond some small distance $\varepsilon$ from the origin:

$$
\int \delta_{\varepsilon}^{3}(\vec{r}) \mathrm{d}^{3} \vec{r}=1 \quad \text { and } \quad \delta_{\varepsilon}^{3}(\vec{r})=0 \quad \text { if } \quad r=|\vec{r}| \geqslant \varepsilon
$$

In the above integral the region of integration should at least include the small region of radius $\varepsilon$ around the origin. The approximate delta function will further be assumed to be nonnegative. It must have large values in the small vicinity around the origin where it is nonzero; otherwise the integral over the small vicinity would be small instead of 1 . But the key is that the values are not infinite, just large. So normal mathematics can be used.

The corresponding approximate Green's function $G_{\varepsilon}=G_{\varepsilon}(\vec{r})$ of the Poisson equation satisfies

$$
-\nabla^{2} G_{\varepsilon}=\delta_{\varepsilon}^{3} \quad \text { with } \quad G_{\varepsilon} \rightarrow 0 \quad \text { when } \quad \vec{r} \rightarrow \infty
$$

In the limit $\varepsilon \rightarrow 0, \delta_{\varepsilon}^{3}(\vec{r})$ becomes the Dirac delta function $\delta^{3}(\vec{r})$ and $G_{\varepsilon}(\vec{r})$ becomes the exact Green's function $G(\vec{r})$.

To find the approximate Green's function, it will be assumed that $\delta_{\varepsilon}^{3}(\vec{r})$ only depends on the distance $r=|\vec{r}|$ from the origin. In other words, it is assumed to be spherically symmetric. Then so is $G_{\varepsilon}$. (Note that this assumption is not strictly necessary. That can be seen from the general solution for the Poisson equation given earlier. But it should at least be assumed that $\delta_{\varepsilon}^{3}(\vec{r})$ is nonnegative. If it could have arbitrarily large negative values, then $G_{\varepsilon}$ could be anything.)

Now integrate both sides of the Poisson equation over a sphere of a chosen radius $r$ :

$$
-\int_{|\overrightarrow{\underline{q}}| \leqslant r} \nabla^{2} G_{\varepsilon} \mathrm{d}^{3} \overrightarrow{\underline{r}}=\int_{|\underline{\underline{r}}| \leqslant r} \delta_{\varepsilon}^{3} \mathrm{~d}^{3} \overrightarrow{\underline{r}}
$$

As noted, the delta function integrates to 1 as long as the vicinity of the origin is included. That means that the right hand side is 1 as long as $r \geqslant \varepsilon$. This will now be assumed. The left hand side can be written out. That gives

$$
-\int_{|\overrightarrow{\underline{r}}| \leqslant r} \nabla \cdot\left(\nabla G_{\varepsilon}\right) \mathrm{d}^{3} \underline{\vec{r}}=1 \quad \text { if } \quad r \geqslant \varepsilon
$$

According to the [divergence] [Gauss] [Ostrogradsky] theorem, the left hand side can be written as a surface integral to give

$$
-\int_{|\overrightarrow{\mid r}|=r} \vec{n} \cdot\left(\nabla G_{\varepsilon}\right) \mathrm{d} S=1 \quad \text { if } \quad r \geqslant \varepsilon
$$

Here $S$ stands for the surface of the sphere of radius $r$. The total surface is $4 \pi r^{2}$. Also $\vec{n}$ is the unit vector orthogonal to the surface, in the outward direction. That is the radial direction. The total differential of calculus then implies that $\vec{n} \cdot \nabla G_{\varepsilon}$ is the radial derivative $\partial G_{\varepsilon} / \partial r$. So,

$$
-\frac{\partial G_{\varepsilon}}{\partial r} 4 \pi r^{2}=1 \quad \text { if } \quad r \geqslant \varepsilon
$$

Because $G_{\varepsilon}$ is required to vanish at large distances, this integrates to

$$
G_{\varepsilon}=\frac{1}{4 \pi r} \quad \text { if } \quad r \geqslant \varepsilon
$$

The exact Green's function $G$ has $\varepsilon$ equal to zero, so

$$
G=\frac{1}{4 \pi r} \quad \text { if } \quad r \neq 0
$$

Finally the rigorous derivation without using poorly defined things like delta functions. In the supposed general solution of the Poisson equation given earlier, change integration variable to $\vec{\rho}=\underline{\vec{r}}-\vec{r}$

$$
u(\vec{r})=\int_{\operatorname{all} \vec{r}} G(\vec{r}-\underline{\vec{r}}) f(\underline{\vec{r}}) \mathrm{d}^{3} \underline{\vec{r}}=\int_{\operatorname{all} \vec{\rho}} G(\vec{\rho}) f(\vec{r}+\vec{\rho}) \mathrm{d}^{3} \vec{\rho} \quad G(\vec{\rho})=\frac{1}{4 \pi|\vec{\rho}|}
$$

It is to be shown that the function $u$ defined this way satisfies the Poisson equation $\nabla^{2} u(\vec{r})=f(\vec{r})$. To do so, apply $\nabla$ twice:

$$
\nabla^{2} u(\vec{r})=\int_{\operatorname{all} \vec{\rho}} G(\vec{\rho}) \nabla^{2} f(\vec{r}+\vec{\rho}) \mathrm{d}^{3} \vec{\rho}=\int_{\text {all } \vec{\rho}} G(\vec{\rho}) \nabla_{\rho}^{2} f(\vec{r}+\vec{\rho}) \mathrm{d}^{3} \vec{\rho}
$$

Here $\nabla_{\rho}$ means differentiation with respect to the components of $\vec{\rho}$ instead of the components of $\vec{r}$. Because $f$ depends only on $\vec{r}+\vec{\rho}$, you get the same answer whichever way you differentiate.

It will be assumed that the function $f$ is well behaved, at least continuous, and becomes zero reasonably quickly at infinity. In that case, you can get a valid approximation to the integral above if you exclude very small and very large values of $\vec{r}$ :

$$
\nabla^{2} u(\vec{r}) \approx \int_{\varepsilon<|\vec{p}|<R} G(\vec{\rho}) \nabla_{\rho}^{2} f(\vec{r}+\vec{\rho}) \mathrm{d}^{3} \vec{\rho}
$$

In particular, this approximation becomes exact in the limits where the constants $\varepsilon \rightarrow 0$ and $R \rightarrow \infty$. The integral can now be rewritten as
$\nabla^{2} u(\vec{r}) \approx \int_{\varepsilon<|\vec{\rho}|<R} \nabla_{\rho}\left[G(\vec{\rho}) \nabla_{\rho} f(\vec{r}+\vec{\rho})\right]-\nabla_{\rho}\left[f(\vec{r}+\vec{\rho}) \nabla_{\rho} G(\vec{\rho})\right]+f(\vec{r}+\vec{\rho}) \nabla_{\rho}^{2} G(\vec{\rho}) \mathrm{d}^{3} \vec{\rho}$
as can be verified by explicitly differentiating out the three terms of the integrand. Next note that the third term is zero, because as seen above $G$ satisfies the homogeneous Poisson equation away from the origin. And the other two terms can be written out using the [divergence] [Gauss] [Ostrogradsky] theorem much like before. This produces integrals over both the bounding sphere of radius $R$, as well as over the bounding sphere of radius $\varepsilon$. But the integrals over the sphere of radius $R$ will be vanishingly small if $f$ becomes zero sufficiently quickly at infinity. Similarly, the integral of the first term over the small sphere is vanishingly small, because $G$ is $1 / 4 \pi \varepsilon$ on the small sphere but the surface of the small sphere is $4 \pi \varepsilon^{2}$. However, in the second term, the derivative of $G$ in the negative radial direction is $1 / 4 \pi \varepsilon^{2}$, which multiplies to 1 against the surface of the small sphere. Therefore the second term produces the average of $f(\vec{r}+\vec{\rho})$ over the small sphere, and that becomes $f(\vec{r})$ in the limit $|\vec{\rho}|=\varepsilon \rightarrow 0$. So the Poisson equation applies.

## D.2.2 The screened Poisson equation

The so-called "screened Poisson equation" is

$$
-\nabla^{2} u+c^{2} u=f \quad \nabla \equiv \hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

Here $f$ is supposed to be a given function and $u$ an unknown function that is to be found. Further $c$ is a given constant. If $c$ is zero, this is the Poisson equation. However, nonzero $c$ corresponds to the inhomogeneous steady KleinGordon equation for a particle with nonzero mass.

The analysis of the screened Poisson equation is almost the same as for the Poisson equation given in the previous subsection. Therefore only the differences will be noted here. The approximate Green's function must satisfy, away from the origin,

$$
-\nabla^{2} G_{\varepsilon}+c^{2} G_{\varepsilon}=0 \quad \text { if } \quad r \geqslant \varepsilon
$$

The solution to this that vanishes at infinity is of the form

$$
G_{\varepsilon}=C \frac{e^{-c r}}{r} \quad \text { if } \quad r \geqslant \varepsilon
$$

where $C$ is some constant. To check this, plug it in, using the expression (N.5) for $\nabla^{2}$ in spherical coordinates. To identify the constant $C$, integrate the full equation

$$
-\nabla^{2} G_{\varepsilon}+c^{2} G_{\varepsilon}=\delta_{\varepsilon}^{3}
$$

over a sphere of radius $\varepsilon$ around the origin and apply the divergence theorem as in the previous subsection. Taking the limit $\varepsilon \rightarrow 0$ then gives $C=1 / 4 \pi$, which gives the exact Green's function as

$$
G(\vec{r})=\frac{e^{-c r}}{4 \pi r} \quad \text { if } \quad r=|\vec{r}| \neq 0
$$

The rigorous derivation is the same as before save for an additional $c^{2} G f$ term in the integrand, which drops out against the $-f \nabla_{\rho}^{2} G$ one.

## D. 3 Lagrangian mechanics

This note gives the derivations for the addendum on the Lagrangian equations of motion.

## D.3.1 Lagrangian equations of motion

To derive the nonrelativistic Lagrangian, consider the system to be build up from elementary particles numbered by an index $j$. You may think of these particles as the atoms you would use if you would do a molecular dynamics computation of the system. Because the system is assumed to be fully determined by the generalized coordinates, the position of each individual particle is fully fixed by the generalized coordinates and maybe time. (For example, it is implicit in a solid body approximation that the atoms are held rigidly in their relative position. Of course, that is approximate; you pay some price for avoiding a full molecular dynamics simulation.)

Newton's second law says that the motion of each individual particle $j$ is governed by

$$
m_{j} \frac{\mathrm{~d}^{2} \vec{r}_{j}}{\mathrm{~d} t^{2}}=-\frac{\partial V}{\partial \vec{r}_{j}}+\vec{F}_{j}^{\prime}
$$

where the derivative of the potential $V$ can be taken to be its gradient, if you (justly) object to differentiating with respect to vectors, and $\vec{F}_{j}^{\prime}$ indicates any part of the force not described by the potential.

Now consider an infinitesimal virtual displacement of the system from its normal evolution in time. It produces an infinitesimal change in position $\delta \vec{r}_{j}(t)$ for each particle. After such a displacement, $\vec{r}_{j}+\delta \vec{r}_{j}$ of course no longer satisfies the correct equations of motion, but the kinetic and potential energies still exist.

In the equation of motion for the correct position $\vec{r}_{j}$ above, take the mass times acceleration to the other side, multiply by the virtual displacement, sum over all particles $j$, and integrate over an arbitrary time interval:

$$
0=\int_{t_{1}}^{t_{2}} \sum_{j}\left[-m_{j} \frac{\mathrm{~d}^{2} \vec{r}_{j}}{\mathrm{~d} t^{2}}-\frac{\partial V}{\partial \vec{r}_{j}}+\vec{F}_{j}^{\prime}\right] \cdot \delta \vec{r}_{j} \mathrm{~d} t
$$

Multiply out and integrate the first term by parts:

$$
0=\int_{t_{1}}^{t_{2}} \sum_{j}\left[m_{j} \frac{\mathrm{~d} \vec{r}_{j}}{\mathrm{~d} t} \cdot \delta \frac{\mathrm{~d} \vec{r}_{j}}{\mathrm{~d} t}-\frac{\partial V}{\partial \vec{r}_{j}} \cdot \delta \vec{r}_{j}+\vec{F}_{j}^{\prime} \delta \vec{r}_{j}\right] \mathrm{d} t
$$

The virtual displacements of interest here are only nonzero over a limited range of times, so the integration by parts did not produce any end point values.

Recognize the first two terms within the brackets as the virtual change in the Lagrangian due to the virtual displacement at that time. Note that this requires that the potential energy depends only on the position coordinates and time, and not also on the time derivatives of the position coordinates. You get

$$
\begin{equation*}
0=\delta \int_{t_{1}}^{t_{2}} \mathcal{L} \mathrm{~d} t+\int_{t_{1}}^{t_{2}} \sum_{j}\left[\vec{F}_{j}^{\prime} \cdot \delta \vec{r}_{j}\right] \mathrm{d} t \tag{D.3}
\end{equation*}
$$

In case that the additional forces $\vec{F}_{j}^{\prime}$ are zero, this produces the action principle: the time integral of the Lagrangian is unchanged under infinitesimal virtual displacements of the system, assuming that they vanish at the end points of integration. More generally, for the virtual work by the additional forces to be zero will require that the virtual displacements respect the rigid constraints, if any. The infinite work done in violating a rigid constraint is not modeled by the potential $V$ in any normal implementation.

Unchanging action is an integral equation involving the Lagrangian. To get ordinary differential equations, take the virtual change in position to be that due to an infinitesimal change $\delta q_{k}(t)$ in a single generic generalized coordinate. Represent the change in the Lagrangian in the expression above by its partial derivatives, and the same for $\delta \vec{r}_{j}$ :

$$
0=\int_{t_{1}}^{t_{2}}\left[\frac{\partial \mathcal{L}}{\partial q_{k}} \delta q_{k}+\frac{\partial \mathcal{L}}{\partial \dot{q}_{k}} \delta \dot{q}_{k}\right] \mathrm{d} t+\int_{t_{1}}^{t_{2}} \sum_{j}\left[\vec{F}_{j}^{\prime} \cdot \frac{\partial \vec{r}_{j}}{\partial q_{k}} \delta q_{k}\right] \mathrm{d} t
$$

The integrand in the final term is by definition the generalized force $Q_{k}$ multiplied by $\delta q_{k}$. In the first integral, the second term can be integrated by parts, and then the integrals can be combined to give

$$
0=\int_{t_{1}}^{t_{2}}\left[\frac{\partial \mathcal{L}}{\partial q_{k}}-\frac{\mathrm{d}}{\mathrm{~d} t}\left(\frac{\partial \mathcal{L}}{\partial \dot{q}_{k}}\right)+Q_{k}\right] \delta q_{k} \mathrm{~d} t
$$

Now suppose that there is any time at which the expression within the square brackets is nonzero. Then a virtual change $\delta q_{k}$ that is only nonzero in a very small time interval around that time, and everywhere positive in that small interval, would produce a nonzero right hand side in the above equation, but it must be zero. Therefore, the expression within brackets must be zero at all times. That gives the Lagrangian equations of motion, because the expression between parentheses is defined as the canonical momentum.

## D.3.2 Hamiltonian dynamics

To derive the Hamiltonian equations, consider the general differential of the Hamiltonian function (regardless of any motion that may go on). According to
the given definition of the Hamiltonian function, and using a total differential for $\mathrm{d} \mathcal{L}$,

$$
\mathrm{d} H=\left(\sum_{k} p_{k}^{\mathrm{c}} \mathrm{~d} \dot{q}_{k}\right)+\sum_{k} \dot{q}_{k} \mathrm{~d} p_{k}^{\mathrm{c}}-\sum_{k} \frac{\partial \mathcal{L}}{\partial q_{k}} \mathrm{~d} q_{k}-\left(\sum_{k} \frac{\partial \mathcal{L}}{\partial \dot{q}_{k}} \mathrm{~d} \dot{q}_{k}\right)-\frac{\partial \mathcal{L}}{\partial t} \mathrm{~d} t
$$

The sums within parentheses cancel each other because of the definition of the canonical momentum. The remaining differences are of the arguments of the Hamiltonian function, and so by the very definition of partial derivatives,

$$
\frac{\partial H}{\partial q_{k}}=-\frac{\partial \mathcal{L}}{\partial q_{k}} \quad \frac{\partial H}{\partial p_{k}^{c}}=\dot{q}_{k} \quad \frac{\partial H}{\partial t}=-\frac{\partial \mathcal{L}}{\partial t}
$$

Now consider an actual motion. For an actual motion, $\dot{q}_{k}$ is the time derivative of $q_{k}$, so the second partial derivative gives the first Hamiltonian equation of motion. The first partial derivative gives the second equation when combined with the Lagrangian equation of motion (A.2).

It is still to be shown that the Hamiltonian of a classical system is the sum of kinetic and potential energy if the position of the system does not depend explicitly on time. The Lagrangian can be written out in terms of the system particles as

$$
\sum_{j} \sum_{\underline{k}=1}^{K} \sum_{\underline{\underline{k}}=1}^{K} \frac{1}{2} m_{j} \frac{\partial \vec{r}_{j}}{\partial q_{\underline{k}}} \cdot \frac{\partial \vec{r}_{j}}{\partial q_{\underline{\underline{k}}}} \dot{q}_{\underline{k}} \dot{q}_{\underline{\underline{k}}}-V\left(q_{1}, q_{2}, \ldots, q_{K}, t\right)
$$

where the sum represents the kinetic energy. The Hamiltonian is defined as

$$
\sum_{k} \dot{q}_{k} \frac{\partial \mathcal{L}}{\partial \dot{q}_{k}}-\mathcal{L}
$$

and straight substitution shows the first term to be twice the kinetic energy.

## D.3.3 Fields

As discussed in \{A.1.5\}, the Lagrangian for fields takes the form

$$
\mathcal{L}=\mathcal{L}_{0}+\int £ \mathrm{~d}^{3} \vec{r}
$$

Here the spatial integration is over all space. The first term depends only on the discrete variables

$$
\mathcal{L}_{0}=\mathcal{L}_{0}\left(\ldots ; q_{k}, \dot{q}_{k} ; \ldots\right)
$$

where $q_{k}=q_{k}(t)$ denotes discrete variable number $k$. The dot indicates the time derivative of that variable. The Lagrangian density also depends on the fields

$$
£=£\left(\ldots ; \varphi_{\alpha}, \varphi_{\alpha_{t}}, \varphi_{\alpha_{1}}, \varphi_{\alpha_{2}}, \varphi_{\alpha_{3}} ; \ldots ; q_{k} ; \dot{q}_{k} ; \ldots\right)
$$

where $\varphi_{\alpha}$ is field number $\alpha$. A subscript $t$ indicates the partial time derivative, and 1,2 , or 3 the partial $x, y$ or $z$ derivative.

The action is

$$
\mathcal{S}=\int_{t_{1}}^{t_{2}}\left(\mathcal{L}_{0}+\int £ \mathrm{~d}^{3} \vec{r}\right) \mathrm{d} t
$$

where the time range from $t_{1}$ to $t_{2}$ must include the times of interest. The action must be unchanged under small deviations from the correct evolution, as long as these deviations vanish at the limits of integration. That requirement defines the Lagrangian. (For simple systems the Lagrangian then turns out to be the difference between kinetic and potential energies. But it is not obvious what to make of that if there are fields.)

Consider now first an infinitesimal deviation $\delta q_{k}=\delta q_{k}(t)$ in a discrete variable $q_{k}$. The change in action that must be zero is then

$$
0=\delta \mathcal{S}=\int_{t_{1}}^{t_{2}}\left(\frac{\partial \mathcal{L}_{0}}{\partial q_{k}} \delta q_{k}+\frac{\partial \mathcal{L}_{0}}{\partial \dot{q}_{k}} \delta \dot{q}_{k}+\int \frac{\partial £}{\partial q_{k}} \mathrm{~d}^{3} \vec{r} \delta q_{k}+\int \frac{\partial £}{\partial \dot{q}_{k}} \mathrm{~d}^{3} \vec{r} \delta \dot{q}_{k}\right) \mathrm{d} t
$$

After an integration by parts of the second and fourth terms that becomes, noting that the deviation must vanish at the initial and final times,

$$
0=\delta \mathcal{S}=\int_{t_{1}}^{t_{2}}\left[\frac{\partial \mathcal{L}_{0}}{\partial q_{k}}-\frac{\mathrm{d}}{\mathrm{~d} t} \frac{\partial \mathcal{L}_{0}}{\partial \dot{q}_{k}}+\int \frac{\partial £}{\partial q_{k}} \mathrm{~d}^{3} \vec{r}-\frac{\mathrm{d}}{\mathrm{~d} t} \int \frac{\partial £}{\partial \dot{q}_{k}} \mathrm{~d}^{3} \vec{r}\right] \delta q_{k} \mathrm{~d} t
$$

This can only be zero for whatever you take $\delta q_{k}=\delta q_{k}(t)$ if the expression within square brackets is zero. That gives the final Lagrangian equation for the discrete variable $q_{k}$ as

$$
\begin{equation*}
\frac{\mathrm{d}}{\mathrm{~d} t}\left(\frac{\partial \mathcal{L}_{0}}{\partial \dot{q}_{k}}+\int \frac{\partial £}{\partial \dot{q}_{k}} \mathrm{~d}^{3} \vec{r}\right)=\frac{\partial \mathcal{L}_{0}}{\partial q_{k}}+\int \frac{\partial £}{\partial q_{k}} \mathrm{~d}^{3} \vec{r} \tag{1}
\end{equation*}
$$

Next consider an infinitesimal deviation $\delta \varphi_{\alpha}=\delta \varphi_{\alpha}(\vec{r} ; t)$ in field $\varphi_{\alpha}$. The change in action that must be zero is then

$$
0=\delta S=\int_{t_{1}}^{t_{2}} \int\left(\frac{\partial £}{\partial \varphi_{\alpha}} \delta \varphi_{\alpha}+\frac{\partial £}{\partial \varphi_{\alpha_{t}}} \delta \varphi_{\alpha_{t}}+\sum_{i=1}^{3} \frac{\partial £}{\partial \varphi_{\alpha_{i}}} \delta \varphi_{\alpha_{i}}\right) \mathrm{d}^{3} \vec{r} \mathrm{~d} t
$$

Now integrate the derivative terms by parts in the appropriate direction to get, noting that the deviation must vanish at the limits of integration,

$$
0=\delta S=\int_{t_{1}}^{t_{2}} \int\left[\frac{\partial £}{\partial \varphi_{\alpha}}-\frac{\partial}{\partial t}\left(\frac{\partial £}{\partial \varphi_{\alpha_{t}}}\right)-\sum_{i=1}^{3} \frac{\partial}{\partial r_{i}}\left(\frac{\partial £}{\partial \varphi_{\alpha_{i}}}\right)\right] \delta \varphi_{\alpha} \mathrm{d}^{3} \vec{r} \mathrm{~d} t
$$

Here $r_{i}$ for $i=1,2$, or 3 stands for $x, y$, or $z$. If the above expression is to be zero for whatever you take the small change $\delta \varphi_{\alpha}=\delta \varphi_{\alpha}(\vec{r} ; t)$ to be, then the expression within square brackets will have to be zero at every position and time. That gives the equation for the field $\varphi_{\alpha}$ :

$$
\begin{equation*}
\frac{\partial}{\partial t}\left(\frac{\partial £}{\partial \varphi_{\alpha_{t}}}\right)+\sum_{i=1}^{3} \frac{\partial}{\partial r_{i}}\left(\frac{\partial £}{\partial \varphi_{\alpha_{i}}}\right)=\frac{\partial £}{\partial \varphi_{\alpha}} \tag{2}
\end{equation*}
$$

The canonical momenta are defined as

$$
\begin{equation*}
p_{k}^{\mathrm{c}} \equiv \frac{\partial \mathcal{L}_{0}}{\partial \dot{q}_{k}}+\int \frac{\partial £}{\partial \dot{q}_{k}} \mathrm{~d}^{3} \vec{r} \quad \pi_{\alpha}^{\mathrm{c}} \equiv \frac{\partial £}{\partial \varphi_{\alpha_{t}}} \tag{3}
\end{equation*}
$$

These are the quantities inside the time derivatives of the Lagrangian equations.
For Hamilton's equations, assume at first that there are no discrete variables. In that case, the Hamiltonian can be written in terms of a Hamiltonian density $h$ :

$$
H=\int h \mathrm{~d}^{3} \vec{r} \quad h=\sum_{\alpha} \pi_{\alpha}^{\mathrm{c}} \varphi_{\alpha_{t}}-£
$$

Take a differential of the Hamiltonian density

$$
\mathrm{d} h=\sum_{\alpha}\left[\pi_{\alpha}^{\mathrm{c}} \mathrm{~d} \varphi_{\alpha_{t}}+\varphi_{\alpha_{t}} \mathrm{~d} \pi_{\alpha}^{\mathrm{c}}-\frac{\partial £}{\partial \varphi_{\alpha_{t}}} \mathrm{~d} \varphi_{\alpha_{t}}-\frac{\partial £}{\partial \varphi_{\alpha_{i}}} \mathrm{~d} \varphi_{\alpha_{i}}-\frac{\partial £}{\partial \varphi_{\alpha}} \mathrm{d} \varphi_{\alpha}\right]
$$

The first and third terms in the square brackets cancel because of the definition of the canonical momentum. Then according to calculus

$$
\frac{\partial h}{\partial \pi_{\alpha}^{\mathrm{c}}}=\varphi_{\alpha_{t}} \quad \frac{\partial h}{\partial \varphi_{\alpha_{i}}}=-\frac{\partial £}{\partial \varphi_{\alpha_{i}}} \quad \frac{\partial h}{\partial \varphi_{\alpha}}=-\frac{\partial £}{\partial \varphi_{\alpha}}
$$

The first of these expressions gives the time derivative of $\varphi_{\alpha}$. The other expressions may be used to replace the derivatives of the Lagrangian density in the Lagrangian equations of motion (2). That gives Hamilton's equations as

$$
\begin{equation*}
\frac{\partial \varphi_{\alpha}}{\partial t}=\frac{\partial h}{\partial \pi_{\alpha}^{\mathrm{c}}} \quad \frac{\partial \pi_{\alpha}^{\mathrm{c}}}{\partial t}=-\frac{\partial h}{\partial \varphi_{\alpha}}+\sum_{i=1}^{3} \frac{\partial}{\partial r_{i}}\left(\frac{\partial h}{\partial \varphi_{\alpha_{i}}}\right) \tag{4}
\end{equation*}
$$

If there are discrete variables, this no longer works. The full Hamiltonian is then

$$
H=\sum_{k} p_{k}^{\mathrm{c}} \dot{q}_{k}+\int \sum_{\alpha} \pi_{\alpha}^{\mathrm{c}} \varphi_{\alpha_{t}} \mathrm{~d}^{3} \vec{r}-\mathcal{L}_{0}-\int £ \mathrm{~d}^{3} \vec{r}
$$

To find Hamilton's equations, the integrals in this Hamiltonian must be approximated. The region of integration is mentally chopped into little pieces of the same volume $d \mathcal{V}$. Then by approximation

$$
\int £ \mathrm{~d}^{3} \vec{r} \approx \sum_{n} £_{n} \mathrm{~d} \mathcal{V}
$$

Here $n$ numbers the small pieces and $£_{n}$ stands for the value of $£$ at the center point of piece $n$. Note that this is essentially the Riemann sum of calculus. A
similar approximation is made for the other integral in the Hamiltonian, and the one in the canonical momenta (3). Then the approximate Hamiltonian becomes

$$
H_{\mathrm{app}}=\sum_{k} p_{k}^{\mathrm{c}} \dot{q}_{k}+\sum_{\alpha, n} \pi_{\alpha_{n}}^{\mathrm{c}} \varphi_{\alpha_{n}} \mathrm{~d} \mathcal{V}-\mathcal{L}_{0}-\sum_{n} £_{n} \mathrm{~d} \mathcal{V}
$$

The differential of this approximate Hamiltonian is

$$
\begin{aligned}
\mathrm{d} H_{\text {app }}= & \sum_{k} \dot{q}_{k} \mathrm{~d} p_{k}^{\mathrm{c}}+\sum_{k} p_{k}^{\mathrm{c}} \mathrm{~d} \dot{q}_{k}+\sum_{\alpha, n} \varphi_{\alpha t_{n}} \mathrm{~d} \mathcal{V} \mathrm{~d} \pi_{\alpha_{n}}^{\mathrm{c}}+\sum_{\alpha, n} \pi_{\alpha_{n}}^{\mathrm{c}} \mathrm{~d} \mathcal{V} \mathrm{~d} \varphi_{\alpha t_{n}} \\
& -\sum_{k} \frac{\partial \mathcal{L}_{0}}{\partial q_{k}} \mathrm{~d} q_{k}-\sum_{k} \frac{\partial \mathcal{L}_{0}}{\partial \dot{q}_{k}} \mathrm{~d} \dot{q}_{k}-\sum_{k, n} \frac{\partial £_{n}}{\partial q_{k}} \mathrm{~d} \mathcal{V} \mathrm{~d} q_{k}-\sum_{k, n} \frac{\partial £_{n}}{\partial \dot{q}_{k}} \mathrm{~d} \mathcal{V} \mathrm{~d} \dot{q}_{k} \\
& -\sum_{\alpha, n} \frac{\partial £_{n}}{\partial \varphi_{\alpha_{n}}} \mathrm{~d} \mathcal{V} \mathrm{~d} \varphi_{\alpha_{n}}-\sum_{\alpha, n} \frac{\partial £_{n}}{\partial \varphi_{\alpha t_{n}}} \mathrm{~d} \mathcal{V} \mathrm{~d} \varphi_{\alpha t_{n}}-\sum_{\alpha, n, i} \frac{\partial £_{n}}{\partial \varphi_{\alpha_{i_{n}}}} \mathrm{~d} \mathcal{V} \mathrm{~d} \varphi_{\alpha i_{n}}
\end{aligned}
$$

The $\mathrm{d} \dot{q}_{k}$ and $\mathrm{d} \varphi_{\alpha t_{n}}$ terms drop out because of the definitions of the canonical momenta. The remainder allows expressions for the partial derivatives of the approximate Hamiltonian to be identified.

The $\mathrm{d} p_{k}^{\mathrm{c}}$ term allows the time derivative of $q_{k}$ to be identified with the partial derivative of $H_{\text {app }}$ with respect to $p_{k}^{c}$. And the Lagrangian expression for the time derivative of $p_{k}^{c}$, as given in (1), may be rewritten in terms of corresponding derivatives of the approximate Hamiltonian. Together that gives, in the limit $\mathrm{d} \mathcal{V} \rightarrow 0$,

$$
\begin{equation*}
\frac{\mathrm{d} q_{k}}{\mathrm{~d} t}=\frac{\partial H}{\partial p_{k}^{\mathrm{c}}} \quad \frac{\mathrm{~d} p_{k}^{\mathrm{c}}}{\mathrm{~d} t}=-\frac{\partial H}{\partial q_{k}} \tag{5}
\end{equation*}
$$

For the field, consider an position $\vec{r}$ corresponding to the center of an arbitrary little volume $n=\underline{n}$. Then the $\mathrm{d} \pi_{\alpha_{\underline{n}}}^{\mathrm{c}}$ term allows the time derivative of $\varphi_{\alpha}$ at this arbitrary position to be identified in terms of the partial derivative of the approximate Hamiltonian with respect to $\pi_{\alpha}^{\mathrm{c}}$ at the same location. And the Lagrangian expression for the time derivative of $\pi_{\alpha}^{\mathrm{c}}$, as given by (2), may be rewritten in terms of corresponding derivatives of the approximate Hamiltonian. Together that gives, in the limit $\mathrm{d} \mathcal{V} \rightarrow 0$, and leaving $\underline{n}$ away since it can be any position,
$\frac{\partial \varphi_{\alpha}}{\partial t}=\lim _{\mathrm{d} \mathcal{V} \rightarrow 0} \frac{1}{\mathrm{~d} \mathcal{V}} \frac{\partial H_{\text {app }}}{\partial \pi_{\alpha}^{\mathrm{c}}} \quad \frac{\partial \pi_{\alpha}^{\mathrm{c}}}{\partial t}=-\lim _{\mathrm{d} \mathcal{V} \rightarrow 0} \frac{1}{\mathrm{~d} \mathcal{V}} \frac{\partial H_{\text {app }}}{\partial \varphi_{\alpha}}+\sum_{i=1}^{3} \frac{\partial}{\partial r_{i}} \lim _{\mathrm{d} \mathcal{V} \rightarrow 0} \frac{1}{\mathrm{~d} \mathcal{V}} \frac{\partial H_{\text {app }}}{\partial \varphi_{\alpha_{i}}}$ (6)
Of course, in real life you would not actually write out these limits. Instead you simply differentiate the normal Hamiltonian $H$ until you have to start differentiating inside an integral, like maybe,

$$
\frac{\partial}{\partial \varphi_{\alpha}} \int £ \mathrm{~d}^{3} \vec{r}
$$

Then you think to yourself that you are not really evaluating this, but actually

$$
\frac{\partial}{\partial \varphi_{\alpha_{\underline{n}}}} \sum_{n} £_{n} \mathrm{~d} \mathcal{V}=\frac{\partial £_{\underline{n}}}{\partial \varphi_{\alpha_{\underline{n}}}} \mathrm{~d} \mathcal{V}
$$

where $\underline{n}$ indicates the position that you are considering the field at. And you are going to divide out the volume $\mathrm{d} \mathcal{V}$. That then boils down to

$$
\frac{\partial}{\partial \varphi_{\alpha}} \int £ \mathrm{~d}^{3} \vec{r} \quad \Longrightarrow \quad \frac{\partial £}{\partial \varphi_{\alpha}}
$$

even though the left hand side would mathematically be nonsense without discretization and division by $\mathrm{d} \mathcal{V}$.

## D. 4 Lorentz transformation derivation

This note derives the Lorentz transformation as discussed in chapter 1.2. The question is what is the relationship between the time and spatial coordinates $t_{\mathrm{A}}, x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}$ that an observer A attaches to an arbitrary event versus the coordinates $t_{\mathrm{B}}, x_{\mathrm{B}}, y_{\mathrm{B}}, z_{\mathrm{B}}$ that an observer B attaches to them.

Note that since the choices what to define as time zero and as the origin are quite arbitrary, it can be arranged that $x_{\mathrm{B}}, y_{\mathrm{B}}, z_{\mathrm{B}}, t_{\mathrm{B}}$ are all zero when $x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}, t_{\mathrm{A}}$ are all zero. That simplifies the mathematics, so it will be assumed. It will also be assumed that the axis systems of the two observers are taken to be parallel and that the $x$ axes are along the direction of relative motion between the observers, figure 1.2.

It will further be assumed that the relationship between the coordinates is linear;

$$
\begin{array}{cl}
t_{\mathrm{B}}=a_{t x} x_{\mathrm{A}}+a_{t y} y_{\mathrm{A}}+a_{t z} z_{\mathrm{A}}+a_{t t} t_{\mathrm{A}} & y_{\mathrm{B}}=a_{y x} x_{\mathrm{A}}+a_{y y} y_{\mathrm{A}}+a_{y z} z_{\mathrm{A}}+a_{y t} t_{\mathrm{A}} \\
x_{\mathrm{B}}=a_{x x} x_{\mathrm{A}}+a_{x y} y_{\mathrm{A}}+a_{x z} z_{\mathrm{A}}+a_{x t} t_{\mathrm{A}} & z_{\mathrm{B}}=a_{z x} x_{\mathrm{A}}+a_{z y} y_{\mathrm{A}}+a_{z z} z_{\mathrm{A}}+a_{z t} t_{\mathrm{A}}
\end{array}
$$

where the $a_{\text {.. }}$ are constants still to be found.
The biggest reason to assume that the transformation should be linear is that if space is populated with observers A and B, rather than just have a single one sitting at the origin of that coordinate system, then a linear transformation assures that all pairs of observers A and B see the exact same transformation. In addition, the transformation from $x_{\mathrm{B}}, y_{\mathrm{B}}, z_{\mathrm{B}}, t_{\mathrm{B}}$ back to $x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}, t_{\mathrm{A}}$ should be of the same form as the one the other way, since the principle of relativity asserts that the two coordinate systems are equivalent. A linear transformation has a back transformation that is also linear.

Another way to look at it is to say that the spatial and temporal scales seen by normal observers are miniscule compared to the scales of the universe. Based on that idea you would expect that the relation between their coordinates would be a linearized Taylor series.

A lot of additional constraints can be put in because of physical symmetries that surely still apply even allowing for relativity. For example, the transformation to $x_{\mathrm{B}}, t_{\mathrm{B}}$ should not depend on the arbitrarily chosen positive directions of the $y$ and $z$ axes, so throw out the $y$ and $z$ terms in those equations. Seen in a mirror along the $x y$-plane, the $y$ transformation should look the same, even if $z$ changes sign, so throw out $z_{\mathrm{A}}$ from the equation for $y_{\mathrm{B}}$. Similarly, there goes $y_{\mathrm{A}}$ in the equation for $z_{\mathrm{B}}$. Since the choice of $y$ and $z$ axes is arbitrary, the remaining $a_{z}$. coefficients must equal the corresponding $a_{y \text {. }}$. ones. Since the basic premise of relativity is that the coordinate systems $A$ and $B$ are equivalent, the $y$ difference between tracks parallel to the direction of motion cannot get longer for B and shorter for A, nor vice-versa, so $a_{y y}=1$. Finally, by the very definition of the relative velocity $v$ of coordinate system B with respect to system $\mathrm{A}, x_{\mathrm{B}}=$ $y_{\mathrm{B}}=z_{\mathrm{B}}=0$ should correspond to $x_{\mathrm{A}}=v t_{\mathrm{A}}$. And by the principle of relativity, $x_{\mathrm{A}}=y_{\mathrm{A}}=z_{\mathrm{A}}=0$ should correspond to $x_{\mathrm{B}}=-v t_{\mathrm{B}}$.

You might be able to think up some more constraints, but this will do. Put it all together to get

$$
\begin{array}{ll}
t_{\mathrm{B}}=a_{t x} x_{\mathrm{A}}+a_{x x} t_{\mathrm{A}} & y_{\mathrm{B}}=a_{y x} x_{\mathrm{A}}+y_{\mathrm{A}}+a_{y t} t_{\mathrm{A}} \\
x_{\mathrm{B}}=a_{x x}\left(x_{\mathrm{A}}-v t_{\mathrm{A}}\right) & z_{\mathrm{B}}=a_{y x} x_{\mathrm{A}}+z_{\mathrm{A}}+a_{y t} t_{\mathrm{A}}
\end{array}
$$

Next the trick is to consider the wave front emitted by some light source that flashes at time zero at the then coinciding origins. Since according to the principle of relativity the two coordinate systems are fully equivalent, in both coordinate systems the wave front forms an expanding spherical shell with radius $c t$ :

$$
x_{\mathrm{A}}^{2}+y_{\mathrm{A}}^{2}+z_{\mathrm{A}}^{2}=c^{2} t_{\mathrm{A}}^{2} \quad x_{\mathrm{B}}^{2}+y_{\mathrm{B}}^{2}+z_{\mathrm{B}}^{2}=c^{2} t_{\mathrm{B}}^{2}
$$

Plug the linearized expressions for $x_{\mathrm{B}}, y_{\mathrm{B}}, z_{\mathrm{B}}, t_{\mathrm{B}}$ in terms of $x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}, t_{\mathrm{A}}$ into the second equation and demand that it is consistent with the first equation, and you obtain the Lorentz transformation. To get the back transformation giving $x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}, t_{\mathrm{A}}$ in terms of $x_{\mathrm{B}}, y_{\mathrm{B}}, z_{\mathrm{B}}, t_{\mathrm{B}}$, solve the Lorentz equations for $x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}$, and $t_{\mathrm{A}}$.

To derive the given transformations between the velocities seen in the two systems, take differentials of the Lorentz transformation formulae. Then take ratios of the corresponding infinitesimal position increments over the corresponding time increments.

## D. 5 Lorentz group property derivation

This note verifies the group property of the Lorentz transformation. It is not recommended unless you have had a solid course in linear algebra.

Note first that a much more simple argument can be given by defining the Lorentz transformation more abstractly, \{A.4\} (A.13). But that is cheating.

Then you have to prove that these Lorentz transform are always the same as the physical ones.

For simplicity it will be assumed that the observers still use a common origin of space and time coordinates.

The group property is easy to verify if the observers B and C are going in the same direction compared to A. Just multiply two matrices of the form (1.13) together and apply the condition that $\gamma^{2}-\beta^{2} \gamma^{2}=1$ for each.

It gets much messier if the observers move in different directions. In that case the only immediate simplification that can be made is to align the coordinate systems so that both relative velocities are in the $x, y$ planes. Then the transformations only involve $z$ in a trivial way and the combined transformation takes the generic form

$$
\Lambda_{C \leftarrow A}=\left(\begin{array}{cccc}
\lambda^{0}{ }_{0} & \lambda^{0}{ }_{1} & \lambda^{0}{ }_{2} & 0 \\
\lambda^{1}{ }_{0} & \lambda^{1}{ }_{1} & \lambda^{1}{ }_{2} & 0 \\
\lambda^{2}{ }_{0} & \lambda^{2}{ }_{1} & \lambda^{2}{ }_{2} & 0 \\
0 & 0 & 0 & 1
\end{array}\right)
$$

It needs to be shown that this is a Lorentz transformation from A directly to C.

Now the spatial, $x, y$, coordinate system of observer C can be rotated to eliminate $\lambda^{2}{ }_{0}$ and the spatial coordinate system of observer A can be rotated to eliminate $\lambda^{0}{ }_{2}$. Next both Lorentz transformations preserve the inner products. Therefore the dot product between the four-vectors $(1,0,0,0)$ and $(0,0,1,0)$ in the A system must be the same as the dot product between columns 1 and 3 in the matrix above. And that means that $\lambda^{1}{ }_{2}$ must be zero, because $\lambda^{1}{ }_{0}$ will not be zero except in the trivial case that systems A and C are at rest compared to each other. Next since the proper length of the vector $(0,0,1,0)$ equals one in the A system, it does so in the C system, so $\lambda^{2}{ }_{2}$ must be one. (Or minus one, but a $180^{\circ}$ rotation of the spatial coordinate system around the $z$-axis can take care of that.) Next, since the dot product of the vectors $(0,1,0,0)$ and $(0,0,1,0)$ is zero, so is $\lambda^{2}{ }_{1}$.

That leaves the four values relating the time and $x$ components. From the fact that the dot product of the vectors $(1,0,0,0)$ and $(0,1,0,0)$ is zero,

$$
-\lambda^{0}{ }_{0} \lambda^{0}{ }_{1}+\lambda^{1}{ }_{0} \lambda^{1}{ }_{1}=0 \quad \Longrightarrow \quad \frac{\lambda^{0}{ }_{1}}{\lambda^{1}{ }_{1}}=\frac{\lambda^{1}{ }_{0}}{\lambda_{0}{ }_{0}} \equiv \beta
$$

where $\beta$ is some constant. Also, since the proper lengths of these vectors are minus one, respectively one,

$$
-\lambda_{0}^{02}+\lambda_{0}^{12}=-1 \quad-\lambda_{1}^{02}+\lambda_{1}^{1}=1
$$

or substituting in for $\lambda^{0}{ }_{1}$ and $\lambda^{1}{ }_{0}$ from the above

$$
-\lambda_{0}^{02}+\beta^{2} \lambda_{0}^{02}=-1 \quad-\beta^{2} \lambda_{1}^{12}+\lambda_{1}^{1}=1
$$

It follows that $\lambda^{0}{ }_{0}$ and $\lambda^{1}{ }_{1}$ must be equal, (or opposite, but since both Lorentz transformations have unit determinant, so must their combination), so call them $\gamma$. The transformation is then a Lorentz transformation of the usual form (1.13). (Since the spatial coordinate system cannot just flip over from left handed to right handed at some point, $\gamma$ will have to be positive.) Examining the transformation of the origin $x_{\mathrm{A}}=y_{\mathrm{A}}=z_{\mathrm{A}}=0$ identifies $\beta$ as $V / c$, with $V$ the relative velocity of system A compared to B, and then the above two equations identify $\gamma$ as the Lorentz factor.

Obviously, if any two Lorentz transformations are equivalent to a single one, then by repeated application any arbitrary number of them are equivalent to a single one.

## D. 6 Lorentz force derivation

To derive the given Lorentz force from the given Lagrangian, plug the canonical momentum and the Lagrangian into the Lagrangian equation of motion. That gives

$$
\frac{\mathrm{d} p_{i}}{\mathrm{~d} t}+q\left(\frac{\partial A_{i}}{\partial t}+\frac{\partial A_{i}}{\partial x_{j}} v_{j}\right)=-q \frac{\partial \varphi}{\partial x_{i}}+q \frac{\partial A_{j}}{\partial x_{i}} v_{j}
$$

This uses the Einstein convention that summation over $j$ is to be understood. Reorder to get

$$
\frac{\mathrm{d} p_{i}}{\mathrm{~d} t}=q\left(-\frac{\partial \varphi}{\partial x_{i}}-\frac{\partial A_{i}}{\partial t}\right)+q\left(\frac{\partial A_{j}}{\partial x_{i}} v_{j}-\frac{\partial A_{i}}{\partial x_{j}} v_{j}\right)
$$

The first parenthetical expression is the electric field as claimed. The quantity in the second parenthetical expression may be rewritten by expanding out the sums over $j$ to give

$$
\frac{\partial A_{i}}{\partial x_{i}} v_{i}-\frac{\partial A_{i}}{\partial x_{i}} v_{i}+\frac{\partial A_{\bar{\imath}}}{\partial x_{i}} v_{\bar{\imath}}-\frac{\partial A_{i}}{\partial x_{\bar{\imath}}} v_{\bar{\imath}}+\frac{\partial A_{\overline{\bar{\imath}}}}{\partial x_{i}} v_{\overline{\bar{\imath}}}-\frac{\partial A_{i}}{\partial x_{\overline{\bar{\imath}}}} v_{\overline{\bar{\imath}}}
$$

where $\bar{\imath}$ follows $i$ in the cyclic sequence $\ldots, 1,2,3,1,2,3, \ldots$ and $\overline{\bar{\imath}}$ precedes it. The first two terms drop out and the others can be recognized as component number $i$ of $\vec{v} \times(\nabla \times \vec{A})$. (For example, just write out the first component of $\vec{v}$ $\times(\nabla \times \vec{A})$ and compare it the expression above for $\bar{\imath}=2$ and $\overline{\bar{\imath}}=3$.) Defining $\overrightarrow{\mathcal{B}}$ as $\nabla \times \vec{A}$, the Lorentz force law results.

## D. 7 Derivation of the Euler formula

To verify the Euler formula, write all three functions involved in terms of their Taylor series, [41, p. 136]

## D. 8 Completeness of Fourier modes

The purpose of this note is to show completeness of the "Fourier modes"

$$
\ldots, \frac{e^{-3 i x}}{\sqrt{2 \pi}}, \frac{e^{-2 i x}}{\sqrt{2 \pi}}, \frac{e^{-\mathrm{i} x}}{\sqrt{2 \pi}}, \frac{1}{\sqrt{2 \pi}}, \frac{e^{\mathrm{i} x}}{\sqrt{2 \pi}}, \frac{e^{2 \mathrm{i} x}}{\sqrt{2 \pi}}, \frac{e^{3 \mathrm{i} x}}{\sqrt{2 \pi}}, \ldots
$$

for describing functions that are periodic of period $2 \pi$. It is to be shown that "all" these functions can be written as combinations of the Fourier modes above. Assume that $f(x)$ is any reasonable smooth function that repeats itself after a distance $2 \pi$, so that $f(x+2 \pi)=f(x)$. Then you can always write it in the form

$$
f(x)=\ldots+c_{-2} \frac{e^{-2 \mathrm{i} x}}{\sqrt{2 \pi}}+c_{-1} \frac{e^{-\mathrm{i} x}}{\sqrt{2 \pi}}+c_{0} \frac{1}{\sqrt{2 \pi}}+c_{1} \frac{e^{\mathrm{i} x}}{\sqrt{2 \pi}}+c_{2} \frac{e^{2 \mathrm{i} x}}{\sqrt{2 \pi}}+c_{3} \frac{e^{3 \mathrm{i} x}}{\sqrt{2 \pi}}+\ldots
$$

or

$$
f(x)=\sum_{k=-\infty}^{\infty} c_{k} \frac{e^{k \mathrm{i} x}}{\sqrt{2 \pi}}
$$

for short. Such a representation of a periodic function is called a "Fourier series." The coefficients $c_{k}$ are called "Fourier coefficients." The factors $1 / \sqrt{2 \pi}$ can be absorbed in the definition of the Fourier coefficients, if you want.

Because of the Euler formula, the set of exponential Fourier modes above is completely equivalent to the set of real Fourier modes

$$
\frac{1}{\sqrt{2 \pi}}, \frac{\cos (x)}{\sqrt{\pi}}, \frac{\sin (x)}{\sqrt{\pi}}, \frac{\cos (2 x)}{\sqrt{\pi}}, \frac{\sin (2 x)}{\sqrt{\pi}}, \frac{\cos (3 x)}{\sqrt{\pi}}, \frac{\sin (3 x)}{\sqrt{\pi}}, \ldots
$$

so that $2 \pi$-periodic functions may just as well be written as

$$
f(x)=a_{0} \frac{1}{\sqrt{2 \pi}}+\sum_{k=1}^{\infty} a_{k} \frac{\cos (k x)}{\sqrt{\pi}}+\sum_{k=1}^{\infty} b_{k} \frac{\sin (k x)}{\sqrt{\pi}}
$$

The extension to functions that are periodic of some other period than $2 \pi$ is a trivial matter of rescaling $x$. For a period $2 \ell$, with $\ell$ any half period, the exponential Fourier modes take the more general form

$$
\ldots, \frac{e^{-k_{2} \mathrm{i} x}}{\sqrt{2 \ell}}, \frac{e^{-k_{1} \mathrm{i} x}}{\sqrt{2 \ell}}, \frac{1}{\sqrt{2 \ell}}, \frac{e^{k_{1} \mathrm{i} x}}{\sqrt{2 \ell}}, \frac{e^{k_{2} \mathrm{i} x}}{\sqrt{2 \ell}}, \ldots \quad k_{1}=\frac{1 \pi}{\ell}, k_{2}=\frac{2 \pi}{\ell}, k_{3}=\frac{3 \pi}{\ell}, \ldots
$$

and similarly the real version of them becomes

$$
\frac{1}{\sqrt{2 \ell}}, \frac{\cos \left(k_{1} x\right)}{\sqrt{\ell}}, \frac{\sin \left(k_{1} x\right)}{\sqrt{\ell}}, \frac{\cos \left(k_{2} x\right)}{\sqrt{\ell}}, \frac{\sin \left(k_{2} x\right)}{\sqrt{\ell}}, \frac{\cos \left(k_{3} x\right)}{\sqrt{\ell}}, \frac{\sin \left(k_{3} x\right)}{\sqrt{\ell}}, \ldots
$$

See [41, p. 141] for detailed formulae.

Often, the functions of interest are not periodic, but are required to be zero at the ends of the interval on which they are defined. Those functions can be handled too, by extending them to a periodic function. For example, if the functions $f(x)$ relevant to a problem are defined only for $0 \leqslant x \leqslant \ell$ and must satisfy $f(0)=f(\ell)=0$, then extend them to the range $-\ell \leqslant x \leqslant 0$ by setting $f(x)=-f(-x)$ and take the range $-\ell \leqslant x \leqslant \ell$ to be the period of a $2 \ell$-periodic function. It may be noted that for such a function, the cosines disappear in the real Fourier series representation, leaving only the sines. Similar extensions can be used for functions that satisfy symmetry or zero-derivative boundary conditions at the ends of the interval on which they are defined. See again [41, p. 141] for more detailed formulae.

If the half period $\ell$ becomes infinite, the spacing between the discrete $k$ values becomes zero and the sum over discrete $k$ values turns into an integral over continuous $k$ values. This is exactly what happens in quantum mechanics for the eigenfunctions of linear momentum. The representation is now no longer called a Fourier series, but a "Fourier integral." And the Fourier coefficients $c_{k}$ are now called the "Fourier transform" $F(k)$. The completeness of the eigenfunctions is now called Fourier's integral theorem or inversion theorem. See [41, pp. 190-191] for more.

The basic completeness proof is a rather messy mathematical derivation, so read the rest of this note at your own risk. The fact that the Fourier modes are orthogonal and normalized was the subject of various exercises in chapter 2.6 and will be taken for granted here. See the solution manual for the details. What this note wants to show is that any arbitrary periodic function $f$ of period $2 \pi$ that has continuous first and second order derivatives can be written as

$$
f(x)=\sum_{k=-\infty}^{k=\infty} c_{k} \frac{e^{k i x}}{\sqrt{2 \pi}}
$$

in other words, as a combination of the set of Fourier modes.
First an expression for the values of the Fourier coefficients $c_{k}$ is needed. It can be obtained from taking the inner product $\left\langle e^{\text {lix }} / \sqrt{2 \pi} \mid f(x)\right\rangle$ between a generic eigenfunction $e^{l i x} / \sqrt{2 \pi}$ and the representation for function $f(x)$ above. Noting that all the inner products with the exponentials representing $f(x)$ will be zero except the one for which $k=l$, if the Fourier representation is indeed correct, the coefficients need to have the values

$$
c_{l}=\int_{x=0}^{2 \pi} \frac{e^{-l i x}}{\sqrt{2 \pi}} f(x) \mathrm{d} x
$$

a requirement that was already noted by Fourier. Note that $l$ and $x$ are just names for the eigenfunction number and the integration variable that you can change at will. Therefore, to avoid name conflicts later, the expression will be
renotated as

$$
c_{k}=\int_{\bar{x}=0}^{2 \pi} \frac{e^{-k \mathrm{i} \bar{x}}}{\sqrt{2 \pi}} f(\bar{x}) \mathrm{d} \bar{x}
$$

Now the question is: suppose you compute the Fourier coefficients $c_{k}$ from this expression, and use them to sum many terms of the infinite sum for $f(x)$, say from some very large negative value $-K$ for $k$ to the corresponding large positive value $K$; in that case, is the result you get, call it $f_{K}(x)$,

$$
f_{K}(x) \equiv \sum_{k=-K}^{k=K} c_{k} \frac{e^{k \mathrm{i} x}}{\sqrt{2 \pi}}
$$

a valid approximation to the true function $f(x)$ ? More specifically, if you sum more and more terms (make $K$ bigger and bigger), does $f_{K}(x)$ reproduce the true value of $f(x)$ to any arbitrary accuracy that you may want? If it does, then the eigenfunctions are capable of reproducing $f(x)$. If the eigenfunctions are not complete, a definite difference between $f_{K}(x)$ and $f(x)$ will persist however large you make $K$. In mathematical terms, the question is whether $\lim _{K \rightarrow \infty} f_{K}(x)=$ $f(x)$.

To find out, the trick is to substitute the integral for the coefficients $c_{k}$ into the sum and then reverse the order of integration and summation to get:

$$
f_{K}(x)=\frac{1}{2 \pi} \int_{\bar{x}=0}^{2 \pi} f(\bar{x})\left[\sum_{k=-K}^{k=K} e^{k i(x-\bar{x})}\right] \mathrm{d} \bar{x}
$$

The sum in the square brackets can be evaluated, because it is a geometric series with starting value $e^{-K \mathrm{i}(x-\bar{x})}$ and ratio of terms $e^{\mathrm{i}(x-\bar{x})}$. Using the formula from [41, item 21.4], multiplying top and bottom with $e^{-\mathrm{i}(x-\bar{x}) / 2}$, and cleaning up with, what else, the Euler formula, the sum is found to equal

$$
\frac{\sin \left(\left(K+\frac{1}{2}\right)(x-\bar{x})\right)}{\sin \left(\frac{1}{2}(x-\bar{x})\right)}
$$

This expression is called the "Dirichlet kernel". You now have

$$
f_{K}(x)=\int_{\bar{x}=0}^{2 \pi} f(\bar{x}) \frac{\sin \left(\left(K+\frac{1}{2}\right)(x-\bar{x})\right)}{2 \pi \sin \left(\frac{1}{2}(x-\bar{x})\right)} \mathrm{d} \bar{x}
$$

The second trick is to split the function $f(\bar{x})$ being integrated into the two parts $f(x)$ and $f(\bar{x})-f(x)$. The sum of the parts is obviously still $f(\bar{x})$, but the first part has the advantage that it is constant during the integration over
$\bar{x}$ and can be taken out, and the second part has the advantage that it becomes zero at $\bar{x}=x$. You get

$$
\begin{aligned}
& f_{K}(x)=f(x) \int_{\bar{x}=0}^{2 \pi} \frac{\sin \left(\left(K+\frac{1}{2}\right)(x-\bar{x})\right)}{2 \pi \sin \left(\frac{1}{2}(x-\bar{x})\right)} \mathrm{d} \bar{x} \\
& \\
& \quad \quad+\int_{\bar{x}=0}^{2 \pi}(f(\bar{x})-f(x)) \frac{\sin \left(\left(K+\frac{1}{2}\right)(x-\bar{x})\right)}{2 \pi \sin \left(\frac{1}{2}(x-\bar{x})\right)} \mathrm{d} \bar{x}
\end{aligned}
$$

Now if you backtrack what happens in the trivial case that $f(x)$ is just a constant, you find that $f_{K}(x)$ is exactly equal to $f(x)$ in that case, while the second integral above is zero. That makes the first integral above equal to one. Returning to the case of general $f(x)$, since the first integral above is still one, it makes the first term in the right hand side equal to the desired $f(x)$, and the second integral is then the error in $f_{K}(x)$.

To manipulate this error and show that it is indeed small for large $K$, it is convenient to rename the $K$-independent part of the integrand to

$$
g(\bar{x})=\frac{f(\bar{x})-f(x)}{2 \pi \sin \left(\frac{1}{2}(x-\bar{x})\right)}
$$

Using l'Hôpital's rule twice, it is seen that since by assumption $f$ has a continuous second derivative, $g$ has a continuous first derivative. So you can use one integration by parts to get

$$
f_{K}(x)=f(x)+\frac{1}{K+\frac{1}{2}} \int_{\bar{x}=0}^{2 \pi} g^{\prime}(\bar{x}) \cos \left(\left(K+\frac{1}{2}\right)(x-\bar{x})\right) \mathrm{d} \bar{x}
$$

And since the integrand of the final integral is continuous, it is bounded. That makes the error inversely proportional to $K+\frac{1}{2}$, implying that it does indeed become arbitrarily small for large $K$. Completeness has been proved.

It may be noted that under the stated conditions, the convergence is uniform; there is a guaranteed minimum rate of convergence regardless of the value of $x$. This can be verified from Taylor series with remainder. Also, the more continuous derivatives the $2 \pi$-periodic function $f(x)$ has, the faster the rate of convergence, and the smaller the number $2 K+1$ of terms that you need to sum to get good accuracy is likely to be. For example, if $f(x)$ has three continuous derivatives, you can do another integration by parts to show that the convergence is proportional to $1 /\left(K+\frac{1}{2}\right)^{2}$ rather than just $1 /\left(K+\frac{1}{2}\right)$. But watch the end points: if a derivative has different values at the start and end of the period, then that derivative is not continuous, it has a jump at the ends. (Such jumps can be incorporated in the analysis, however, and have less effect
than it may seem. You get a better practical estimate of the convergence rate by directly looking at the integral for the Fourier coefficients.)

The condition for $f(x)$ to have a continuous second derivative can be relaxed with more work. If you are familiar with the Lebesgue form of integration, it is fairly easy to extend the result above to show that it suffices that the absolute integral of $f^{2}$ exists, something that will be true in quantum mechanics applications.

## D. 9 Momentum operators are Hermitian

To check that the linear momentum operators are Hermitian, assume that $\Psi_{1}$ and $\Psi_{2}$ are any two proper, reasonably behaved, wave functions. By definition:

$$
\left\langle\Psi_{1} \mid \widehat{p}_{x} \Psi_{2}\right\rangle=\int_{x=-\infty}^{\infty} \int_{y=-\infty}^{\infty} \int_{z=-\infty}^{\infty} \Psi_{1}^{*} \frac{\hbar}{\mathrm{i}} \Psi_{2, x} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z
$$

Here the subscript $x$ indicates differentiation with respect to $x$. This can be rewritten as

$$
\begin{equation*}
\int_{x=-\infty}^{\infty} \int_{y=-\infty}^{\infty} \int_{z=-\infty}^{\infty}\left[\left(\Psi_{1}^{*} \frac{\hbar}{\mathrm{i}} \Psi_{2}\right)_{x}-\Psi_{1, x}^{*} \frac{\hbar}{\mathrm{i}} \Psi_{2}\right] \mathrm{d} x \mathrm{~d} y \mathrm{~d} z \tag{1}
\end{equation*}
$$

as can be checked by simply differentiating out the product in the first term.
Now the first term in the integral can be integrated with respect to $x$ and is then seen to produce zero. The reason is that $\Psi_{1}$ and $\Psi_{2}$ must become zero at large distances, otherwise their square integral cannot be zero. That leaves only the second term. And that equals

$$
\left\langle\widehat{p}_{x} \Psi_{1} \mid \Psi_{2}\right\rangle=\int_{x=-\infty}^{\infty} \int_{y=-\infty}^{\infty} \int_{z=-\infty}^{\infty}\left(\frac{\hbar}{\mathrm{i}} \frac{\partial \Psi_{1}}{\partial x}\right)^{*} \Psi_{2} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z
$$

(Recall that the complex conjugate of $i$ is $-i$, hence the minus sign.)
For the mathematically picky, it is maybe a good idea to examine the claim that the first term in the integral in (1) integrates to zero a bit more closely. The integral is definitely zero if the system is not in infinite space, but in a periodic box. The reason is that in that case the lower and upper limits of integration are equal and drop out against each other. To be rigorous in infinite space, you will at first need to limit the region of integration to a distance no more than some large number $R$ away from the origin. (It will be assumed that the initial inner product is well defined, in the sense that the integral has a finite limit in the limit $R \rightarrow \infty$. In that case, the integral can be approximated to arbitrary accuracy by just taking $R$ large enough.) Using the divergence theorem, the first integral is

$$
\int_{S}\left(\Psi_{1}^{*} \frac{\hbar}{\mathrm{i}} \Psi_{2}\right) n_{x} \mathrm{~d} S
$$

where $S$ is the surface of the sphere $r=R$ and $n_{x}$ the $x$-component of the unit vector $\hat{\imath}_{r}$ normal to the surface. Now since the absolute square integrals of the wave functions are finite, for large enough $R$ their square integrals outside $R$ become arbitrarily small. The Cauchy Schwartz inequality then says that the above integral integrated with respect to $r$ must become vanishingly small. And that is not possible unless the integral itself becomes vanishingly small at almost all locations. So you can define a sequence for $R$ where the inner product with the linear momentum swapped over approaches the original inner product. In particular, the two inner products are equal to the degree that they are well defined in the first place.

## D. 10 The curl is Hermitian

For later reference, it will be shown that the curl operator, $\nabla \times$ is Hermitian. In other words,

$$
\int_{\text {all }} \vec{A}^{*} \cdot \nabla \times \vec{B} \mathrm{~d}^{3} \vec{r}=\int_{\text {all }} \nabla \times \vec{A}^{*} \cdot \vec{B} \mathrm{~d}^{3} \vec{r}
$$

The rules of engagement are as follows:

- The Cartesian axes are numbered using an index $i$, with $i=1,2$, and 3 for $x, y$, and $z$ respectively.
- Also, $r_{i}$ indicates the coordinate in the $i$ direction, $x, y$, or $z$.
- Derivatives with respect to a coordinate $r_{i}$ are indicated by a simple subscript $i$.
- If the quantity being differentiated is a vector, a comma is used to separate the vector index from differentiation ones.
- Index $\bar{\imath}$ is the number immediately following $i$ in the cyclic sequence .. 123123... and $\overline{\bar{\imath}}$ is the number immediately preceding $i$.
- A bare $\int$ integral sign is assumed to be an integration over all space, or over the entire box for particles in a box. The $\mathrm{d}^{3} \vec{r}$ is normally omitted for brevity and to be understood.
- A superscript * indicates a complex conjugate.

In index notation, the integral in the left hand side above reads:

$$
\sum_{i} \int A_{i}^{*}\left(B_{\overline{\bar{v}}, \bar{i}}-B_{\bar{i}, \bar{i}}\right)
$$

which is the same as

$$
\sum_{i} \int\left[\left(A_{i}^{*} B_{\overline{\bar{\imath}}}\right)_{\bar{\imath}}-\left(A_{i}^{*} B_{\bar{\imath}}\right)_{\overline{\bar{\imath}}}-A_{i, \bar{\imath}}^{*} B_{\overline{\bar{\imath}}}+A_{i, \overline{\bar{\imath}}}^{*} B_{\overline{\bar{\imath}}}\right]
$$

as can be checked by differentiating out the first two terms. Now the third and fourth terms in the integral are $\nabla \times \vec{A}^{*} \cdot \vec{B}$, as you can see from moving all
indices in the third term one unit forward in the cyclic sequence, and those in the fourth term one unit back. (Such a shift does not change the sum; the same terms are simply added in a different order.)

So, if the integral of the first two terms is zero, the fact that curl is Hermitian has been verified. Note that the terms can be integrated. Then, if the system is in a periodic box, the integral is indeed zero because the upper and lower limits of integration are equal. An infinite domain will need to be truncated at some large distance $R$ from the origin. Then shift indices and apply the divergence theorem to get

$$
-\int_{S}\left(\vec{A}^{*} \times \vec{B}\right) \cdot \hat{\imath}_{r} \mathrm{~d} S
$$

where $S$ is the surface of the sphere $r=R$ and $\hat{\imath}_{r}$ the unit vector normal to the sphere surface. It follows that the integral is zero if $\vec{A}$ and $\vec{B}$ go to zero at infinity quickly enough. Or at least their cross product has to go to zero quickly enough.

## D. 11 Extension to three-dimensional solutions

Maybe you have some doubt whether you really can just multiply one-dimensional eigenfunctions together, and add one-dimensional energy values to get the three-dimensional ones. Would a book that you find for free on the Internet lie? OK, let's look at the details then. First, the three-dimensional Hamiltonian, (really just the kinetic energy operator), is the sum of the one-dimensional ones:

$$
H=H_{x}+H_{y}+H_{z}
$$

where the one-dimensional Hamiltonians are:

$$
H_{x}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial x^{2}} \quad H_{y}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial y^{2}} \quad H_{z}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial z^{2}}
$$

To check that any product $\psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)$ of one-dimensional eigenfunctions is an eigenfunction of the combined Hamiltonian $H$, note that the partial Hamiltonians only act on their own eigenfunction, multiplying it by the corresponding eigenvalue:

$$
\begin{aligned}
& \left(H_{x}+H_{y}+H_{z}\right) \psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z) \\
& \quad=E_{x} \psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)+E_{y} \psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)+E_{z} \psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)
\end{aligned}
$$

or

$$
H \psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)=\left(E_{x}+E_{y}+E_{z}\right) \psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)
$$

Therefore, by definition $\psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)$ is an eigenfunction of the threedimensional Hamiltonian, with an eigenvalue that is the sum of the three onedimensional ones. But there is still the question of completeness. Maybe the
above eigenfunctions are not complete, which would mean a need for additional eigenfunctions that are not products of one-dimensional ones.

The one-dimensional eigenfunctions $\psi_{n_{x}}(x)$ are complete, see [41, p. 141] and earlier exercises in this book. So, you can write any wave function $\Psi(x, y, z)$ at given values of $y$ and $z$ as a combination of $x$-eigenfunctions:

$$
\Psi(x, y, z)=\sum_{n_{x}} c_{n_{x}} \psi_{n_{x}}(x)
$$

but the coefficients $c_{n_{x}}$ will be different for different values of $y$ and $z$; in other words they will be functions of $y$ and $z: c_{n_{x}}=c_{n_{x}}(y, z)$. So, more precisely, you have

$$
\Psi(x, y, z)=\sum_{n_{x}} c_{n_{x}}(y, z) \psi_{n_{x}}(x),
$$

But since the $y$-eigenfunctions are also complete, at any given value of $z$, you can write each $c_{n_{x}}(y, z)$ as a sum of $y$-eigenfunctions:

$$
\Psi(x, y, z)=\sum_{n_{x}}\left(\sum_{n_{y}} c_{n_{x} n_{y}} \psi_{n_{y}}(y)\right) \psi_{n_{x}}(x),
$$

where the coefficients $c_{n_{x} n_{y}}$ will be different for different values of $z, c_{n_{x} n_{y}}=$ $c_{n_{x} n_{y}}(z)$. So, more precisely,

$$
\Psi(x, y, z)=\sum_{n_{x}}\left(\sum_{n_{y}} c_{n_{x} n_{y}}(z) \psi_{n_{y}}(y)\right) \psi_{n_{x}}(x)
$$

But since the $z$-eigenfunctions are also complete, you can write $c_{n_{x} n_{y}}(z)$ as a sum of $z$-eigenfunctions:

$$
\Psi(x, y, z)=\sum_{n_{x}}\left(\sum_{n_{y}}\left(\sum_{n_{z}} c_{n_{x} n_{y} n_{z}} \psi_{n_{z}}(z)\right) \psi_{n_{y}}(y)\right) \psi_{n_{x}}(x) .
$$

Since the order of doing the summation does not make a difference,

$$
\Psi(x, y, z)=\sum_{n_{x}} \sum_{n_{y}} \sum_{n_{z}} c_{n_{x} n_{y} n_{z}} \psi_{n_{x}}(x) \psi_{n_{y}}(y) \psi_{n_{z}}(z)
$$

So, any wave function $\Psi(x, y, z)$ can be written as a sum of products of one-dimensional eigenfunctions; these products are complete.

## D. 12 The harmonic oscillator solution

If you really want to know how the harmonic oscillator wave function can be found, here it is. Read at your own risk.

The ODE (ordinary differential equation) to solve is

$$
-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \psi_{x}}{\partial x^{2}}+\frac{1}{2} m \omega^{2} x^{2} \psi_{x}=E_{x} \psi_{x}
$$

where the spring constant $c$ was rewritten as the equivalent expression $m \omega^{2}$.
Now the first thing you always want to do with this sort of problems is to simplify it as much as possible. In particular, get rid of as much dimensional constants as you can by rescaling the variables: define a new scaled $x$-coordinate $\xi$ and a scaled energy $\epsilon$ by

$$
x \equiv \ell \xi \quad E_{x} \equiv E_{0} \epsilon
$$

If you make these replacements into the ODE above, you can make the coefficients of the two terms in the left hand side equal by choosing $\ell=\sqrt{\hbar / m \omega}$. In that case both terms will have the same net coefficient $\frac{1}{2} \hbar \omega$. Then if you cleverly choose $E_{0}=\frac{1}{2} \hbar \omega$, the right hand side will have that coefficient too, and you can divide it away and end up with no coefficients at all:

$$
-\frac{\partial^{2} \psi_{x}}{\partial \xi^{2}}+\xi^{2} \psi_{x}=\epsilon \psi_{x}
$$

Looks a lot cleaner, not?
Now examine this equation for large values of $\xi$ (i.e. large $x$ ). You get approximately

$$
\frac{\partial^{2} \psi_{x}}{\partial \xi^{2}} \approx \xi^{2} \psi_{x}+\ldots
$$

If you write the solution as an exponential, you can ballpark that it must take the form

$$
\psi_{x}=e^{ \pm \frac{1}{2} \xi^{2}+\ldots}
$$

where the dots indicate terms that are small compared to $\frac{1}{2} \xi^{2}$ for large $\xi$. The form of the solution is important, since $e^{+\frac{1}{2} \xi^{2}}$ becomes infinitely large at large $\xi$. That is unacceptable: the probability of finding the particle cannot become infinitely large at large $x$ : the total probability of finding the particle must be one, not infinite. The only solutions that are acceptable are those that behave as $e^{-\frac{1}{2} \xi^{2}+\ldots}$ for large $\xi$.

Now split off the leading exponential part by defining a new unknown $h(\xi)$ by

$$
\psi_{x} \equiv e^{-\frac{1}{2} \xi^{2}} h(\xi)
$$

Substituting this in the ODE and dividing out the exponential, you get:

$$
-\frac{\partial^{2} h}{\partial \xi^{2}}+2 \xi \frac{\partial h}{\partial \xi}+h=\epsilon h
$$

Now try to solve this by writing $h$ as a power series, (say, a Taylor series):

$$
h=\sum_{p} c_{p} \xi^{p}
$$

where the values of $p$ run over whatever the appropriate powers are and the $c_{p}$ are constants. If you plug this into the ODE, you get

$$
\sum_{p} p(p-1) c_{p} \xi^{p-2}=\sum_{p}(2 p+1-\epsilon) c_{p} \xi^{p}
$$

For the two sides to be equal, they must have the same coefficient for every power of $\xi$.

There must be a lowest value of $p$ for which there is a nonzero coefficient $c_{p}$, for if $p$ took on arbitrarily large negative values, $h$ would blow up strongly at the origin, and the probability to find the particle near the origin would then be infinite. Denote the lowest value of $p$ by $q$. This lowest power produces a power of $\xi^{q-2}$ in the left hand side of the equation above, but there is no corresponding power in the right hand side. So, the coefficient $q(q-1) c_{q}$ of $\xi^{q-2}$ will need to be zero, and that means either $q=0$ or $q=1$. So the power series for $h$ will need to start as either $c_{0}+\ldots$ or $c_{1} \xi+\ldots$. The constant $c_{0}$ or $c_{1}$ is allowed to have any nonzero value.

But note that the $c_{q} \xi^{q}$ term normally produces a term $(2 q+1-\epsilon) c_{q} \xi^{q}$ in the right hand side of the equation above. For the left hand side to have a matching $\xi^{q}$ term, there will need to be a further $c_{q+2} \xi^{q+2}$ term in the power series for $h$,

$$
h=c_{q} \xi^{q}+c_{q+2} \xi^{q+2}+\ldots
$$

where $(q+2)(q+1) c_{q+2}$ will need to equal $(2 q+1-\epsilon) c_{q}$, so $c_{q+2}=(2 q+1-$ $\epsilon) c_{q} /(q+2)(q+1)$. This term in turn will normally produce a term $(2(q+2)+$ $1-\epsilon) c_{q+2} \xi^{q+2}$ in the right hand side which will have to be canceled in the left hand side by a $c_{q+4} \xi^{q+4}$ term in the power series for $h$. And so on.

So, if the power series starts with $q=0$, the solution will take the general form

$$
h=c_{0}+c_{2} \xi^{2}+c_{4} \xi^{4}+c_{6} \xi^{6}+\ldots
$$

while if it starts with $q=1$ you will get

$$
h=c_{1} \xi+c_{3} \xi^{3}+c_{5} \xi^{5}+c_{7} \xi^{7}+\ldots
$$

In the first case, you have a symmetric solution, one which remains the same when you flip over the sign of $\xi$, and in the second case you have an antisymmetric solution, one which changes sign when you flip over the sign of $\xi$.

You can find a general formula for the coefficients of the series by making the change in notations $p=2+\bar{p}$ in the left-hand-side sum:

$$
\sum_{\bar{p}=q}(\bar{p}+2)(\bar{p}+1) c_{\bar{p}+2} \xi^{\bar{p}}=\sum_{p=q}(2 p+1-\epsilon) c_{p} \xi^{p}
$$

Note that you can start summing at $\bar{p}=q$ rather than $q-2$, since the first term in the sum is zero anyway. Next note that you can again forget about the difference between $\bar{p}$ and $p$, because it is just a symbolic summation variable. The symbolic sum writes out to the exact same actual sum whether you call the symbolic summation variable $p$ or $\bar{p}$.

So for the powers in the two sides to be equal, you must have

$$
c_{p+2}=\frac{2 p+1-\epsilon}{(p+2)(p+1)} c_{p}
$$

In particular, for large $p$, by approximation

$$
c_{p+2} \approx \frac{2}{p} c_{p}
$$

Now if you check out the Taylor series of $e^{\xi^{2}}$, (i.e. the Taylor series of $e^{x}$ with $x$ replaced by $\xi^{2}$,) you find it satisfies the exact same equation. So, normally the solution $h$ blows up something like $e^{\xi^{2}}$ at large $\xi$. And since $\psi_{x}$ was $e^{-\frac{1}{2} \xi^{2}} h$, normally $\psi_{x}$ takes on the unacceptable form $e^{+\frac{1}{2} \xi^{2}+\ldots}$. (If you must have rigor here, estimate $h$ in terms of $C e^{\alpha \xi^{2}}$ where $\alpha$ is a number slightly less than one, plus a polynomial. That is enough to show unacceptability of such solutions.)

What are the options for acceptable solutions? The only possibility is that the power series terminates. There must be a highest power $p$, call it $p=n$, whose term in the right hand side is zero

$$
0=(2 n+1-\epsilon) c_{n} \xi^{n}
$$

In that case, there is no need for a further $c_{n+2} \xi^{n+2}$ term, the power series will remain a polynomial of degree $n$. But note that all this requires the scaled energy $\epsilon$ to equal $2 n+1$, and the actual energy $E_{x}$ is therefore $(2 n+1) \hbar \omega / 2$. Different choices for the power at which the series terminates produce different energies and corresponding eigenfunctions. But they are discrete, since $n$, as any power $p$, must be a nonnegative integer.

With $\epsilon$ identified as $2 n+1$, you can find the ODE for $h$ listed in table books, like [41, 29.1], under the name "Hermite's differential equation." They then identify the polynomial solutions as the so-called "Hermite polynomials,"
except for a normalization factor. To find the normalization factor, i.e. $c_{0}$ or $c_{1}$, demand that the total probability of finding the particle anywhere is one, $\int_{-\infty}^{\infty}\left|\psi_{x}\right|^{2} \mathrm{~d} x=1$. You should be able to find the value for the appropriate integral in your table book, like [41, 29.15].

Putting it all together, the generic expression for the eigenfunctions can be found to be:

$$
\begin{equation*}
h_{n}=\frac{1}{\left(\pi \ell^{2}\right)^{1 / 4}} \frac{H_{n}(\xi)}{\sqrt{2^{n} n!}} e^{-\xi^{2} / 2} \quad n=0,1,2,3,4,5, \ldots \tag{D.4}
\end{equation*}
$$

where the details of the "Hermite polynomials" $H_{n}$ can be found in table books like [41, pp. 167-168]. They are readily evaluated on a computer using the "recurrence relation" you can find there, for as far as computer round-off error allows (up to $n$ about 70.)

Quantum field theory allows a much neater way to find the eigenfunctions. It is explained in addendum $\{$ A. 15.5$\}$ or equivalently in $\{$ D. 64$\}$.

## D. 13 The harmonic oscillator and uncertainty

The given qualitative explanation of the ground state of the harmonic oscillator in terms of the uncertainty principle is questionable. In particular, position, linear momentum, potential energy, and kinetic energy are uncertain for the ground state. This note gives a solid argument, but it uses some advanced ideas discussed in chapter 4.4 and 4.5.3.

As explained more fully in chapter 4.4, the "expectation value" of the kinetic energy is defined as the average value expected for kinetic energy measurements. Similarly, the expectation value of the potential energy is defined as the average value expected for potential energy measurements.

From the precise form of expectation values in quantum mechanics, it follows that total energy must be the sum of the kinetic and potential energy expectation values. For the harmonic oscillator ground state, that gives

$$
E_{x 0}=\frac{1}{2} \hbar \omega=\frac{1}{2 m}\left\langle p_{x}^{2}\right\rangle+\frac{m}{2} \omega^{2}\left\langle x^{2}\right\rangle
$$

Here $\langle$.$\rangle stands for the average of the enclosed quantity. Only the motion in the$ $x$-direction will be considered here. The $y$ and $z$ directions go exactly the same way.

Now any value of $p_{x}$ can be written as equal to the average value $\left\langle p_{x}\right\rangle$ plus a deviation from that average $\Delta p_{x}$. Then

$$
\left\langle p_{x}^{2}\right\rangle=\left\langle\left(\left\langle p_{x}\right\rangle+\Delta p_{x}\right)^{2}\right\rangle=\left\langle p_{x}\right\rangle^{2}+2\left\langle p_{x}\right\rangle\left\langle\Delta p_{x}\right\rangle+\left\langle\left(\Delta p_{x}\right)^{2}\right\rangle
$$

Note that an average is a constant that is not affected by further averaging. Next note that the average of $\Delta p_{x}$ is zero, otherwise the average of $p_{x}+\Delta p_{x}$
would not be $\left\langle p_{x}\right\rangle$. So:

$$
\left\langle p_{x}^{2}\right\rangle=\left\langle p_{x}\right\rangle^{2}+\left\langle\left(\Delta p_{x}\right)^{2}\right\rangle
$$

Of course, a similar expression holds for $\left\langle x^{2}\right\rangle$, so the ground state energy is

$$
\begin{equation*}
\frac{1}{2} \hbar \omega=\frac{1}{2 m}\left\langle p_{x}\right\rangle^{2}+\frac{m}{2} \omega^{2}\langle x\rangle^{2}+\frac{1}{2 m}\left\langle\left(\Delta p_{x}\right)^{2}\right\rangle+\frac{m}{2} \omega^{2}\left\langle(\Delta x)^{2}\right\rangle \tag{1}
\end{equation*}
$$

Consider the last two terms. Call them $a^{2}$ and $b^{2}$ for now. Note that

$$
(a-b)^{2} \geqslant 0 \quad \Longrightarrow \quad a^{2}+b^{2} \geqslant 2 a b=\omega \sqrt{\left\langle\left(\Delta p_{x}\right)^{2}\right\rangle} \sqrt{\left\langle(\Delta x)^{2}\right\rangle}
$$

as follows from multiplying out the square. The $\geqslant$ becomes $=$ when $a$ and $b$ are equal.

Now the first square root above is a measure of the uncertainty in $p_{x}$. If $\Delta p_{x}$ is always zero, then $p_{x}$ is always its average value, without any uncertainty. Similarly, the second square root above is a measure of the uncertainty in $x$. The Heisenberg uncertainty principle can be made quantitative as, chapter 4.5.3,

$$
\sqrt{\left\langle\left(\Delta p_{x}\right)^{2}\right\rangle} \sqrt{\left\langle(\Delta x)^{2}\right\rangle} \geqslant \frac{1}{2} \hbar
$$

Therefore

$$
a^{2}+b^{2} \geqslant \frac{1}{2} \hbar \omega
$$

So the minimum value of the final two terms in the expression (1) for the ground state energy is the complete ground state energy. Therefore, in order that the right hand side in (1) does not exceed the left hand side, the first two terms must be zero. So the average particle momentum and position are both zero. In addition, for the estimates of the final two terms, equalities are needed, not inequalities. That means that $a$ must be $b$. That then means that the expectation kinetic energy must be the expectation potential energy. And the two must be the very minimum allowed by the Heisenberg relation; otherwise there is still that inequality.

## D. 14 The spherical harmonics

This note derives and lists properties of the spherical harmonics.

## D.14.1 Derivation from the eigenvalue problem

This analysis will derive the spherical harmonics from the eigenvalue problem of square angular momentum of chapter 4.2.3. It will use similar techniques as for the harmonic oscillator solution, $\{$ D. 12$\}$.

The imposed additional requirement that the spherical harmonics $Y_{l}^{m}$ are eigenfunctions of $L_{z}$ means that they are of the form $\Theta_{l}^{m}(\theta) e^{\mathrm{i} m \phi}$ where function
$\Theta_{l}^{m}(\theta)$ is still to be determined. (There is also an arbitrary dependence on the radius $r$, but it does not have anything to do with angular momentum, hence is ignored when people define the spherical harmonics.) Substitution into $\widehat{L}^{2} \psi$ $=L^{2} \psi$ with $\widehat{L}^{2}$ as in (4.22) yields an ODE (ordinary differential equation) for $\Theta_{l}^{m}(\theta)$ :

$$
-\frac{\hbar^{2}}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial \Theta_{l}^{m}}{\partial \theta}\right)+\frac{\hbar^{2} m^{2}}{\sin ^{2} \theta} \Theta_{l}^{m}=L^{2} \Theta_{l}^{m}
$$

It is convenient define a scaled square angular momentum by $L^{2}=\hbar^{2} \lambda^{2}$ so that you can divide away the $\hbar^{2}$ from the ODE.

More importantly, recognize that the solutions will likely be in terms of cosines and sines of $\theta$, because they should be periodic if $\theta$ changes by $2 \pi$. If you want to use power-series solution procedures again, these transcendental functions are bad news, so switch to a new variable $x=\cos \theta$. At the very least, that will reduce things to algebraic functions, $\operatorname{since} \sin \theta$ is in terms of $x=\cos \theta$ equal to $\sqrt{1-x^{2}}$. Converting the ODE to the new variable $x$, you get

$$
-\left(1-x^{2}\right) \frac{\mathrm{d}^{2} \Theta_{l}^{m}}{\mathrm{~d} x^{2}}+2 x \frac{\mathrm{~d} \Theta_{l}^{m}}{\mathrm{~d} x}+\frac{m^{2}}{1-x^{2}} \Theta_{l}^{m}=\lambda^{2} \Theta_{l}^{m}
$$

As you may guess from looking at this ODE, the solutions $\Theta_{l}^{m}$ are likely to be problematic near $x= \pm 1$, (physically, near the $z$-axis where $\sin \theta$ is zero.) If you examine the solution near those points by defining a local coordinate $\xi$ as in $x= \pm(1-\xi)$, and then deduce the leading term in the power series solutions with respect to $\xi$, you find that it is either $\xi^{m / 2}$ or $\xi^{-m / 2}$, (in the special case that $m=0$, that second solution turns out to be $\ln \xi$.) Either way, the second possibility is not acceptable, since it physically would have infinite derivatives at the $z$-axis and a resulting expectation value of square momentum, as defined in chapter 4.4.3, that is infinite. You need to have that $\Theta_{l}^{m}$ behaves as $\xi^{m / 2}$ at each end, so in terms of $x$ it must have a factor $(1-x)^{m / 2}$ near $x=1$ and $(1+x)^{m / 2}$ near $x=-1$. The two factors multiply to $\left(1-x^{2}\right)^{m / 2}$ and so $\Theta_{l}^{m}$ can be written as $\left(1-x^{2}\right)^{m / 2} f_{l}^{m}$ where $f_{l}^{m}$ must have finite values at $x=1$ and $x$ $=-1$.

If you substitute $\Theta_{l}^{m}=\left(1-x^{2}\right)^{m / 2} f_{l}^{m}$ into the ODE for $\Theta_{l}^{m}$, you get an ODE for $f_{l}^{m}$ :

$$
-\left(1-x^{2}\right) \frac{\mathrm{d}^{2} f_{l}^{m}}{\mathrm{~d} x^{2}}+2(1+m) x \frac{\mathrm{~d} f_{l}^{m}}{\mathrm{~d} x}+\left(m^{2}+m\right) f_{l}^{m}=\lambda^{2} f_{l}^{m}
$$

Plug in a power series, $f_{l}^{m}=\sum c_{p} x^{p}$, to get, after clean up,

$$
\sum p(p-1) c_{p} x^{p-2}=\sum\left[(p+m)(p+m+1)-\lambda^{2}\right] c_{p} x^{p}
$$

Using similar arguments as for the harmonic oscillator, you see that the starting power will be zero or one, leading to basic solutions that are again odd or even.

And just like for the harmonic oscillator, you must again have that the power series terminates; even in the least case that $m=0$, the series for $f_{l}^{m}$ at $|x|=$ 1 is like that of $\ln \left(1-x^{2}\right)$ and will not converge to the finite value stipulated. (For rigor, use Gauss's test.)

To get the series to terminate at some final power $p=n$, you must have according to the above equation that $\lambda^{2}=(n+m)(n+m+1)$, and if you decide to call $n+m$ the azimuthal quantum number $l$, you have $\lambda^{2}=l(l+1)$ where $l$ $\geqslant m$ since $l=n+m$ and $n$, like any power $p$, is greater or equal to zero.

The rest is just a matter of table books, because with $\lambda^{2}=l(l+1)$, the ODE for $f_{l}^{m}$ is just the $m$-th derivative of the differential equation for the $L_{l}$ Legendre polynomial, [41, 28.1], so the $f_{l}^{m}$ must be just the $m$-th derivative of those polynomials. In fact, you can now recognize that the ODE for the $\Theta_{l}^{m}$ is just Legendre's associated differential equation [41, 28.49], and that the solutions that you need are the associated Legendre functions of the first kind [41, 28.50].

To normalize the eigenfunctions on the surface area of the unit sphere, find the corresponding integral in a table book, like [41, 28.63]. As mentioned at the start of this long and still very condensed story, to include negative values of $m$, just replace $m$ by $|m|$. There is one additional issue, though, the sign pattern. In order to simplify some more advanced analysis, physicists like the sign pattern to vary with $m$ according to the so-called "ladder operators." That requires, $\{$ D.64\}, that starting from $m=0$, the spherical harmonics for $m>$ 0 have the alternating sign pattern of the "ladder-up operator," and those for $m<0$ the unvarying sign of the "ladder-down operator." Physicists will still allow you to select your own sign for the $m=0$ state, bless them.

The final solution is

$$
\begin{equation*}
Y_{l}^{m}(\theta, \phi)=(-1)^{\max (m, 0)} \sqrt{\frac{2 l+1}{4 \pi} \frac{(l-|m|)!}{(l+|m|)!}} P_{l}^{|m|}(\cos \theta) e^{\mathrm{i} m \phi} \tag{D.5}
\end{equation*}
$$

where the properties of the associated Legendre functions of the first kind $P_{l}^{|m|}$ can be found in table books like [41, pp. 162-166]. This uses the following definition of the associated Legendre polynomials:

$$
P_{l}^{m}(x) \equiv\left(1-x^{2}\right)^{m / 2} \frac{\mathrm{~d}^{m} P_{l}(x)}{\mathrm{d} x^{m}}
$$

where $P_{l}$ is the normal Legendre polynomial. Needless to say, some other authors use different definitions, potentially putting in a factor $(-1)^{m}$.

## D.14.2 Parity

One special property of the spherical harmonics is often of interest: their "parity." The parity of a wave function is 1 , or even, if the wave function stays the
same if you replace $\vec{r}$ by $-\vec{r}$. The parity is -1 , or odd, if the wave function stays the same save for a sign change when you replace $\vec{r}$ by $-\vec{r}$. It turns out that the parity of the spherical harmonics is $(-1)^{l}$; so it is -1 , odd, if the azimuthal quantum number $l$ is odd, and 1 , even, if $l$ is even.

To see why, note that replacing $\vec{r}$ by $-\vec{r}$ means in spherical coordinates that $\theta$ changes into $\pi-\theta$ and $\phi$ into $\phi+\pi$. According to trig, the first changes $\cos \theta$ into $-\cos \theta$. That leaves $P_{l}(\cos \theta)$ unchanged for even $l$, since $P_{l}$ is then a symmetric function, but it changes the sign of $P_{l}$ for odd $l$. So the sign change is $(-1)^{l}$. The value of $m$ has no effect, since while the factor $e^{\mathrm{i} m \phi}$ in the spherical harmonics produces a factor $(-1)^{|m|}$ under the change in $\phi, m$ also puts $|m|$ derivatives on $P_{l}$, and each derivative produces a compensating change of sign in $P_{l}^{|m|}(\cos \theta)$.

## D.14.3 Solutions of the Laplace equation

The "Laplace equation" is

$$
\nabla^{2} u=0
$$

Solutions $u$ to this equation are called "harmonic functions." In spherical coordinates, the Laplace equation has solutions of the form

$$
r^{l} Y_{l}^{m}(\theta \phi)
$$

This is a complete set of solutions for the Laplace equation inside a sphere. Any solution $u$ of the Laplace equation inside a sphere is a linear combination of these solutions.

As you can see in table 4.3, each solution above is a power series in terms of Cartesian coordinates.

For the Laplace equation outside a sphere, replace $r^{l}$ by $1 / r^{l+1}$ in the solutions above. Note that these solutions are not acceptable inside the sphere because they blow up at the origin.

To check that these are indeed solutions of the Laplace equation, plug them in, using the Laplacian in spherical coordinates given in (N.5). Note here that the angular derivatives can be simplified using the eigenvalue problem of square angular momentum, chapter 4.2.3.

## D.14.4 Orthogonal integrals

The spherical harmonics are orthonormal on the unit sphere:

$$
\begin{equation*}
\int_{\text {all }} Y_{\underline{\underline{l}}}{ }^{*} Y_{l}^{m} \mathrm{~d} \Omega=\delta_{l \underline{l}} \delta_{m \underline{m}} \quad \mathrm{~d} \Omega \equiv \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \tag{D.6}
\end{equation*}
$$

Here $\delta_{l \underline{l}}$ is defined to be 0 if $\underline{l}$ and $l$ are different, and 1 if they are equal, and similar for $\delta_{m \underline{m}}$. In other words, the integral above is 1 if $l=\underline{l}$ and $m=\underline{m}$, and

0 in every other case. This expresses physically that the spherical harmonics, as eigenfunctions of the Hermitian $z$ and square angular momentum operators, are orthonormal. Mathematically, it allows you to integrate each spherical harmonic separately and quickly when you are finding $\int|\psi|^{2} \mathrm{~d}^{3} \vec{r}$ for a wave function $\psi$ expressed in terms of spherical harmonics.

Further

$$
\begin{equation*}
\int_{\text {all }}\left(\frac{Y_{\underline{l}}^{\underline{m}^{*}}}{\partial \theta} \frac{Y_{l}^{m}}{\partial \theta}+\frac{1}{\sin ^{2} \theta} \frac{Y_{\underline{l}}^{\underline{m}^{*}}}{\partial \phi} \frac{Y_{l}^{m}}{\partial \phi}\right) \mathrm{d} \Omega=l(l+1) \delta_{\underline{l l}} \delta_{\underline{m} m} \tag{D.7}
\end{equation*}
$$

This expression simplifies your life when you are finding the $\int|\nabla \psi|^{2} \mathrm{~d}^{3} \vec{r}$ for a wave function $\psi$ expressed in terms of spherical harmonics.

See the notations for more on spherical coordinates and $\nabla$.
To verify the above expression, integrate the first term in the integral by parts with respect to $\theta$ and the second term with respect to $\phi$ to get

$$
-\int \bar{Y}\left(\frac{1}{\sin \theta}(Y \sin \theta)_{\theta}+\frac{1}{\sin ^{2} \theta} Y_{\phi \phi}\right) \mathrm{d} \Omega
$$

and then apply the eigenvalue problem of chapter 4.2.3.

## D.14.5 Another way to find the spherical harmonics

There is a more intuitive way to derive the spherical harmonics: they define the power series solutions to the Laplace equation. In particular, each $r^{l} Y_{l}^{m}$ is a different power series solution $P$ of the Laplace equation $\nabla^{2} P=0$ in Cartesian coordinates. Each takes the form

$$
\sum_{\alpha+\beta+\gamma=l} c_{\alpha \beta \gamma} x^{\alpha} y^{\beta} z^{\gamma}
$$

where the coefficients $c_{\alpha \beta \gamma}$ are such as to make the Laplacian zero.
Even more specifically, the spherical harmonics are of the form

$$
\begin{array}{cl}
\sum_{2 a+b=l-m} c_{a b} u^{a+m} v^{a} z^{b} & a, b, m \geqslant 0 \\
\sum_{2 a+b=l-|m|} c_{a b} u^{a} v^{a+|m|} z^{b} & a, b,-m \geqslant 0
\end{array}
$$

where the coordinates $u=x+\mathrm{i} y$ and $v=x-\mathrm{i} y$ serve to simplify the Laplacian. That these are the basic power series solutions of the Laplace equation is readily checked.

To get from those power series solutions back to the equation for the spherical harmonics, one has to do an inverse separation of variables argument for the
solution of the Laplace equation in a sphere in spherical coordinates (compare also the derivation of the hydrogen atom.) Also, one would have to accept on faith that the solution of the Laplace equation is just a power series, as it is in 2D, with no additional nonpower terms, to settle completeness. In other words, you must assume that the solution is analytic.

## D.14.6 Still another way to find them

The simplest way of getting the spherical harmonics is probably the one given later in derivation $\{\mathrm{D} .64\}$.

## D. 15 The hydrogen radial wave functions

This will be child's play for harmonic oscillator, $\{\mathrm{D} .12\}$, and spherical harmonics, $\{\mathrm{D} .14\}$, veterans. If you replace the angular terms in $(4.33)$ by $l(l+1) \hbar^{2}$, and then divide the entire equation by $\hbar^{2}$, you get

$$
-\frac{1}{R} \frac{\mathrm{~d}}{\mathrm{~d} r}\left(r^{2} \frac{\mathrm{~d} R}{\mathrm{~d} r}\right)+l(l+1)-2 \frac{m_{\mathrm{e}} e^{2}}{4 \pi \epsilon_{0} \hbar^{2}} r=\frac{2 m_{\mathrm{e}}}{\hbar^{2}} r^{2} E
$$

Since $l(l+1)$ is nondimensional, all terms in this equation must be. In particular, the ratio in the third term must be the reciprocal of a constant with the dimensions of length; so, define the constant to be the Bohr radius $a_{0}$. It is convenient to also define a correspondingly nondimensionalized radial coordinate as $\rho=r / a_{0}$. The final term in the equation must be nondimensional too, and that means that the energy $E$ must take the form $\left(\hbar^{2} / 2 m_{\mathrm{e}} a_{0}^{2}\right) \epsilon$, where $\epsilon$ is a nondimensional energy. In terms of these scaled coordinates you get

$$
-\frac{1}{R} \frac{\mathrm{~d}}{\mathrm{~d} \rho}\left(\rho^{2} \frac{\mathrm{~d} R}{\mathrm{~d} \rho}\right)+l(l+1)-2 \rho=\rho^{2} \epsilon
$$

or written out

$$
-\rho^{2} R^{\prime \prime}-2 \rho R^{\prime}+\left[l(l+1)-2 \rho-\epsilon \rho^{2}\right] R=0
$$

where the primes denote derivatives with respect to $\rho$.
Similar to the case of the harmonic oscillator, you must have solutions that become zero at large distances $\rho$ from the nucleus: $\int|\psi|^{2} \mathrm{~d}^{3} \vec{r}$ gives the probability of finding the particle integrated over all possible positions, and if $\psi$ does not become zero sufficiently rapidly at large $\rho$, this integral would become infinite, rather than one (certainty) as it should. Now the ODE above becomes for large $\rho$ approximately $R^{\prime \prime}+\epsilon R=0$, which has solutions of the rough form $\cos (\sqrt{\epsilon} \rho+\alpha)$ for positive $\epsilon$ that do not have the required decay to zero. Zero scaled energy $\epsilon$ is still too much, as can be checked by solving in terms of Bessel
functions, so you must have that $\epsilon$ is negative. In classical terms, the earth can only hold onto the moon since the moon's total energy is less than the potential energy far from the earth; if it was not, the moon would escape.

Anyway, for bound states, you must have the scaled energy $\epsilon$ negative. In that case, the solution at large $\rho$ takes the approximate form $R \approx e^{ \pm \sqrt{-\epsilon} \rho}$. Only the negative sign is acceptable. You can make things a lot easier for yourself if you peek at the final solution and rewrite $\epsilon$ as being $-1 / n^{2}$ (that is not really cheating, since you are not at this time claiming that $n$ is an integer, just a positive number.) In that case, the acceptable exponential behavior at large distance takes the form $e^{-\frac{1}{2} \xi}$ where $\xi=2 \rho / n$. Split off this exponential part by writing $R=e^{-\frac{1}{2} \xi} \bar{R}$ where $\bar{R}(\xi)$ must remain bounded at large $\xi$. Substituting these new variables, the ODE becomes

$$
-\xi^{2} \bar{R}^{\prime \prime}+\xi(\xi-2) \bar{R}^{\prime}+[l(l+1)-(n-1) \xi] \bar{R}=0
$$

where the primes indicate derivatives with respect to $\xi$.
If you do a power series solution of this ODE, you see that it must start with either power $\xi^{l}$ or with power $\xi^{-l-1}$. The latter is not acceptable, since it would correspond to an infinite expectation value of energy. You could now expand the solution further in powers of $\xi$, but the problem is that tabulated polynomials usually do not start with a power $l$ but with power zero or one. So you would not easily recognize the polynomial you get. Therefore it is best to split off the leading power by defining $\bar{R}=\xi^{l} \overline{\bar{R}}$, which turns the ODE into

$$
\xi \overline{\bar{R}}^{\prime \prime}+[2(l+1)-\xi] \overline{\bar{R}}^{\prime}+[n-l-1] \overline{\bar{R}}=0
$$

Substituting in a power series $\overline{\bar{R}}=\sum c_{p} \xi^{p}$, you get

$$
\sum p[p+2 l+1] c_{p} \xi^{p-1}=\sum[p+l+1-n] c_{p} \xi^{p}
$$

The acceptable lowest power $p$ of $\xi$ is now zero. Again the series must terminate, otherwise the solution would behave as $e^{\xi}$ at large distance, which is unacceptable. Termination at a highest power $p=q$ requires that $n$ equals $q+l+1$. Since $q$ and $l$ are integers, so must be $n$, and since the final power $q$ is at least zero, $n$ is at least $l+1$. The correct scaled energy $\epsilon=-1 / n^{2}$ with $n>l$ has been obtained.

With $n$ identified, you can identify the ODE as Laguerre's associated differential equation, e.g. [41, 30.26], the ( $2 l+1$ )-th derivative of Laguerre's differential equation, e.g. [41, 30.1], and the polynomial solutions as the associated Laguerre polynomials $L_{n+l}^{2 l+1}$, e.g. [41, 30.27], the $(2 l+1)$-th derivatives of the Laguerre's polynomials $L_{n+l}$, e.g. [41,30.2]. To normalize the wave function use an integral from a table book, e.g. [41, 30.46].

Putting it all together, the generic expression for hydrogen eigenfunctions are, drums please:

$$
\begin{equation*}
\psi_{n l m}=-\frac{2}{n^{2}} \sqrt{\frac{(n-l-1)!}{\left[(n+l)!a_{0}\right]^{3}}}\left(\frac{2 \rho}{n}\right)^{l} L_{n+l}^{2 l+1}\left(\frac{2 \rho}{n}\right) e^{-\rho / n} Y_{l}^{m}(\theta, \phi) \tag{D.8}
\end{equation*}
$$

The properties of the associated Laguerre polynomials $L_{n+l}^{2 l+1}(2 \rho / n)$ are in table books like [41, pp. 169-172], and the spherical harmonics were given earlier in chapter 4.2.3 and in derivation $\{\mathrm{D} .14\},(\mathrm{D} .5)$.

Do keep in mind that different references have contradictory definitions of the associated Laguerre polynomials. This book follows the notations of [41, pp. 169-172], who define

$$
L_{n}(x)=e^{x} \frac{\mathrm{~d}^{n}}{\mathrm{~d} x^{n}}\left(x^{n} e^{-x}\right), \quad L_{n}^{m}=\frac{\mathrm{d}^{m}}{\mathrm{~d} x^{m}} L_{n}(x)
$$

In other words, $L_{n}^{m}$ is simply the $m$-th derivative of $L_{n}$, which certainly tends to simplify things. According to [25, p. 152], the "most nearly standard" notation defines

$$
L_{n}^{m}=(-1)^{m} \frac{\mathrm{~d}^{m}}{\mathrm{~d} x^{m}} L_{n+m}(x)
$$

Combine the messy definition of the spherical harmonics (D.5) with the uncertain definition of the Laguerre polynomials in the formulae (D.8) for the hydrogen energy eigenfunctions $\psi_{n l m}$ above, and there is of course always a possibility of getting an eigenfunction wrong if you are not careful.

Sometimes the value of the wave functions at the origin is needed. Now from the above solution (D.8), it is seen that

$$
\begin{equation*}
\psi_{n l m} \propto r^{l} \quad \text { for } \quad r \rightarrow 0 \tag{D.9}
\end{equation*}
$$

so only the eigenfunctions $\psi_{n 00}$ are nonzero at the origin. To find the value requires $L_{n}^{1}(0)$ where $L_{n}^{1}$ is the derivative of the Laguerre polynomial $L_{n}$. Skimming through table books, you can find that $L_{n}(0)=n!$, [41, 30.19], while the differential equation for these function implies that $L_{n}^{\prime}(0)=-n L_{n}(0)$. Therefore:

$$
\begin{equation*}
\psi_{n 00}(0)=\frac{1}{\sqrt{n^{3} \pi a_{0}^{3}}} \tag{D.10}
\end{equation*}
$$

## D. 16 Constant spherical potentials derivations

This note gives the derivations for constant potentials in spherical coordinates.

## D.16.1 The eigenfunctions

The derivation of the given spherical eigenfunction is almost comically trivial compared to similar problems in quantum mechanics.

Following the lines of the hydrogen atom derivation, chapter 4.3.2, the radial functions $R_{E l}$ are found to satisfy the equation

$$
\frac{\mathrm{d}}{\mathrm{~d} r}\left(r^{2} \frac{\mathrm{~d} R_{E l}}{\mathrm{~d} r}\right)+\left[\frac{p_{\mathrm{c}}^{2}}{\hbar^{2}} r^{2}-l(l+1)\right] R_{E l}=0
$$

To clean this up a bit more, define new dependent and independent variables. In particular, set $R_{E l}=f_{l}$ and $r=x \hbar / p_{\mathrm{c}}$. That produces the spherical Bessel equation

$$
\frac{\mathrm{d}}{\mathrm{~d} x}\left(x^{2} \frac{\mathrm{~d} f_{l}}{\mathrm{~d} x}\right)+\left[x^{2}-l(l+1)\right] f_{l}=0
$$

It is now to be shown that the solutions $f_{l}$ to this equation are the Hankel and Bessel functions as given earlier.

To do so, make another change of dependent variable by setting $f_{l}=x^{l} g_{l}$. That gives for the $g_{l}$ :

$$
x \frac{\mathrm{~d}^{2} g_{l}}{\mathrm{~d} x^{2}}+2(l+1) \frac{\mathrm{d} g_{l}}{\mathrm{~d} x}+x g_{l}=0
$$

Check, by simply plugging it in, that $e^{i x} / x$ is a solution for $l=0$.
Now make a further change in independent variable from $x$ to $\xi=\frac{1}{2} x^{2}$ to give

$$
2 \xi \frac{\mathrm{~d}^{2} g_{l}}{\mathrm{~d} \xi^{2}}+2(l+1) \frac{\mathrm{d} g_{l}}{\mathrm{~d} \xi}+g_{l}=0
$$

Note that the equation for $l=1$ is obtained by differentiating the one for $l=$ 0 , (taking $g_{l}^{\prime}$ as the new unknown.). That implies that the $\xi$-derivative of the solution for $l=0$ above is a solution for $l=1$. Keep differentiating to get solutions for all values of $l$. That produces the spherical Hankel functions of the first kind; the remaining constant is just an arbitrarily chosen normalization factor.

Since the original differential equation is real, the real and imaginary parts of these Hankel functions, as well as their complex conjugates, must be solutions too. That gives the spherical Bessel functions and Hankel functions of the second kind, respectively.

Note that all of them are just finite sums of elementary functions. And that physicists do not even disagree over their definition, just their names.

## D.16.2 The Rayleigh formula

To derive the Rayleigh formula, convert the linear momentum eigenfunction to spherical coordinates by setting $z=r \cos \theta$. Also, for brevity set $x=p_{\infty} r / \hbar$.

That turns the linear momentum eigenfunction into

$$
e^{\mathrm{i} x \cos \theta}=\sum_{\underline{l}=0}^{\infty} \frac{(\mathrm{i} x \cos \theta)^{\underline{l}}}{\underline{l}!}
$$

the latter from Taylor series expansion of the exponential.
Now this is an energy eigenfunction. It can be written in terms of the spherical eigenfunctions

$$
\psi_{E l m}=j_{l}(x) Y_{l}^{m}(\theta, \phi)
$$

with the same energy because the $\psi_{\text {Elm }}$ are complete. In addition, the only eigenfunctions needed are those with $m=0$. The reason is that the spherical harmonics $Y_{l}^{m}$ are simply Fourier modes in the $\phi$ direction, $\{\mathrm{D} .14\}$ (D.5), and the linear momentum eigenfunction above does not depend on $\phi$. Therefore

$$
\sum_{\underline{l}=0}^{\infty} \frac{(\mathrm{i} x \cos \theta)^{\underline{l}}}{\underline{l}!}=\sum_{l=0}^{\infty} c_{\mathrm{w}, l} j_{l}(x) Y_{l}^{0}(\theta)
$$

for suitable coefficients $c_{\mathrm{w}, l}$.
To find these coefficients, find the lowest power of $x$ in $j_{l}$ by writing the sine in (A.19) as a Taylor series and then switching to $x^{2}$ as independent variable. Similarly, find the highest power of $\cos \theta$ in $Y_{l}^{0},\{\mathrm{D} .14\}$ (D.5), by looking up the Rodrigue's formula for the Legendre polynomial appearing in it. That gives

$$
\sum_{\underline{l}=0}^{\infty} \frac{(\mathrm{i} x \cos \theta)^{\underline{l}}}{\underline{l}!}=\sum_{l=0}^{\infty} c_{\mathrm{w}, l}\left(\frac{2^{l} l!}{(2 l+1)!} x^{l}+\ldots\right) \sqrt{\frac{2 l+1}{4 \pi}}\left(\frac{(2 l)!}{2^{l}(l!)^{2}} \cos ^{l} \theta+\ldots\right)
$$

Each coefficient $c_{\mathrm{w}, l}$ must be chosen to match the term with $\underline{l}=l$ in the first sum, because the terms for the other values for $l$ do not have a low enough power of $x$ or a high enough power of the cosine. That gives the Rayleigh values of the coefficients as listed earlier.

## D. 17 Inner product for the expectation value

To see that $\langle\Psi \mid A\rangle$ works for getting the expectation value, just write $\Psi$ out in terms of the eigenfunctions $\alpha_{n}$ of $A$ :

$$
\left\langle c_{1} \alpha_{1}+c_{2} \alpha_{2}+c_{3} \alpha_{3}+\ldots\right| A\left|c_{1} \alpha_{1}+c_{2} \alpha_{2}+c_{3} \alpha_{3}+\ldots\right\rangle
$$

Now by the definition of eigenfunctions $A \alpha_{n}=a_{n} \alpha_{n}$ for every $n$, so you get

$$
\left\langle c_{1} \alpha_{1}+c_{2} \alpha_{2}+c_{3} \alpha_{3}+\ldots \mid c_{1} a_{1} \alpha_{1}+c_{2} a_{2} \alpha_{2}+c_{3} a_{3} \alpha_{3}+\ldots\right\rangle
$$

Since eigenfunctions are orthonormal:

$$
\left\langle\alpha_{1} \mid \alpha_{1}\right\rangle=1 \quad\left\langle\alpha_{2} \mid \alpha_{2}\right\rangle=1 \quad\left\langle\alpha_{3} \mid \alpha_{3}\right\rangle=1 \quad \ldots
$$

$$
\left\langle\alpha_{1} \mid \alpha_{2}\right\rangle=\left\langle\alpha_{2} \mid \alpha_{1}\right\rangle=\left\langle\alpha_{1} \mid \alpha_{3}\right\rangle=\left\langle\alpha_{3} \mid \alpha_{1}\right\rangle=\left\langle\alpha_{2} \mid \alpha_{3}\right\rangle=\left\langle\alpha_{3} \mid \alpha_{2}\right\rangle=\ldots=0
$$

So, multiplying out produces the desired result:

$$
\langle\Psi \mid A \Psi\rangle=\left|c_{1}\right|^{2} a_{1}+\left|c_{2}\right|^{2} a_{2}+\left|c_{3}\right|^{2} a_{3}+\ldots \equiv\langle A\rangle
$$

## D. 18 Eigenfunctions of commuting operators

Any two operators $A$ and $B$ that commute, $A B=B A$, have a common set of eigenfunctions, provided only that each has a complete set of eigenfunctions. (In other words, the operators do not necessarily have to be Hermitian. Unitary, anti-Hermitian, etcetera, operators all qualify.)

First note the following:
if $\alpha_{i}$ is an eigenfunction of $A$ with eigenvalue $a_{i}$, then $B \alpha_{i}$ is either also an eigenfunction of $A$ with eigenvalue $a_{i}$ or is zero.

To see that, note that since $A$ and $B$ commute $A B \alpha_{i}=B A \alpha_{i}$ which is $a_{i} B \alpha_{i}$. Comparing start and end, the combination $B \alpha_{i}$ must be an eigenfunction of $A$ with eigenvalue $a_{i}$ if it is not zero. (Eigenfunctions may not be zero.)

Now assume that there is just a single independent eigenfunction $\alpha_{i}$ for each distinct eigenvalue $a_{i}$ of $A$. Then if $B \alpha_{i}$ is nonzero, it can only be a multiple of that single eigenfunction. By definition, that makes $\alpha_{i}$ an eigenfunction of $B$ too, with as eigenvalue the multiple. On the other hand, if $B \alpha_{i}$ is zero, then $\alpha_{i}$ is still an eigenfunction of $B$, now with eigenvalue zero. So under the stated assumption, $A$ and $B$ have the exact same eigenfunctions, proving the assertion of this derivation.

However, frequently there is "degeneracy," i.e. there is more than one eigenfunction $\alpha_{i, 1}, \alpha_{i, 2}, \ldots$ for a single eigenvalue $a_{i}$. Then the fact that, say, $B \alpha_{i, 1}$ is an eigenfunction of $A$ with eigenvalue $a_{i}$ no longer means that $B \alpha_{i, 1}$ is a multiple of $\alpha_{i, 1}$; it only means that $B \alpha_{i, 1}$ is some combination of all of $\alpha_{i, 1}, \alpha_{i, 2}, \ldots$. Which means that $\alpha_{i, 1}$ is not in general an eigenfunction of $B$.

To deal with that, it has to be assumed that the problem has been numerically approximated by some finite-dimensional one. Then $A$ and $B$ will be matrices, and the number of independent eigenfunctions (or rather, eigenvectors now) of $A$ and $B$ will be finite and equal. That allows the problem to be addressed one eigenfunction at a time.

Assume now that $\beta$ is an eigenfunction of $B$, with eigenvalue $b$, that is not yet an eigenfunction of $A$ too. By completeness, it can still be written as a combination of the eigenfunctions of $A$, and more particularly as $\beta=\beta_{a_{i}}+\beta_{o}$ where $\beta_{a_{i}}$ is a combination of the eigenfunctions of $A$ with eigenvalue $a_{i}$ and $\beta_{o}$ a combination of the eigenfunctions of $A$ with other eigenvalues. There must be such eigenfunctions with $\beta_{a_{i}}$ nonzero, because without using the $\alpha_{i}$ you cannot
create an equal number of independent eigenfunctions of $B$ as of $A$. By definition

$$
B\left(\beta_{a_{i}}+\beta_{o}\right)=b\left(\beta_{a_{i}}+\beta_{o}\right)
$$

but that must mean that

$$
B \beta_{a_{i}}=b \beta_{a_{i}}
$$

since if it is not, $B \beta_{0}$ cannot make up the difference; as seen earlier, $B \beta_{0}$ only consists of eigenfunctions of $A$ that do not have eigenvalue $a_{i}$. According to the above equation, $\beta_{a_{i}}$, which is already an eigenfunction of $A$ with eigenvalue $a_{i}$, is also an eigenfunction of $B$ with eigenvalue $b$. So replace one of the $\alpha_{i, 1}$, $\alpha_{i, 2}, \ldots$ with $\beta_{a_{i}}$. (If you write $\beta_{a_{i}}$ in terms of the $\alpha_{i, 1}, \alpha_{i, 2}, \ldots$, then the function you replace may not appear with a zero coefficient.) Similarly replace an eigenfunction of $B$ with eigenvalue $b$ with $\beta_{a_{i}}$. Then $A$ and $B$ have one more common eigenfunction. Keep going in this way and eventually all eigenfunctions of $B$ are also eigenfunctions of $A$ and vice versa.

Similar arguments can be used recursively to show that more generally, a set of operators $A, B, C, \ldots$ that all commute have a single common set of eigenfunctions. The trick is to define an artificial new operator, call it $P$, that has the common eigenfunctions of $A$ and $B$, but whose eigenvalues are distinct for any two eigenfunctions unless these eigenfunctions have the same eigenvalues for both $A$ and $B$. Then the eigenfunctions of $P$, even if you mess with them, remain eigenfunctions of $A$ and $B$. So go find common eigenfunctions for $P$ and C.

The above derivation assumed that the problem was finite-dimensional, or discretized some way into a finite-dimensional one like you do in numerical solutions. The latter is open to some suspicion, because even the most accurate numerical approximation is never truly exact. Unfortunately, in the infinitedimensional case the derivation gets much trickier. However, as the hydrogen atom and harmonic oscillator eigenfunction examples indicate, typical infinite systems in nature do obey the theorem anyway.

## D. 19 The generalized uncertainty relationship

This note derives the generalized uncertainty relationship.
For brevity, define $A^{\prime}=A-\langle A\rangle$ and $B^{\prime}=B-\langle B\rangle$, then the general expression for standard deviation says

$$
\sigma_{A}^{2} \sigma_{B}^{2}=\left\langle A^{\prime 2}\right\rangle\left\langle B^{\prime 2}\right\rangle=\left\langle\Psi \mid A^{\prime 2} \Psi\right\rangle\left\langle\Psi \mid B^{\prime 2} \Psi\right\rangle
$$

Hermitian operators can be taken to the other side of inner products, so

$$
\sigma_{A}^{2} \sigma_{B}^{2}=\left\langle A^{\prime} \Psi \mid A^{\prime} \Psi\right\rangle\left\langle B^{\prime} \Psi \mid B^{\prime} \Psi\right\rangle
$$

Now the Cauchy-Schwartz inequality says that for any $f$ and $g$,

$$
|\langle f \mid g\rangle| \leqslant \sqrt{\langle f \mid f\rangle} \sqrt{\langle g \mid g\rangle}
$$

(See the notations for more on this theorem.) Using the Cauchy-Schwartz inequality in reversed order, you get

$$
\sigma_{A}^{2} \sigma_{B}^{2} \geqslant\left|\left\langle A^{\prime} \Psi \mid B^{\prime} \Psi\right\rangle\right|^{2}=\left|\left\langle A^{\prime} B^{\prime}\right\rangle\right|^{2}
$$

Now by the definition of the inner product, the complex conjugate of $\left\langle A^{\prime} \Psi \mid B^{\prime} \Psi\right\rangle$ is $\left\langle B^{\prime} \Psi \mid A^{\prime} \Psi\right\rangle$, so the complex conjugate of $\left\langle A^{\prime} B^{\prime}\right\rangle$ is $\left\langle B^{\prime} A^{\prime}\right\rangle$, and averaging a complex number with minus its complex conjugate reduces its size, since the real part averages away, so

$$
\sigma_{A}^{2} \sigma_{B}^{2} \geqslant\left|\frac{\left\langle A^{\prime} B^{\prime}\right\rangle-\left\langle B^{\prime} A^{\prime}\right\rangle}{2}\right|^{2}
$$

The quantity in the top is the expectation value of the commutator $\left[A^{\prime}, B^{\prime}\right]$. Writing it out shows that $\left[A^{\prime}, B^{\prime}\right]=[A, B]$.

## D. 20 Derivation of the commutator rules

This note explains where the formulae of chapter 4.5.4 come from.
The general assertions are readily checked by simply writing out both sides of the equation and comparing. And some are just rewrites of earlier ones.

Position and potential energy operators commute since they are just ordinary numerical multiplications, and these commute.

The linear momentum operators commute because the order in which differentiation is done is irrelevant. Similarly, commutators between angular momentum in one direction and position in another direction commute since the other directions are not affected by the differentiation.

The commutator between the position $X$ and linear momentum $p_{x}$ in the $x$ direction was worked out in the previous subsection to figure out Heisenberg's uncertainty principle. Of course, three-dimensional space has no preferred direction, so the result applies the same in any direction, including the $y$ and $z$ directions.

The angular momentum commutators are simplest obtained by just grinding out

$$
\left[\widehat{L}_{x}, \widehat{L}_{y}\right]=\left[\widehat{y p} \widehat{p}_{z}-\widehat{z} \widehat{p}_{y}, \widehat{z} \widehat{p}_{x}-\widehat{x} \widehat{p}_{z}\right]
$$

using the linear combination and product manipulation rules and the commutators for linear angular momentum. To generalize the result you get, you cannot just arbitrarily swap $x, y$, and $z$, since, as every mechanic knows, a right-handed screw is not the same as a left-handed one, and some axes swaps would turn one
into the other. But you can swap axes according to the "xyzxyzx..." "cyclic permutation" scheme, as in:

$$
x \rightarrow y, \quad y \rightarrow z, \quad z \rightarrow x
$$

which produces the other two commutators if you do it twice:

$$
\left[\widehat{L}_{x}, \widehat{L}_{y}\right]=\mathrm{i} \hbar \widehat{L}_{z} \quad \longrightarrow \quad\left[\widehat{L}_{y}, \widehat{L}_{z}\right]=\mathrm{i} \hbar \widehat{L}_{x} \quad \longrightarrow \quad\left[\widehat{L}_{z}, \widehat{L}_{x}\right]=\mathrm{i} \hbar \widehat{L}_{y}
$$

For the commutators with square angular momentum, work out

$$
\left[\widehat{L}_{x}, \widehat{L}_{x}^{2}+\widehat{L}_{y}^{2}+\widehat{L}_{z}^{2}\right]
$$

using the manipulation rules and the commutators between angular momentum components.

A commutator like $\left[\widehat{x}, \widehat{L}_{x}\right]=\left[\widehat{x}, \widehat{y p}_{z}-\widehat{z} \widehat{p}_{y}\right]$ is zero because everything commutes in it. However, in a commutator like $\left[\widehat{x}, \widehat{L}_{y}\right]=\left[\widehat{x}, \widehat{z} \widehat{p}_{x}-\widehat{x} \widehat{p}_{z}\right], \widehat{x}$ does not commute with $\widehat{p}_{x}$, so multiplying out and taking the $\widehat{z}$ out of $\left[\widehat{x}, \widehat{z} \widehat{x}_{x}\right]$ at its own side, you get $\widehat{z}\left[\widehat{x}, \widehat{p}_{x}\right]$, and the commutator left is the canonical one, which has value $\mathrm{i} \hbar$. Plug these results and similar into $\left[\widehat{x}^{2}+\widehat{y}^{2}+\widehat{z}^{2}, L_{x}\right]$ and you get zero.

For a commutator like $\left[\widehat{x}, \widehat{L}^{2}\right]=\left[\widehat{x}, \widehat{L}_{x}^{2}+\widehat{L}_{y}^{2}+\widehat{L}_{z}^{2}\right]$, the $L_{x}^{2}$ term produces zero because $\widehat{L}_{x}$ commutes with $\widehat{x}$, and in the remaining term, taking the various factors out at their own sides of the commutator produces

$$
\begin{aligned}
{\left[\widehat{x}, \widehat{L}^{2}\right] } & =\widehat{L}_{y}\left[\widehat{x}, \widehat{L}_{y}\right]+\left[\widehat{x}, \widehat{L}_{y}\right] \widehat{L}_{y}+\widehat{L}_{z}\left[\widehat{x}, \widehat{L}_{z}\right]+\left[\widehat{x}, \widehat{L}_{z}\right] \widehat{L}_{z} \\
& =\mathrm{i} \hbar \widehat{L}_{y} \widehat{z}+\mathrm{i} \hbar \widehat{z} \widehat{L}_{y}-\mathrm{i} \hbar \widehat{L}_{z} \widehat{y}-\mathrm{i} \hbar \widehat{y} \widehat{L}_{z}
\end{aligned}
$$

the final equality because of the commutators already worked out. Now by the nature of the commutator, you can swap the order of the terms in $\widehat{L}_{y} \widehat{z}$ as long as you add the commutator $\left[\widehat{L}_{y}, \widehat{z}\right]$ to make up for it, and that commutator was already found to be i$\hbar \widehat{x}$, The same way the order of $\widehat{L}_{z} \widehat{y}$ can be swapped to give

$$
\left[\widehat{x}, \widehat{L}^{2}\right]=-2 \hbar^{2} \widehat{x}-2 \mathrm{i} \hbar\left(\widehat{y} \widehat{L}_{z}-\widehat{z} \widehat{L}_{y}\right)
$$

and the parenthetical expression can be recognized as the $x$-component of $\widehat{\vec{r}} \times$ $\widehat{\vec{L}}$, giving one of the expressions claimed.

Instead you can work out the parenthetical expression further by substituting in the definitions for $\widehat{L}_{z}$ and $\widehat{L}_{y}$ :

$$
\left[\widehat{x}, \widehat{L}^{2}\right]=-2 \hbar^{2} \widehat{x}-2 \mathrm{i} \hbar\left(\widehat{y}\left(\widehat{x} \widehat{p}_{y}-\widehat{y} \widehat{p}_{x}\right)-\widehat{z}\left(\widehat{z} \widehat{p}_{x}-\widehat{x} \widehat{p}_{z}\right)-\widehat{x}\left(\widehat{x} \widehat{p}_{x}-\widehat{x} \widehat{p}_{x}\right)\right)
$$

where the third term added within the big parentheses is self-evidently zero. This can be reordered to the $x$-component of the second claimed expression. And as always, the other components are of course no different.

The commutators between linear and angular momentum go almost identically, except for additional swaps in the order between position and momentum operators using the canonical commutator.

To derive the first commutator in (4.73), consider the $z$-component as the example:

$$
\left[x \widehat{L}_{y}-y \widehat{L}_{x}, \widehat{L}^{2}\right]=\left[x, \widehat{L}^{2}\right] \widehat{L}_{y}-\left[y, \widehat{L}^{2}\right] L_{x}
$$

because $L^{2}$ commutes with $\widehat{\vec{L}}$, and using (4.68)

$$
\left[x \widehat{L}_{y}-y \widehat{L}_{x}, \widehat{L}^{2}\right]=-2 \hbar^{2} x \widehat{L}_{y}-2 \mathrm{i} \hbar\left(y \widehat{L}_{z} \widehat{L}_{y}-z \widehat{L}_{y}^{2}\right)+2 \hbar^{2} y \widehat{L}_{x}+2 \mathrm{i} \hbar\left(z \widehat{L}_{x}^{2}-x \widehat{L}_{z} \widehat{L}_{x}\right)
$$

Now use the commutator $\left[\widehat{L}_{y}, \widehat{L}_{z}\right.$ ] to get rid of $\widehat{L}_{z} \widehat{L}_{y}$ and [ $\widehat{L}_{z}, \widehat{L}_{x}$ ] to get rid of $\widehat{L}_{z} \widehat{L}_{x}$ and clean up to get

$$
\left[x \widehat{L}_{y}-y \widehat{L}_{x}, \widehat{L}^{2}\right]=2 \mathrm{i} \hbar\left(-y \widehat{L}_{y} \widehat{L}_{z}+z \widehat{L}_{y}^{2}+z \widehat{L}_{x}^{2}-x \widehat{L}_{x} \widehat{L}_{z}\right)
$$

Now $\vec{r} \cdot \widehat{\vec{L}}=\vec{r} \cdot(\vec{r} \times \widehat{\vec{p}})=0$ so $x \widehat{L}_{x}+y \widehat{L}_{y}=-z \widehat{L}_{z}$, which gives the claimed expression. To verify the second equation of (4.73), use (4.68), the first of (4.73), and the definition of $\left[\vec{r}, \widehat{L}^{2}\right]$.

## D. 21 Solution of the hydrogen molecular ion

The key to the variational approximation to the hydrogen molecular ion is to be able to accurately evaluate the expectation energy

$$
\langle E\rangle=\left\langle a \psi_{1}+b \psi_{\mathrm{r}}\right| H\left|a \psi_{1}+b \psi_{\mathrm{r}}\right\rangle
$$

This can be multiplied out and simplified by noting that $\psi_{1}$ and $\psi_{\mathrm{r}}$ are eigenfunctions of the partial Hamiltonians. For example,

$$
H \psi_{1}=E_{1} \psi_{1}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{\mathrm{r}}} \psi_{1}
$$

where $E_{1}$ is the -13.6 eV hydrogen atom ground state energy. The expression can be further simplified by noting that by symmetry

$$
\left\langle\psi_{\mathrm{r}} \mid r_{1}^{-1} \psi_{\mathrm{r}}\right\rangle=\left\langle\psi_{1} \mid r_{\mathrm{r}}^{-1} \psi_{1}\right\rangle \quad\left\langle\psi_{1} \mid r_{1}^{-1} \psi_{\mathrm{r}}\right\rangle=\left\langle\psi_{\mathrm{r}} \mid r_{\mathrm{r}}^{-1} \psi_{1}\right\rangle
$$

and that $\psi_{1}$ and $\psi_{\mathrm{r}}$ are real, so that the left and right sides of the various inner products can be reversed. Also, $a$ and $b$ are related by the normalization requirement

$$
a^{2}+b^{2}+2 a b\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle=1
$$

Cleaning up the expectation energy in this way, the result is
$\langle E\rangle=E_{1}-$

$$
\frac{e^{2}}{4 \pi \epsilon_{0}}\left[\left\langle\psi_{1} \mid r_{\mathrm{r}}^{-1} \psi_{1}\right\rangle-\frac{1}{d}+2 a b\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle\left\{\frac{\left\langle\psi_{1} \mid r_{1}^{-1} \psi_{\mathrm{r}}\right\rangle}{\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle}-\left\langle\psi_{1} \mid r_{\mathrm{r}}^{-1} \psi_{1}\right\rangle\right\}\right]
$$

which includes the proton to proton repulsion energy (the $1 / d$ ). The energy $E_{1}$ is the -13.6 eV amount of energy when the protons are far apart.

Numerical integration is not needed; the inner product integrals in this expression can be done analytically. To do so, take the origin of a spherical coordinate system $(r, \theta, \phi)$ at the left proton, and the axis towards the right one, so that

$$
r_{1}=\left|\vec{r}-\vec{r}_{\mathrm{lp}}\right|=r \quad r_{\mathrm{r}}=\left|\vec{r}-\vec{r}_{\mathrm{rp}}\right|=\sqrt{d^{2}+r^{2}-2 d r \cos (\theta)}
$$

In those terms,

$$
\psi_{1}=\frac{1}{\sqrt{\pi a_{0}^{3}}} e^{-r / a_{0}} \quad \psi_{\mathrm{r}}=\frac{1}{\sqrt{\pi a_{0}^{3}}} e^{-\sqrt{d^{2}+r^{2}-2 d r \cos (\theta)} / a_{0}}
$$

Then integrate angles first using $\mathrm{d}^{3} \vec{r}=r^{2} \sin (\theta) \mathrm{d} r \mathrm{~d} \theta \mathrm{~d} \phi=-r^{2} \mathrm{~d} r \mathrm{~d} \cos (\theta) \mathrm{d} \phi$. Do not forget that $\sqrt{x^{2}}=|x|$, not $x$, e.g. $\sqrt{(-3)^{2}}=3$, not -3 . More details are in [25, pp. 305-307].

The "overlap integral" turns out to be

$$
\left\langle\psi_{1} \mid \psi_{\mathbf{r}}\right\rangle=e^{-d / a_{0}}\left[1+\frac{d}{a_{0}}+\frac{1}{3}\left(\frac{d}{a_{0}}\right)^{2}\right]
$$

and provides a measure of how much the regions of the two wave functions overlap. The "direct integral" is

$$
\left\langle\psi_{1} \mid r_{\mathrm{r}}^{-1} \psi_{1}\right\rangle=\frac{1}{d}-\left[\frac{1}{a_{0}}+\frac{1}{d}\right] e^{-2 d / a_{0}}
$$

and gives the classical potential of an electron density of strength $\left|\psi_{1}\right|^{2}$ in the field of the right proton, except for the factor $-e^{2} / 4 \pi \epsilon_{0}$. The "exchange integral" is

$$
\left\langle\psi_{1} \mid r_{1}^{-1} \psi_{\mathrm{r}}\right\rangle=\left[\frac{1}{a_{0}}+\frac{d}{a_{0}^{2}}\right] e^{-d / a_{0}}
$$

and is somewhat of a twilight term, since $\psi_{1}$ suggests that the electron is around the left proton, but $\psi_{\mathrm{r}}$ suggests it is around the right one.

## D. 22 Unique ground state wave function

This derivation completes $\{$ A. 8$\}$. In particular, it proves that ground states are unique, given a real, noninfinite, potential that only depends on position. The derivation also proves that ground states cannot become zero. So they can be taken to be positive.

The basic idea is first to assume tentatively that there would be two independent ground state wave functions. These could then be taken to be orthonormal as usual. That means that the inner product of the two wave functions would be zero. However, it can be shown, see below, that ground state wave functions cannot cross zero. That means that both wave functions can be taken to be everywhere positive. (The one exception is at impenetrable boundaries, where the wave function is forced to be zero, rather than positive. But that exception does not change the argument here.) Now if you check the definition of the inner product, you see that the inner product of two positive wave functions is positive, not zero. But the orthonormality says that it is zero. So there is a contradiction. That means that the made assumption, that there are two independent ground states, must be wrong. So the ground state must be unique.

Figure D.1: Right: the absolute value of the wave function has a kink at a zero crossing. Middle: the kink has been slightly blunted. Right: an alternate way of blunting.

To finish the proof then, it must still be shown that ground states that cross zero are not possible. Tentatively suppose that you had a ground state whose wave function did cross zero. Near a zero crossing, the wave function $\psi$ will then look something like the left part of figure D.1. (For a multi-dimensional wave function, you can take this figure to be some arbitrary one-dimensional cross section through the zero crossing.) Note from the figure that the absolute value $|\psi|$ has a kink at the zero crossing.

Next recall from $\{\mathrm{A} .8\}$ that $|\psi|$ has the ground state energy just like $\psi$. So it should not be possible to lower the energy below that of $|\psi|$. But the problem is now that the wave function shown in the middle in figure D. 1 does have less energy. This wave function looks generally the same as $|\psi|$, except that the kink
has been blunted just a little bit. More precisely, this wave function has been prevented from becoming any smaller than some very small number $\varepsilon$.

To see why this wave function has less energy, compare what happens to the kinetic and potential energies. The energy is the sum of a kinetic energy integral $I_{T}$ and a potential energy integral $I_{V}$. These are given by

$$
I_{T}=\frac{\hbar^{2}}{2 m} \int_{\text {all }}(\nabla \psi)^{2} \mathrm{~d}^{3} \vec{r} \quad I_{V}=\int_{\text {all }} V \psi^{2} \mathrm{~d}^{3} \vec{r}
$$

In the region that is blunted, the integrand of the kinetic energy integral is now zero, instead of whatever positive value it had in the left figure. The constant $\varepsilon$ has zero derivatives. So the kinetic energy has been decreased noticeably.

You might at first think that the potential energy can compensate by increasing more than the kinetic energy decreases. But that does not work, because the integrand of the potential energy integral is proportional to $|\psi|^{2}$, and that is negligibly small in the blunted region. In fact, $|\psi|^{2}$ is no larger than $\varepsilon^{2}$, and $\varepsilon$ was a very small number. So, if the kinetic energy decreases and the potential energy stays virtually the same, the conclusion is unavoidable. The energy decreases. The wave function in the middle in the figure has less energy than the ones on the left. So the ones on the left cannot be ground states. So ground state wave functions cannot cross zero.

That is basically it. Unfortunately, there are a few loose ends in the reasoning above. That is even if you ignore that "small" is not a valid mathematical concept. A number is either zero or not zero; that is all in mathematics. The correct mathematical statement is: "there is a number $\varepsilon$ small enough that the kinetic energy decrease exceeds the potential energy increase." (Note that "small enough" does not imply small. All positive numbers less than 1000 are small enough to be less than 1000 .) But that is so picky.

More importantly, you might object that after blunting, the wave function will no longer be normalized. But you can correct for that by dividing the given expression of the expectation energy by the square norm of the wave function. In particular, using a prime to indicate a quantity after blunting the wave function, the correct energy is

$$
\langle E\rangle^{\prime}=\frac{I_{T}^{\prime}+I_{V}^{\prime}}{\left\langle\psi^{\prime} \mid \psi^{\prime}\right\rangle} \quad\left\langle\psi^{\prime} \mid \psi^{\prime}\right\rangle=\int_{\text {all }}\left(\psi^{\prime}\right)^{2} \mathrm{~d}^{3} \vec{r}
$$

Now note that the square norm changes negligibly under the smoothing, because its integrand involves $|\psi|^{2}$ just like the potential energy. So dividing by the square norm should not make a difference.

In fact, there is a trick to avoid the normalization problem completely. Simply redefine the potential energy by a constant to make the expectation energy zero. You can always do that; changing the definition of the potential energy by constant does not make a difference physically. And if the expectation energy
$\langle E\rangle$ is zero, then so is $I_{\mathrm{T}}+I_{\mathrm{V}}$. Therefore the change in energy due to blunting becomes

$$
\langle E\rangle^{\prime}-\langle E\rangle=\langle E\rangle^{\prime}=\frac{I_{T}^{\prime}+I_{V}^{\prime}}{\left\langle\psi^{\prime} \mid \psi^{\prime}\right\rangle}=\frac{I_{T}^{\prime}+I_{V}^{\prime}-\left(I_{T}+I_{V}\right)}{\left\langle\psi^{\prime} \mid \psi^{\prime}\right\rangle}
$$

Comparing start and end, you see that the sign of the change in energy is the same as the sign of the change in the kinetic and potential energy integrals. Regardless of whether $\psi^{\prime}$ is normalized. And the sign of the change in energy is all that counts. If it is negative, you do not have a ground state. So if $I_{T}+I_{V}$ decreases due to blunting, you do not have a ground state. Because of this trick, the normalization problem can be ignored in the rest of the derivations.

You might further object that the given arguments do not account for the possibility that the wave function could cross zero with zero slope. In that case, the integrand of the original kinetic energy would be vanishingly small too. True.

But in one dimension, you can use the Cauchy-Schwartz inequality of the notations section on $|\psi|$ to show that the decrease in kinetic energy will still be more than the increase in potential energy. For simplicity, the coordinate $x$ will be taken zero at the original zero crossing, as in the middle graph of figure D.1. Now consider the part of the blunted region at negative $x$. Here the original kinetic energy integral was:

$$
\begin{aligned}
I_{T}=\frac{\hbar^{2}}{2 m} \int_{-\delta}^{0}\left|\psi_{x}\right|^{2} \mathrm{~d} x & =\frac{\hbar^{2}}{2 m} \int_{-\delta}^{0}\left|\psi_{x}\right|^{2} \mathrm{~d} x \quad \frac{1}{\delta} \int_{-\delta}^{0} 1 \mathrm{~d} x \\
& \geqslant \frac{\hbar^{2}}{2 m \delta}\left(\int_{-\delta}^{0}\left|\psi_{x}\right| 1 \mathrm{~d} x\right)^{2} \\
& \geqslant \frac{\hbar^{2}}{2 m \delta}\left(\int_{-\delta}^{0}-\psi_{x} \mathrm{~d} x\right)^{2} \\
& =\frac{\hbar^{2} \varepsilon^{2}}{2 m \delta}
\end{aligned}
$$

The first inequality above is the Cauchy-Schwartz inequality. The final equality applies because the change in $\psi$ is the integral of its derivative. Comparing start and end above, the kinetic energy decrease is at least $\hbar^{2} \varepsilon^{2} / 2 m \delta$. On the other hand for the increase in potential energy

$$
I_{V}^{\prime}-I_{V}=\int_{-\delta}^{0} V\left(\varepsilon^{2}-|\psi|^{2}\right) \mathrm{d} x \leqslant \int_{-\delta}^{0} V_{\max } \varepsilon^{2} \mathrm{~d} x=V_{\max } \varepsilon^{2} \delta
$$

where $V_{\max }$ is the maximum (redefined) potential in the region. (Note that if $\psi$ is not monotonuous, $-\delta$ and $\delta_{2}$ are defined as the points closest to the origin where $\varepsilon$ is reached. So by definition $|\psi|$ does not exceed $\varepsilon$.) It is seen that the maximum potential energy decrease is proportional to $\delta$. However, the
minimum kinetic energy decrease is proportional to $1 / \delta$. So for small enough $\delta$, potential energy increase cannot compete with kinetic energy decrease. More specifically, taking $\delta^{2}$ small compared to $\hbar^{2} / 2 m V_{\max }$ makes the potential energy increase small compared to the kinetic energy decrease. So the net energy will decrease, showing that the original wave function is indeed not a ground state. (If $V_{\max }$ is negative, the potential energy will decrease, and net energy decrease is automatic.)

The same arguments normally apply for the blunted region at positive $x$. However, there is a possible exception. If after $\psi$ reaches zero, it stays zero, there will be no position $\delta_{2}$. At least not one vanishingly close to zero. To deal with this possibility, a slightly more sophisticated blunting can be used. That one is shown to the right in figure D.1. Here the blunting region is taken to be symmetric around the origin. The value of $\delta$ is taken as the smallest distance from the origin where $\varepsilon$ is reached. Therefore once again $|\psi|$ does not exceed $\varepsilon$. Note that the modified wave function now has some kinetic energy left. In particular it has left

$$
\frac{\hbar^{2}}{2 m} \int_{-\delta}^{\delta}\left|\frac{\varepsilon-\varepsilon_{2}}{2 \delta}\right|^{2} \mathrm{~d} x=\frac{\hbar^{2}\left(\varepsilon-\varepsilon_{2}\right)^{2}}{4 m \delta} \leqslant \frac{\hbar^{2} \varepsilon^{2}}{4 m \delta}
$$

However, as seen above, the negative blunted part has kinetic energy of at least $\hbar^{2} \varepsilon^{2} / 2 m \delta$. So the kinetic energy decrease is still at least half of what it was. That is enough not to change the basic story.

Note that in neither approach, the zero crossing point can be at an impenetrable boundary. Neither blunted wave function is zero at $x=0$ at it should be at an impenetrable boundary. That explains why ground state wave functions can indeed become zero at impenetrable boundaries. The ground state of the particle in a pipe provides an example, chapter 3.5.

Also note the need to assume that the potential does not become positive infinity. If the potential is positive infinity in a finite region, then the wave function is in fact zero inside that region. The particle cannot penetrate into such a region. Its surface acts just like an impenetrable boundary.

How about wave functions in more than one dimension? That is easy, if you will allow a very minor assumption. The minor assumption is that there is at least a single crossing point where the gradient of $\psi$ is continuous and nonzero. It does not have to be true at all the zero crossing points, just at one of them. And in fact it does not even have to be true for either one of the two supposed ground states. It is enough if it is true for a single point in some linear combination of them. So it is very hard to imagine ground states for which the assumption would not apply.

Accepting that assumption, things are straightforward. Take the blunted wave function essentially like the middle graph in figure D.1. The $x$-direction is now the direction of the gradient at the point. However, rather than limiting the wave function to stay above $\varepsilon$, demand that it stays above $\varepsilon\left(\ell^{2}-r^{2}\right) / \ell^{2}$.

Here $r$ is the distance from the considered zero crossing point, and $\ell$ is a number small enough that the variation in the gradient is no more than say $50 \%$ within a distance $\ell$ from the zero crossing point. There is then again some kinetic energy left, but it is negligibly small. The estimates in each cross section of the blunted region are essentially the same as in the one-dimensional case.

However, all that does require that one minor assumption. You might wonder about pathological cases. For example, what if one wave function is only nonzero where the other is zero and vice-versa? With zero gradient at every single point of the zero crossings to boot? Of course, you and I know that ground states are not just stupidly going to be zero in sizable parts of the region. Why would the electron stay out of some region completely? Would not its uncertainty in position at least produce a very tiny probability for the elecron to be inside them? But proving it rigorously is another matter. Then there are somewhat more reasonable conjectures, like that a wave function would become zero at a single point not at the boundary. (That would still give a unique ground state. But would you not want to know whether it really could happen?) How about fractal wave functions? Or just discontinuous ones? In one dimension the wave function must be continuous, period. A discontinuity would produce a delta function in the derivative, which would produce infinite kinetic energy. But in multiple dimensions, things become much less obvious. (Note however that in real life, a noticeably singularity in $\psi$ at a point would require quite a singular potential at that point.)

You might guess that you could use the approach of the right graph in figure D. 1 in multiple dimensions, taking the $x$ coordinate in the direction normal to the zero crossing surface. But first of all that requires that the zero crossing surface is rectifiable. That excludes lone zero crossing points, or fractal crossing surfaces. And in addition there is a major problem with trying to show that the derivatives in directions other than $x$ remain small.

There is however a method somewhat similar to the one of the right graph that continues to work in more than one dimensions. In particular, in three dimensions this method uses a small sphere of radius $\delta$ around the supposed point of zero wave function. The method can show in, any number of dimensions, that $|\psi|$ cannot become zero. (Except at impenetrable boundaries as always.) The method does not make any unjustified a priory assumptions like a nonzero gradient. However, be warned: it is going to be messy. Only mathematically inclined students should read the rest of this derivation.

The discussion will use three dimensions as an example. That corresponds, for example, to the electron of the hydrogen molecular ion. But the same arguments can be made in any number of dimensions. For example, you might have a particle confined in a two-dimensional quantum well. In that case, the sphere around the point of zero wave function becomes a circle. Similarly, in a one-dimensional quantum wire, the sphere becomes the line segment $-\delta \leqslant x$ $\leqslant \delta$. If you have two nonconfined electrons instead of just one, you are in six
dimensions. All these cases can be covered mathematically by generalizing the three-dimensional sphere to a "hypersphere." A two-dimensional hypersphere is physically a circle, and a one-dimensional hypersphere is a line segment. As discussed in the notations section, a general $n$-dimensional hypersphere has an $n$-dimensional "volume" and surface "area" given by:

$$
\mathcal{V}_{n}=C_{n} \delta^{n} \quad A_{n}=n C_{n} \delta^{n-1}
$$

For example, $C_{3}=4 \pi / 3$, so the above expressions give the correct volume and surface of a sphere in three dimensions. In two dimensions, the "volume" is physically the area of the circle, and the "area" is its perimeter. The derivations will need that the $n$-dimensional infinitesimal integration element is

$$
\mathrm{d}^{n} \vec{r}=\mathrm{d} A_{n} \mathrm{~d} r
$$

Here $\mathrm{d} A_{n}$ is an infinitesimal segment of the spherical surface of radius $r$. You can relate this to the way that you do integration in polar or spherical coordinates. However, the above expression does not depend on exactly how the angular coordinates on hypersphere areas are defined.

To show that points of zero wave function are not possible, once again first the opposite will be assumed. So it will be assumed that there is some point where $|\psi|$ becomes zero. Then a contradiction will be established. That means that the assumption must be incorrect; there are no points of zero wave function.

To find the contradiction, define a radial coordinate $r$ as the distance away from the supposed point of zero $|\psi|$. Next at every distance $r$, define $\varphi(r)$ as the average value $|\psi|$ on the spherical surface of radius $r$ :

$$
\varphi(r) \equiv \int|\psi| \frac{\mathrm{d} A_{n}}{A_{n}}
$$

Function $\varphi(r)$ will need to be continuous for $r \neq 0$, otherwise the implied jump in wave function values would produce infinite kinetic energy. For $|\psi|$ to become zero at $r=0$, as assumed, requires that $\varphi(r)$ is also continuous at $r=0$ and that $\varphi(0)=0$. (Note that $|\psi|$ must be continuous and zero at $r=0$. Otherwise it would have values that stay a finite amount above zero however close you get to $r=0$. Then $|\psi|$ would not be zero in a meaningful sense. And here we want to exclude points of zero wave function. Excluding points of indeterminate wave function will be left as an exercise for the reader. But as already mentioned, that sort of singular behavior would require quite a singular potential.)

Take now some small sphere, of some small radius $\delta$, around the supposed point of zero wave function. The value of $\varphi$ on the outer surface of this sphere will be called $\varepsilon$. It will be assumed that there are no values of $\varphi(r)$ greater than $\epsilon$ inside the sphere. (If there are, you can always reduce the value of $\delta$ to get rid of them.)

The blunting inside this sphere will now be achieved by replacing the $\varphi(r)$ part of $|\psi|$ by $\varepsilon$. So the blunted wave function is:

$$
\psi^{\prime} \equiv|\psi|-\varphi(r)+\varepsilon
$$

Consider now first what the corresponding increase in the potential energy integral inside the sphere is:

$$
I_{V}^{\prime}-I_{V}=\int\left[V(|\psi|-\varphi(r)+\varepsilon)^{2}-V(|\psi|)^{2}\right] \mathrm{d}^{3} \vec{r}
$$

Multiplying out the square, that becomes:

$$
I_{V}^{\prime}-I_{V}=\int 2 V|\psi|(\varepsilon-\varphi(r)) \mathrm{d}^{3} \vec{r}+\int V(\varepsilon-\varphi(r))^{2} \mathrm{~d}^{3} \vec{r}
$$

Since $\varphi(r)$ is nonnegative, it follows that the increase in potential energy is limited as

$$
I_{V}^{\prime}-I_{V} \leqslant 2 V_{\max } \varepsilon \int|\psi| \mathrm{d}^{3} \vec{r}+V_{\max } \varepsilon^{2} \int \mathrm{~d}^{3} \vec{r} \quad \int \mathrm{~d}^{3} \vec{r}=C_{n} \delta^{n}
$$

Note that the hypersphere formula for the volume of the sphere has been used. The purpose is to make the final result valid in any number $n$ of dimensions, not just three dimensions. The remaining integral in the above expression can be rewritten as

$$
\int|\psi| \mathrm{d}^{3} \vec{r}=\iint|\psi| \mathrm{d} A_{n} \mathrm{~d} r=\int\left[\int|\psi| \mathrm{d} A_{n} / A_{n}\right] A_{n} \mathrm{~d} r=\int \varphi A_{n} \mathrm{~d} r \leqslant \varepsilon C_{n} \delta^{n}
$$

So finally

$$
I_{V}^{\prime}-I_{V} \leqslant 3 V_{\max } \varepsilon^{2} C_{n} \delta^{n}
$$

The next question is what happens to the kinetic energy. In three-dimensional spherical coordinates, the kinetic energy after blunting is

$$
I_{T}^{\prime}=\frac{\hbar^{2}}{2 m} \int\left[\left(\frac{\partial \psi^{\prime}}{\partial r}\right)^{2}+\left(\frac{1}{r} \frac{\partial \psi^{\prime}}{\partial \theta}\right)^{2}+\left(\frac{1}{r \sin \theta} \frac{\partial \psi^{\prime}}{\partial \phi}\right)^{2}\right] \mathrm{d}^{3} \vec{r}
$$

The initial kinetic energy is given by a similar expression, with $|\psi|$ replacing $\psi^{\prime}$. Now the expression for the angular derivatives in the integrand will be different in a different number of dimensions. For example, in two-dimensional polar coordinates, there will be no $\phi$-derivative. But these angular derivatives are unchanged by the blunting and drop out in the difference in kinetic energy. So the decrease in kinetic energy becomes, after substituting for $\psi^{\prime}$ and simplifying:

$$
I_{T}-I_{T}^{\prime}=\frac{\hbar^{2}}{2 m} \iint 2\left(\frac{\partial|\psi|}{\partial r}\right)\left(\frac{\partial \varphi}{\partial r}\right) \mathrm{d} A_{n} \mathrm{~d} r-\frac{\hbar^{2}}{2 m} \iint\left(\frac{\partial \varphi}{\partial r}\right)^{2} \mathrm{~d} A_{n} \mathrm{~d} r
$$

Since $\varphi$ does not depend on the angular coordinates, that can be written

$$
I_{T}-I_{T}^{\prime}=\frac{\hbar^{2}}{2 m} \int 2\left[\int\left(\frac{\partial|\psi|}{\partial r}\right) \frac{\mathrm{d} A_{n}}{A_{n}}\right]\left(\frac{\partial \varphi}{\partial r}\right) A_{n} \mathrm{~d} r-\frac{\hbar^{2}}{2 m} \int\left(\frac{\partial \varphi}{\partial r}\right)^{2} A_{n} \mathrm{~d} r
$$

The expression between square brackets is just the $r$-derivative of $\varphi$. So the decrease in kinetic energy becomes, substituting in for $A_{n}$,

$$
I_{T}-I_{T}^{\prime}=\frac{\hbar^{2}}{2 m} \int\left(\frac{\partial \varphi}{\partial r}\right)^{2} n C_{n} r^{n-1} \mathrm{~d} r
$$

Note that the kinetic energy does decrease. The right hand side is positive. And if the maximum potential $V_{\max }$ in the vicinity of the point is negative, the potential energy decreases too. So that cannot be a ground state. It follows that the ground state wave function cannot become zero when $V_{\max }$ is negative or zero. (Do recall that the potential $V$ was redefined. In terms of the original potential, there cannot be a zero if the potential is less than the expectation value of energy.)

But how about positive $V_{\max }$ ? Here the factor $r^{n-1}$ in the kinetic energy integral is a problem in more than one dimension. In particular, if almost all the changes in $\varphi$ occur at small $r$, the factor $r^{n-1}$ will make the kinetic energy change small. Therefore there is no assurance that the kinetic energy decrease exceeds the potential energy increase. So a ground state cannot immediately be dismissed like in one dimension.

The solution is a trick. You might say that only a mathematician would think up a trick like that. However, the author insists that he is an aerospace engineer, not a mathematician. The first thing to note that there is a constraint on how much $\varphi$ can change in the outer half of the sphere, for $r \geqslant \delta / 2$. There the factor $r^{n-1}$ is at least $\delta^{n-1} / 2^{n-1}$. So the kinetic energy decrease is at least

$$
I_{T}-I_{T}^{\prime} \geqslant \frac{\hbar^{2}}{2 m} \frac{n C_{n}}{2^{n-1}} \delta^{n-1} \int_{\delta / 2}^{\delta}\left(\frac{\partial \varphi}{\partial r}\right)^{2} \mathrm{~d} r
$$

Now the remaining integral can be estimated by the Cauchy-Schwartz inequality as before. Comparing this with the maximum possible increase in potential energy will give a limit on the maximum change in $\varphi$ in the outer half of the sphere. In particular

$$
\varepsilon-\varepsilon_{\operatorname{mid}} \leqslant \sqrt{\frac{32^{n-1}}{n} \frac{m V_{\max }}{\hbar^{2}}} \delta \varepsilon
$$

where $\varepsilon_{\text {mid }}$ denotes the value of $\varphi$ at the midpoint $r=\delta / 2$.
If the above inequality is not satisfied, the kinetic energy decrease would exceed the potential energy increase and it cannot be a ground state. Note
that if the sphere is chosen small, the relative decrease in $\varphi$ is small too. For example, suppose you choose a sphere, call it sphere 1 , with a radius

$$
\delta_{1} \leq \frac{1}{4} \sqrt{\frac{n}{32^{n-1}} \frac{\hbar^{2}}{m V_{\max }}}
$$

In that case,

$$
\varepsilon_{1}-\varepsilon_{\text {mid }, 1} \leqslant \frac{1}{4} \varepsilon_{1}
$$

That means that $\varphi$ can at most decrease by $25 \%$ going from the outside surface to the midpoint:

$$
\varepsilon_{\text {mid }, 1} \geqslant \frac{3}{4} \varepsilon_{1}
$$

You might say, "Why not?" And indeed, there would be nothing wrong with the idea that almost all the change would occur in the inner half of the sphere. But the idea is now to drive the mathematics into a corner from which eventually there is no escape. Suppose that you now define the inner half of sphere 1 to be a sphere 2 . So the radius $\delta_{2}$ of this sphere is half that of sphere 1 , and its value of $\varepsilon$ is

$$
\varepsilon_{2}=\varepsilon_{\text {mid }, 1} \geqslant \frac{3}{4} \varepsilon_{1}
$$

(If there are $\varphi$ values in the second sphere that exceed $\varepsilon_{2}$, you need to further reduce $\delta_{2}$ to get rid of them. But all that does is reduce the possible changes in $\varphi$ even more.) In this second sphere, the allowed relative decrease in its outer half is a factor 2 smaller than in sphere 1 , because $\delta$ is a factor two smaller:

$$
\varepsilon_{\mathrm{mid}, 2} \geqslant \frac{7}{8} \varepsilon_{2}
$$

Now take the midpoint as the radius of a sphere 3. Then

$$
\varepsilon_{3}=\varepsilon_{\text {mid }, 2} \geqslant \frac{7}{8} \varepsilon_{2} \geqslant \frac{3}{4} \frac{7}{8} \varepsilon_{1}
$$

Keep doing this and for sphere number $i$ you get

$$
\varepsilon_{i}=\frac{3}{4} \frac{7}{8} \frac{15}{16} \frac{31}{32} \ldots \frac{2^{i}-1}{2^{i}} \varepsilon_{1}
$$

This must become zero for infinite $i$, because the sphere radii contract to zero and $\varphi$ is zero at $r=0$. But it does not! The allowed changes are simply too small to reach zero. Just take the logarithm:

$$
\ln \varepsilon_{i}=\ln \left(1-\frac{1}{4}\right)+\ln \left(1-\frac{1}{8}\right)+\ln \left(1-\frac{1}{16}\right)+\ln \left(1-\frac{1}{32}\right)+\ldots+\ln \varepsilon_{1}
$$

If $\varepsilon_{i}$ becomes zero, its logarithm must become minus infinity. But the infinite sum does not become infinite. Just use the Taylor series approximation $\ln (1-x)$ $\approx-x$ :

$$
\ln \left(1-\frac{1}{4}\right)+\ln \left(1-\frac{1}{8}\right)+\ln \left(1-\frac{1}{16}\right)+\ln \left(1-\frac{1}{32}\right)+\ldots=-\left[\frac{1}{4}+\frac{1}{8}+\frac{1}{16}+\frac{1}{32}+\ldots\right]
$$

The sum within square brackets is a geometric series that has a finite limit, not an infinite one.

So there is a contradiction. At some stage the decrease in kinetic energy must exceed the increase in potential energy. At that stage, the energy can be reduced by applying the blunting. So the assumed wave function cannot be a ground state.

You might still object that a Taylor series approximation is not exact. But in the region of interest

$$
\ln (1-x) \geqslant-\frac{\ln \left(1-\frac{1}{4}\right)}{-\frac{1}{4}} x
$$

and the additional ratio is just a constant, about 1.15, that does not make a difference.

Woof.

## D. 23 Solution of the hydrogen molecule

To find the approximate solution for the hydrogen molecule, the key is to be able to find the expectation energy of the approximate wave functions $a \psi_{1} \psi_{\mathrm{r}}+b \psi_{\mathrm{r}} \psi_{1}$.

First, for given $a / b$, the individual values of $a$ and $b$ can be computed from the normalization requirement

$$
\begin{equation*}
a^{2}+b^{2}+2 a b\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle^{2}=1 \tag{D.11}
\end{equation*}
$$

where the value of the overlap integral $\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle$ was given in derivation $\{\mathrm{D} .21\}$.
The inner product

$$
\left\langle a \psi_{1} \psi_{\mathrm{r}}+b \psi_{\mathrm{r}} \psi_{\mathrm{l}}\right| H\left|a \psi_{1} \psi_{\mathrm{r}}+b \psi_{\mathrm{r}} \psi_{1}\right\rangle_{6}
$$

is a six-dimensional integral, but when multiplied out, a lot of it can be factored into products of three-dimensional integrals whose values were given in derivation $\{\mathrm{D} .21\}$. Cleaning up the inner product, and using the normalization condition, you can get:

$$
\langle E\rangle=2 E_{1}-\frac{e^{2}}{4 \pi \epsilon_{0}}\left[A_{1}+2 a b\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle^{2} A_{2}\right]
$$

using the abbreviations

$$
\begin{gathered}
A_{1}=2\left\langle\psi_{1} \mid r_{\mathrm{r}}^{-1} \psi_{1}\right\rangle-\frac{1}{d}-\left\langle\psi_{1} \psi_{\mathrm{r}} \mid r_{12}^{-1} \psi_{1} \psi_{\mathrm{r}}\right\rangle \\
A_{2}=\frac{2\left\langle\psi_{1} \mid r_{1}^{-1} \psi_{\mathrm{r}}\right\rangle}{\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle}-2\left\langle\psi_{1} \mid r_{\mathrm{r}}^{-1} \psi_{1}\right\rangle-\frac{\left\langle\psi_{1} \psi_{\mathrm{r}} \mid r_{12}^{-1} \psi_{\mathrm{r}} \psi_{1}\right\rangle}{\left\langle\psi_{\mathrm{l}} \mid \psi_{\mathrm{r}}\right\rangle^{2}}+\left\langle\psi_{1} \psi_{\mathrm{r}} \mid r_{12}^{-1} \psi_{1} \psi_{\mathrm{r}}\right\rangle
\end{gathered}
$$

Values for several of the inner products in these expressions are given in derivation $\{\mathrm{D} .21\}$. Unfortunately, these involving the distance $r_{12}=\left|\vec{r}_{1}-\vec{r}_{2}\right|$ between the electrons cannot be done analytically. And one of the two cannot even be reduced to a three-dimensional integral, and needs to be done in six dimensions. (It can be reduced to five dimensions, but that introduces a nasty singularity and sticking to six dimensions seems a better idea.) So, it gets really elaborate, because you have to ensure numerical accuracy for singular, high-dimensional integrals. Still, it can be done with some perseverance.

In any case, the basic idea is still to print out expectation energies, easy to obtain or not, and to examine the print-out to see at what values of $a / b$ and $d$ the energy is minimal. That will be the ground state.

The results are listed in the main text, but here are some more data that may be of interest. At the $1.62 a_{0}$ nuclear spacing of the ground state, the antisymmetric state $a / b=-1$ has a positive energy of 7 eV above separate atoms and is therefore unstable.

The nucleus to electron attraction energies are 82 eV for the symmetric state, and 83.2 eV for the antisymmetric state, so the antisymmetric state has the lower potential energy, like in the hydrogen molecular ion case, and unlike what you read in some books. The symmetric state has the lower energy because of lower kinetic energy, not potential energy.

Due to electron cloud merging, for the symmetric state the electron to electron repulsion energy is 3 eV lower than you would get if the electrons were point charges located at the nuclei. For the antisymmetric state, it is 5.8 eV lower.

As a consequence, the antisymmetric state also has less potential energy with respect to these repulsions. Adding it all together, the symmetric state has quite a lot less kinetic energy than the antisymmetric one.

## D. 24 Hydrogen molecule ground state and spin

The purpose of this note is to verify that the inclusion of spin does not change the spatial form of the ground state of the hydrogen molecule. The lowest expectation energy $\langle E\rangle=\left\langle\psi_{\mathrm{gs}} \mid H \psi_{\mathrm{gs}}\right\rangle$, characterizing the correct ground state, only occurs if all spatial components $\psi_{ \pm \pm}$of the ground state with spin,

$$
\psi_{\mathrm{gs}}=\psi_{++} \uparrow \uparrow+\psi_{+-} \uparrow \downarrow+\psi_{-+\downarrow} \downarrow \uparrow+\psi_{--\downarrow \downarrow}
$$

are proportional to the no-spin spatial ground state $\psi_{\mathrm{gs}, 0}$.
The reason is that the assumed Hamiltonian (5.3) does not involve spin at all, only spatial coordinates, so, for example,

$$
\left(H \psi_{++} \uparrow \uparrow\right) \equiv H\left(\psi_{++}\left(\vec{r}_{1}, \vec{r}_{2}\right) \uparrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)\right)=\left(H \psi_{++}\right) \uparrow \uparrow
$$

and the same for the other three terms in $H \psi_{\mathrm{gs}}$. So the expectation value of energy becomes

$$
\begin{aligned}
\langle E\rangle= & \left\langle\psi_{++} \uparrow \uparrow+\psi_{+-} \uparrow \downarrow+\psi_{-+} \downarrow \uparrow+\psi_{--} \downarrow \downarrow\right. \\
& \left|\left(H \psi_{++}\right) \uparrow \uparrow+\left(H \psi_{+-}\right) \uparrow \downarrow+\left(H \psi_{-+}\right) \downarrow \uparrow+\left(H \psi_{--}\right) \downarrow \downarrow\right\rangle
\end{aligned}
$$

Because of the orthonormality of the spin states, this multiplies out into inner products of matching spin states as

$$
\langle E\rangle=\left\langle\psi_{++} \mid H \psi_{++}\right\rangle+\left\langle\psi_{+-} \mid H \psi_{+-}\right\rangle+\left\langle\psi_{-+} \mid H \psi_{-+}\right\rangle+\left\langle\psi_{--} \mid H \psi_{--}\right\rangle .
$$

In addition, the wave function must be normalized, $\left\langle\psi_{\mathrm{gs}} \mid \psi_{\mathrm{gs}}\right\rangle=1$, or

$$
\left\langle\psi_{++} \mid \psi_{++}\right\rangle+\left\langle\psi_{+-} \mid \psi_{+-}\right\rangle+\left\langle\psi_{-+} \mid \psi_{-+}\right\rangle+\left\langle\psi_{--} \mid \psi_{--}\right\rangle=1
$$

Now when $\psi_{++}, \psi_{+-}, \psi_{-+}$, and $\psi_{--}$are each proportional to the no-spin spatial ground state $\psi_{\mathrm{gs}, 0}$ with the lowest energy $E_{\mathrm{gs}}$, their individual contributions to the energy will be given by $\left\langle\psi_{ \pm \pm} \mid H \psi_{ \pm \pm}\right\rangle=E_{\mathrm{gs}}\left\langle\psi_{ \pm \pm} \mid \psi_{ \pm \pm}\right\rangle$, the lowest possible. Then the total energy $\langle E\rangle$ will be $E_{g s}$. Anything else will have more energy and can therefore not be the ground state.

It should be pointed out that to a more accurate approximation, spin causes the electrons to be somewhat magnetic, and that produces a slight dependence of the energy on spin; compare addendum \{A.39\}. This note ignored that, as do most other derivations in this book.

## D. 25 Number of boson states

For identical bosons, the number is $I+N-1$ choose $I$. To see that think of the $I$ bosons as being inside a series of $N$ single particle-state "boxes." The idea is as illustrated in figure D.2; the circles are the bosons and the thin lines separate the boxes. In the picture as shown, each term in the group of states has one boson in the first single-particle function, three bosons in the second, three bosons in the third, etcetera.

Figure D.2: Bosons in single-particle-state boxes.
Each picture of this type corresponds to exactly one system state. To figure out how many different pictures there are, imagine there are numbers written from 1 to $I$ on the bosons and from $I+1$ to $I+N-1$ on the separators between the boxes. There are then $(I+N-1)$ ! ways to arrange that total of $I+N-1$ objects. (There are $I+N-1$ choices for which object to put first, times $I+N-2$ choices for which object to put second, etcetera.) However, the $I$ ! different ways
to order the subset of boson numbers do not produce different pictures if you erase the numbers again, so divide by $I!$. The same way, the different ways to order the subset of box separator numbers do not make a difference, so divide by $(N-1)$ !.

For example, if $I=2$ and $N=4$, you get $5!/ 2!3$ ! or 10 system states.

## D. 26 Density of states

This note derives the density of states for particles in a box.
Consider the wave number space, as shown to the left in figure 6.1. Each point represents one spatial state. The first question is how many points have a wave number vector whose length $\underline{k}$ is less than some given value $k$. Since the length of the wave number vector is the distance from the origin in wave number state, the points with $\underline{k}<k$ form an octant of a sphere with radius $k$. In fact, you can think of this problem as finding the number of red points in figure 6.11.

Now the octant of the sphere has a "volume" (in wave number space, not a physical volume)

$$
\text { octant volume: } \frac{1}{8} \frac{4}{3} \pi k^{3}
$$

Conversely, every wave number point is the top-left front corner of a little block of "volume"

$$
\text { single state volume: } \quad \Delta k_{x} \Delta k_{y} \Delta k_{z}
$$

where $\Delta k_{x}, \Delta k_{y}$, and $\Delta k_{z}$ are the spacings between the points in the $x, y$, and $z$ directions respectively. To find the approximate number of points inside the octant of the sphere, take the ratio of the two "volumes:"

$$
\text { number of spatial states inside: } \frac{\pi k^{3}}{6 \Delta k_{x} \Delta k_{y} \Delta k_{z}}
$$

Now the spacings between the points are given in terms of the sides $\ell_{x}, \ell_{y}$, and $\ell_{z}$ of the box containing the particles as, (6.3),

$$
\Delta k_{x}=\frac{\pi}{\ell_{x}} \quad \Delta k_{y}=\frac{\pi}{\ell_{y}} \quad \Delta k_{z}=\frac{\pi}{\ell_{z}}
$$

Plug this into the expression for the number of points in the octant to get:

$$
\begin{equation*}
\text { number of spatial states inside: } \frac{\mathcal{V}}{6 \pi^{2}} k^{3} \tag{D.12}
\end{equation*}
$$

where $\mathcal{V}$ is the (physical) volume of the box $\ell_{x} \ell_{y} \ell_{z}$. Each wave number point corresponds to one spatial state, but if the spin of the particles is $s$ then each spatial state still has $2 s+1$ different spin values. Therefore multiply by $2 s+1$ to get the number of states.

To get the density of states on a wave number basis, take the derivative with respect to $k$. The number of states $\mathrm{d} N$ in a small wave number range $\mathrm{d} k$ is then:

$$
\mathrm{d} N=\mathcal{V} \mathcal{D}_{k} \mathrm{~d} k \quad \mathcal{D}_{k}=\frac{2 s+1}{2 \pi^{2}} k^{2}
$$

The factor $\mathcal{D}_{k}$ is the density of states on a wave number basis.
To get the density of states on an energy basis, simply eliminate $k$ in terms of the single-particle energy $E^{\mathrm{p}}$ using $E^{\mathrm{p}}=\hbar k^{2} / 2 m$. That gives:

$$
\mathrm{d} N=\mathcal{V} \mathcal{D} \mathrm{d} E^{\mathrm{p}} \quad \mathcal{D}=\frac{2 s+1}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \sqrt{E^{\mathrm{p}}}
$$

The used expression for the kinetic energy $E^{p}$ is only valid for nonrelativistic speeds.

The above arguments fail in the presence of confinement. Recall that each state is the top-left front corner of a little block in wave number space of volume $\Delta k_{x} \Delta k_{y} \Delta k_{z}$. The number of states with wave number $\underline{k}$ less than some given value $k$ was found by computing how many such little block volumes are contained within the octant of the sphere of radius $k$.

The problem is that a wave number $\underline{k}$ is only inside the sphere octant if all of its little block is inside. Even if $99 \%$ of its block is inside, the state itself will still be outside, not $99 \%$ in. That makes no difference if the states are densely spaced in wave number space, like in figure 6.11. In that case almost all little blocks are fully inside the sphere. Only a thin layer of blocks near the surface of the sphere are partially outside it.

However, confinement in a given direction makes the corresponding spacing in wave number space large. And that changes things.

In particular, if the $y$-dimension $\ell_{y}$ of the box containing the particles is small, then $\Delta k_{y}=\pi / \ell_{y}$ is large. That is illustrated in figure 6.12. In this case, there are no states inside the sphere at all if $k$ is less than $\Delta k_{y}$. Regardless of what (D.12) claims. In the range $\Delta k_{y}<k<2 \Delta k_{y}$, illustrated by the red sphere in figure 6.12, the red sphere gobbles up a number of states from the plate $\underline{k}_{y}$ $=\Delta k_{y}$. This number of states can be estimated as

$$
\frac{\frac{1}{4} \pi\left(k_{x}^{2}+k_{z}^{2}\right)}{\Delta k_{x} \Delta k_{z}}
$$

since the top of this ratio is the area of the quarter circle of states and the bottom is the rectangular area occupied per state.

This expression can be cleaned up by noting that

$$
k_{x}^{2}+k_{z}^{2}=k^{2}-k_{y}^{2}=k^{2}-\left(n_{y} \Delta k_{y}\right)^{2}
$$

with $n_{y}=1$ for the lowest plate. Substituting for $\Delta k_{x}, \Delta k_{y}$, and $\Delta k_{z}$ in terms of the box dimensions then gives

$$
\begin{equation*}
\text { spatial states per plate: } \frac{A}{4 \pi}\left[k^{2}-\left(n_{y} \frac{\pi}{\ell_{y}}\right)^{2}\right] \quad \text { if } \quad[\ldots]>0 \tag{D.13}
\end{equation*}
$$

Here $A=\ell_{x} \ell_{z}$ is the area of the quantum well and $n_{y}=1$ is the plate number. For nonrelativistic speeds $k^{2}$ is proportional to the energy $E^{\mathrm{p}}$. Therefore the density of states, which is the derivative of the number of states with respect to energy, is constant.

In the range $2 \pi / \ell_{y}<k<3 \pi / \ell_{y}$ a second quarter circle of states gets added. To get the number of additional states in that circle, use $n_{y}=2$ for the plate number in (D.13). For still larger values of $k$, just keep summing plates as long as the expression between the square brackets in (D.13) remains positive.

If the $z$-dimension of the box is also small, like in a quantum wire, the states in wave number space separate into individual lines, figure 6.13. There are now no states until the sphere of radius $k$ hits the line that is closest to the origin, having quantum numbers $n_{y}=n_{z}=1$. Beyond that value of $k$, the number of states on the line that is within the sphere is

$$
\frac{\sqrt{k^{2}-\left(n_{y} \Delta k_{y}\right)^{2}-\left(n_{z} \Delta k_{z}\right)^{2}}}{\Delta k_{x}}
$$

since the top is the length of the line inside the sphere and the bottom the spacing of the states on the line. Cleaning up, that gives

$$
\begin{equation*}
\text { spatial states per line: } \frac{\ell}{\pi}\left[k^{2}-\left(n_{y} \frac{\pi}{\ell_{y}}\right)^{2}-\left(n_{z} \frac{\pi}{\ell_{z}}\right)^{2}\right]^{1 / 2} \quad \text { if }[\ldots]>0 \tag{D.14}
\end{equation*}
$$

with $\ell=\ell_{x}$ the length of the quantum wire. For still larger values of $k$ sum over all values of $n_{y}$ and $n_{z}$ for which the argument of the square root remains positive.

For nonrelativistic speeds, $k^{2}$ is proportional to the energy. Therefore the above number of states is proportional to the square root of the amount of energy above the one at which the line of states is first hit. Differentiating to get the density of states, the square root becomes an reciprocal square root.

If the box is small in all three directions, figure 6.14, the number of states simply becomes the number of points inside the sphere:
spatial states per point: 1

$$
\begin{equation*}
\left[k^{2}-\left(n_{x} \frac{\pi}{\ell_{x}}\right)^{2}-\left(n_{y} \frac{\pi}{\ell_{y}}\right)^{2}-\left(n_{z} \frac{\pi}{\ell_{z}}\right)^{2}\right]>0 \tag{D.15}
\end{equation*}
$$

In other words, to get the total number of states inside, simply add a 1 for each set of natural numbers $n_{x}, n_{y}$, and $n_{z}$ for which the expression in brackets is positive. The derivative with respect to energy, the density of states, becomes a series of delta functions at the energies at which the states are hit.

## D. 27 Radiation from a hole

To find how much blackbody radiation is emitted from a small hole in a box, first imagine that all photons move in the direction normal to the hole with the
speed of light $c$. In that case, in a time interval $\mathrm{d} t$, a cylinder of photons of volume $A c \mathrm{~d} t$ would leave through the hole, where $A$ is the hole area. To get the electromagnetic energy in that cylinder, simply multiply by Planck's blackbody spectrum $\rho$. That gives the surface radiation formula except for an additional factor $\frac{1}{4}$. Half of that factor is due to the fact that on average only half of the photons will have a velocity component in the direction normal to the hole that is towards the hole. The other half will have a velocity component in that direction that is away from the hole. In addition, because the photons move in all directions, the average velocity component of the photons that move towards the hole is only half the speed of light.

More rigorously, assume that the hole is large compared to $c \mathrm{~d} t$. The fraction of photons with velocity directions within in a spherical element $\sin \theta \mathrm{d} \theta \mathrm{d} \phi$ will be $\sin \theta \mathrm{d} \theta \mathrm{d} \phi / 4 \pi$. The amount of these photons that exits will be those in a skewed cylinder of volume $A c \cos \theta \mathrm{~d} t$. To get the energy involved multiply by $\rho$. So the energy leaving in this small range of velocity directions is

$$
\rho A c \mathrm{~d} t \cos \theta \frac{\sin \theta \mathrm{~d} \theta \mathrm{~d} \phi}{4 \pi}
$$

Integrate over all $\phi$ and $\theta$ up to 90 degrees to get $\frac{1}{4} \rho A c \mathrm{~d} t$ for the total energy that exits.

Note also from the above expression that the amount of energy leaving per unit time, unit area, and unit solid angle is

$$
\frac{\rho c}{4 \pi} \cos \theta
$$

where $\theta$ is the angle from the normal to the hole.

## D. 28 Kirchhoff's law

Suppose you have a material in thermodynamic equilibrium at a given temperature that has an emissivity at a given frequency that exceeds the corresponding absorptivity. Place it in a closed box. Since it emits more radiation at the given frequency than it absorbs from the surrounding blackbody radiation, the amount of radiation at that frequency will go up. That violates Plank's blackbody spectrum, because it remains a closed box. The case that the emissivity is less than the absorptivity goes similarly.

Note some of the implicit assumptions made in the argument. First, it assumes linearity, in the sense that emission or absorption at one frequency does not affect that at another, that absorption does not affect emission, and that the absorptivity is independent of the amount absorbed. It assumes that the surface is separable from the object you are interested in. Transparent materials require special consideration, but the argument that a layer of such material must emit the same fraction of blackbody radiation as it absorbs remains valid.

The argument also assumes the validity of Plank's blackbody spectrum. However you can make do without. Kirchhoff did. He (at first) assumed that there are gage materials that absorb and emit only in a narrow range of frequencies, and that have constant absorptivity $a_{\mathrm{g}}$ and emissivity $e_{\mathrm{g}}$ in that range. Place a plate of that gage material just above a plate of whatever material is to be examined. Insulate the plates from the surrounding. Wait for thermal equilibrium.

Outside the narrow frequency range, the material being examined will have to absorb the same radiation energy that it emits, since the gage material does not absorb nor emit outside the range. In the narrow frequency range, the radiation energy $\dot{E}$ going up to the gage plate must equal the energy coming down from it again, otherwise the gage plate would continue to heat up. If $B$ is the blackbody value for the radiation in the narrow frequency range, then the energy going down from the gage plate consists of the radiation that the gage plate emits plus the fraction of the incoming radiation that it reflects instead of absorbs:

$$
\dot{E}=e_{\mathrm{g}} B+\left(1-a_{\mathrm{g}}\right) \dot{E} \quad \Longrightarrow \quad \dot{E} / B=e_{\mathrm{g}} / a_{\mathrm{g}}
$$

Similarly for the radiation going up from the material being examined:

$$
\dot{E}=e B+(1-a) \dot{E} \quad \Longrightarrow \quad \dot{E} / B=e / a
$$

By comparing the two results, $e / a=e_{\mathrm{g}} / a_{\mathrm{g}}$. Since you can examine any material in this way, all materials must have the same ratio of emissivity to absorptivity in the narrow range. Assuming that gage materials exist for every frequency range, at any frequency $e / a$ must be the same for all materials. So it must be the blackbody value 1 .

No, this book does not know where to order these gage materials, [38]. And the same argument cannot be used to show that the absorptivity must equal emissivity in each individual direction of radiation, since direction is not preserved in reflections.

## D. 29 The thermionic emission equation

This note derives the thermionic emission equation for a typical metal following [42, p. 364ff]. The derivation is semi-classical.

To simplify the analysis, it will be assumed that the relevant electrons in the interior of the metal can be modeled as a free-electron gas. In other words, it will be assumed that in the interior of the metal the forces from surrounding particles come from all directions and so tend to average out.
(The free-electron gas assumption is typically qualitatively reasonable for the valence electrons of interest if you define the zero of the kinetic energy of the gas to be at the bottom of the conduction band. You can also reduce errors
by replacing the true mass of the electron by some suitable "effective mass." But the zero of the energy drops out in the final expression, and the effective mass of typical simple metals is not greatly different from the true mass. See chapter 6.22 .3 for more on these issues.)

Assume that the surface through which the electrons escape is normal to the $x$-direction. Then the classical expression for the current of escaping electrons is

$$
j=\rho e v_{x}
$$

where $\rho$ is the number of electrons per unit volume that is capable of escaping and $v_{x}$ is their velocity in the $x$-direction. Note that the current above is supposed to be the current inside the metal of the electrons that will escape.

An electron can only escape if its energy $E^{\mathrm{p}}$ exceeds

$$
E_{\mathrm{esc}}^{\mathrm{p}}=\mu+e \varphi_{\mathrm{w}}
$$

where $\mu$ is the Fermi level, because the work function $\varphi_{\mathrm{w}}$ is defined that way. The number of electrons per unit volume in an energy range $d E^{\mathrm{p}}$ above $E_{\text {esc }}^{\mathrm{p}}$ can be found as

$$
e^{-\left(e \varphi_{\mathrm{w}}+E^{\mathrm{p}}-E_{\mathrm{esc}}^{\mathrm{p}}\right) / k_{\mathrm{B}} T} \frac{2}{4 \pi^{2}}\left(\frac{2 m_{\mathrm{e}}}{\hbar^{2}}\right)^{3 / 2} \sqrt{E^{\mathrm{p}}} \mathrm{~d} E^{\mathrm{p}}
$$

That is because the initial exponential is a rewritten Maxwell-Boltzmann distribution (6.21) that gives the number of electrons per state, while the remainder is the number of states in the energy range according to the density of states (6.6).

Normally, the typical thermal energy $k_{\mathrm{B}} T$ is very small compared to the minimum energy $e \varphi_{\mathrm{w}}$ above the Fermi level needed to escape. Then the exponential of the Maxwell-Boltzmann distribution is very small. That makes the amount of electrons with sufficient energy to escape very small. In addition, with increasing energy above $E_{\text {esc }}^{\mathrm{p}}$ the amount of electrons very quickly becomes much smaller still. Therefore only a very small range of energies above the minimum energy $E_{\text {esc }}^{\mathrm{p}}$ gives a contribution.

Further, even if an electron has in principle sufficient energy to escape, it can only do so if enough of its momentum is in the $x$-direction. Only momentum that is in the $x$-direction can be used to overcome the nuclei that pull it back towards the surface when it tries to escape. Momentum in the other two directions only produces motion parallel to the surface. So only a fraction, call it $f_{\text {esc }}$, of the electrons that have in principle enough energy to escape can actually do so. A bit of geometry shows how much. All possible end points of the momentum vectors with a magnitude $p$ form a spherical surface with area $4 \pi p^{2}$. But only a small circle on that surface around the $x$-axis, with an approximate radius of $\sqrt{p^{2}-p_{\text {esc }}^{2}}$, has enough $x$-momentum for the electron to escape, so
where the final equality applies since the kinetic energy is proportional to the square momentum.

Since the velocity for the escaping electrons is mostly in the $x$-direction, $E^{\mathrm{p}}$ $\approx \frac{1}{2} m_{\mathrm{e}} v_{x}^{2}$, which can be used to express $v_{x}$ in terms of energy.

Putting it all together, the current density becomes

$$
j=\int_{E^{\mathrm{p}}=E_{\mathrm{esc}}^{\mathrm{p}}}^{\infty} e^{-\left(e \varphi_{\mathrm{w}}+E^{\mathrm{p}}-E_{\mathrm{esc}}^{\mathrm{p}}\right) / k_{\mathrm{B}} T} \frac{2}{4 \pi^{2}}\left(\frac{2 m_{\mathrm{e}}}{\hbar^{2}}\right)^{3 / 2} \sqrt{E^{\mathrm{p}}} \frac{E^{\mathrm{p}}-E_{\mathrm{esc}}^{\mathrm{p}}}{4 E^{\mathrm{p}}}\left(\frac{2 E^{\mathrm{p}}}{m_{\mathrm{e}}}\right)^{1 / 2} \mathrm{~d} E^{\mathrm{p}}
$$

Rewriting in terms of a new integration variable $u=\left(E^{\mathrm{p}}-E_{\mathrm{esc}}^{\mathrm{p}}\right) / k_{\mathrm{B}} T$ gives the thermionic emission equation.

If an external electric field $\mathcal{E}_{\text {ext }}$ helps the electrons escape, it lowers the energy that the electrons need to do so. Consider the potential energy in the later stages of escape, at first still without the additional electric field. When the electron looks back at the metal surface that it is escaping from, it sees a positron mirror image of itself inside the metal. Of course, there is not really a positron inside the metal; rearrangement of the surface electrons of the metal create this illusion. The surface electrons rearrange themselves to make the total component of the electric field in the direction parallel to the surface zero. Indeed, they have to keep moving until they do so, since the metal has negligible electrical resistance in the direction parallel to the surface. Now it just so happens that a positron mirror image of the electron has exactly the same effect as this rearrangement. The escaping electron pushes the surface electrons away from itself; that force has a repulsive component along the surface. The positron mirror image however attracts the surface electrons towards itself, exactly cancelling the component of force along the surface exerted by the escaping electron.

The bottom line is that it seems to the escaping electron that it is pulled back not by surface charges, but by a positron mirror image of itself. Therefore, including now an additional external electrical field, the total potential in the later stages of escape is:

$$
V=-\frac{e^{2}}{16 \pi \epsilon_{0} d}-e \mathcal{E}_{\mathrm{ext}} d+\mathrm{constant}
$$

where $d$ is the distance from the surface. The first term is the attracting force due to the positron image, while the second is due to the external electric field. The constant depends on where the zero of energy is defined. Note that only half the energy of attraction between the electron and the positron image should be assigned to the electron; the other half can be thought of as "work" on the image. If that is confusing, just write down the force on the electron and integrate it to find its potential energy.

If there is no external field, the maximum potential energy that the electron must achieve occurs at infinite distance $d$ from the metal surface. If there is an electric field, it lowers the maximum potential energy, and it now occurs
somewhat closer to the surface. Setting the derivative of $V$ with respect to $d$ to zero to identify the maximum, and then evaluating $V$ at that location shows that the external field lowers the maximum potential energy that must be achieved to escape by $\sqrt{e^{3} \mathcal{E} / 4 \pi \epsilon_{0}}$.

## D. 30 Number of conduction band electrons

This note finds the number of electrons in the conduction band of a semiconductor, and the number of holes in the valence band.

By definition, the density of states $\mathcal{D}$ is the number of single-particle states per unit energy range and unit volume. The fraction of electrons in those states is given by $\iota_{\mathrm{e}}$. Therefore the number of electrons in the conduction band per unit volume is given by

$$
i_{\mathrm{e}}=\int_{E_{\mathrm{c}}^{\mathrm{p}}}^{E_{\mathrm{top}}^{\mathrm{p}}} \mathcal{D} \iota_{\mathrm{e}} \mathrm{~d} E^{\mathrm{p}}
$$

where $E_{\mathrm{c}}^{\mathrm{p}}$ is the energy at the bottom of the conduction band and $E_{\mathrm{top}}^{\mathrm{p}}$ that at the top of the band.

To compute this integral, for $\iota_{\mathrm{e}}$ the Maxwell-Boltzmann expression (6.33) can be used, since the number of electrons per state is invariably small. And for the density of states the expression (6.6) for the free-electron gas can be used if you substitute in a suitable effective mass of the electrons and replace $\sqrt{E^{\mathrm{p}}}$ by $\sqrt{E^{\mathrm{p}}-E_{\mathrm{c}}^{\mathrm{p}}}$.

Also, because $\iota_{\mathrm{e}}$ decreases extremely rapidly with energy, only a very thin layer at the bottom of the conduction band makes a contribution to the number of electrons. The integrand of the integral for $i_{\mathrm{e}}$ is essentially zero above this layer. Therefore you can replace the upper limit of integration with infinity without changing the value of $i_{\mathrm{e}}$. Now use a change of integration variable to $u$ $=\sqrt{\left(E^{\mathrm{p}}-E_{\mathrm{c}}^{\mathrm{p}}\right) / k_{\mathrm{B}} T}$ and an integration by parts to reduce the integral to the one found under "!" in the notations section. The result is as stated in the text.

For holes, the derivation goes the same way if you use $\iota_{\mathrm{h}}$ from (6.34) and integrate over the valence band energies.

## D. 31 Integral Schrödinger equation

In this note, the integral Schrödinger equation is derived from the partial differential equation version.

First the time-independent Schrödinger equation is rewritten in the form

$$
\begin{equation*}
\left(\nabla^{2}+k^{2}\right) \psi=f \quad k=\frac{\sqrt{2 m E}}{\hbar} \quad f=\frac{2 m V}{\hbar^{2}} \psi \tag{D.16}
\end{equation*}
$$

The left equation is known as the "Helmholtz equation."

The Helmholtz equation is not at all specific to quantum mechanics. In general it describes basic wave propagation at a frequency related to the value of the constant $k$. The right hand side $f$ describes the amount of wave motion that is created at a given location. Quantum mechanics is somewhat weird in that $f$ involves the unknown wave function $\psi$ that you want to find. In simpler applications, $f$ is a given function.

The general solution to the Helmholtz equation can be written as

$$
\begin{equation*}
\left(\nabla^{2}+k^{2}\right) \psi=f \quad \Longrightarrow \quad \psi=\psi_{0}-\int_{\text {all } \vec{r}^{\prime}} \frac{e^{\mathrm{i}\left|\overrightarrow{r^{\prime}}-\vec{r}\right|}}{4 \pi\left|\vec{r}^{\prime}-\vec{r}\right|} f\left(\vec{r}^{\prime}\right) \mathrm{d}^{3} \vec{r}^{\prime} \tag{D.17}
\end{equation*}
$$

Here $\psi_{0}$ is any solution of the homogeneous Helmholtz equation, the equation without $f$.

To see why this is the solution of the Helmholtz equation requires a bit of work. First consider the solution of the Helmholtz equation for the special case that $f$ is a delta function at the origin:

$$
\left(\nabla^{2}+k^{2}\right) G=\delta^{3}(\vec{r})
$$

The solution $G$ to this problem is called the "Green's function of the Helmholtz equation.

The Green's function can be found relatively easily. Away from the origin $G$ is a solution of the homogeneous Helmholtz equation, because the delta function is everywhere zero except at the origin. In terms of quantum mechanics, the homogeneous Helmholtz equation means a particle in free space, $V=0$. Possible solutions for $G$ are then spherical harmonics times spherical Hankel functions of the first and second kinds, \{A.6\}. However, Hankel functions of the first kind are preferred for physical reasons; they describe waves that propagate away from the region of wave generation to infinity. Hankel functions of the second kind describe waves that come in from infinity. Incoming waves, if any, are usually much more conveniently described using the homogeneous solution $\psi_{0}$.

Further, since the problem for $G$ is spherically symmetric, the solution should not depend on the angular location. The spherical harmonic must be the constant $Y_{0}^{0}$. That makes the correct solution a multiple of the spherical Hankel function $h_{0}^{(1)}$, which means proportional to $e^{\mathrm{i} k r} / r$. You can easily check by direct substitution that this does indeed satisfy the homogeneous Helmholtz equation away from the origin in spherical coordinates.

To get the correct constant of proportionality, integrate the Helmholtz equation for $G$ above over a small sphere around the origin. In the right hand side use the fact that the integral of a delta function is by definition equal to 1 . In the left hand side, use the divergence theorem to avoid having to try to integrate the singular second order derivatives of $G$ at the origin. That shows that the complete Green's function is

$$
G(\vec{r})=-\frac{e^{\mathrm{i} k r}}{4 \pi r} \quad r=|\vec{r}|
$$

(You might worry about the mathematical justification for these manipulations. Singular functions like $G$ are not proper solutions of partial differential equations. However, the real objective is to find the limiting solution $G$ when a slightly smoothed delta function becomes truly singular. The described manipulations are justified in this limiting process.)

The next step is to solve the Helmholtz equation for an arbitrary right hand side $f$, rather than a delta function. To do so, imagine the region subdivided into infinitely many infinitesimal volume elements $\mathrm{d} \vec{r}^{\prime}$. In each volume element, approximate the function $f$ by a delta function spike $\delta\left(\vec{r}-\vec{r}^{\prime}\right) f\left(\vec{r}^{\prime}\right) \mathrm{d} \vec{r}^{\prime}$. Such a spike integrates to the same value as $f$ does over the volume element. Each spike produces a solution given by

$$
G\left(\vec{r}-\vec{r}^{\prime}\right) f\left(\vec{r}^{\prime}\right) \mathrm{d} \vec{r}^{\prime}
$$

Integrate over all volume elements to get the solution of the Helmholtz equation (D.17). Substitute in what $f$ is for the Schrödinger equation to get the integral Schrödinger equation.

## D. 32 Integral conservation laws

This section derives the integral conservation laws given in addendum \{A.14\}.
The rules of engagement are as follows:

- The Cartesian axes are numbered using an index $i$, with $i=1,2$, and 3 for $x, y$, and $z$ respectively.
- Also, $r_{i}$ indicates the coordinate in the $i$ direction, $x, y$, or $z$.
- Derivatives with respect to a coordinate $r_{i}$ are indicated by a simple subscript $i$.
- Time derivatives are indicated by a subscript t .
- A bare $\int$ integral sign is assumed to be an integration over all space, or over the entire box for particles in a box. The $\mathrm{d}^{3} \vec{r}$ is normally omitted for brevity and to be understood.
- A superscript * indicates a complex conjugate.

First it will be shown that according to the Schrödinger equation $\int|\Psi|^{2}$ is constant. The Schrödinger equation in free space is

$$
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=-\frac{\hbar^{2}}{2 m} \nabla^{2} \Psi
$$

Taking the right hand term to the other side and writing it in index notation gives

$$
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}+\sum_{i} \frac{\hbar^{2}}{2 m} \Psi_{i i}=0
$$

Multiply the left hand side by $\Psi^{*} / \mathrm{i} \hbar$ and add the complex conjugate of the same equation to get

$$
\Psi^{*} \frac{\partial \Psi}{\partial t}+\Psi \frac{\partial \Psi^{*}}{\partial t}+\sum_{i} \frac{\hbar}{2 m \mathrm{i}}\left(\Psi^{*} \Psi_{i i}-\Psi \Psi_{i i}^{*}\right)=0
$$

To show that the integral $\int|\Psi|^{2}$ is constant, it must be shown that its time derivative is zero. Now the first two terms above are the time derivative of $|\Psi|^{2}$ $=\Psi^{*} \Psi$. So integrated over all space, they give the time derivative that must be shown to be zero. And the equation above shows that it is indeed zero provided that the remaining sum in it integrates to zero over all space.

The constant is not important in showing that this is true, so just examine for any $i$

$$
\int\left(\Psi^{*} \Psi_{i i}-\Psi \Psi_{i i}^{*}\right)
$$

This equals

$$
\int\left(\Psi^{*} \Psi_{i}-\Psi \Psi_{i}^{*}\right)_{i}
$$

as can be seen by differentiating out the parenthetical expression with respect to $r_{i}$. The above integrand can be integrated with respect to $r_{i}$. It will then be zero for a periodic box since the expression in parenthesis is the same at the upper and lower limits of integration. It will also be zero for an impenetrable container, since $\Psi$ will then be zero on the surface of the container. It will also be zero in an infinite region provided that $\Psi$ and its derivatives vanish at large distances.

There is another way to see that $\int|\Psi|^{2}$ is constant. First recall that any solution of the Schrödinger equation takes the form

$$
\Psi=\sum_{n} c_{n} e^{-\mathrm{i} E_{n} t} \psi_{n}(\vec{r})
$$

Here the $\psi_{n}$ are the energy eigenfunctions. Then

$$
\int|\Psi|^{2}=\int \Psi^{*} \Psi=\int \sum_{\underline{n}} c_{\underline{n}}^{*} e^{\mathrm{i} E_{\underline{n}} t} \psi_{\underline{n}}(\vec{r}) \sum_{n} c_{n} e^{-\mathrm{i} E_{n} t} \psi_{n}(\vec{r})
$$

Now because of orthonormality of the eigenfunctions, the integration only produces a nonzero result when $\underline{n}=n$, and then the product of the eigenfunctions integrates to 1 . So

$$
\int|\Psi|^{2}=\sum_{n} c_{n}^{*} c_{n}
$$

That does not depend on time, and the normalization requirement makes it 1.

This also clarifies what goes wrong with the Klein-Gordon equation. For the Klein-Gordon equation

$$
\Psi=\sum_{n} c_{n} e^{-\mathrm{i} E_{n} t} \psi_{n}(\vec{r})+\sum_{n} d_{n} e^{\mathrm{i} E_{n} t} \psi_{n}(\vec{r})
$$

The first sum are the particle states and the second sum the antiparticle states. That gives:

$$
\int|\Psi|^{2}=\sum_{n}\left(c_{n}^{*} c_{n}+d_{n}^{*} d_{n}+c_{n}^{*} d_{n} e^{2 \mathrm{i} E_{n} t}+d_{n}^{*} c_{n} e^{-2 \mathrm{i} E_{n} t}\right)
$$

The final two terms in the sum oscillate in time. So the integral is no longer constant.

The exception is if there are only particle states (no $d_{n}$ ) or only antiparticle states (no $c_{n}$ ). In those two cases, the integral is constant. In general

$$
\Psi=\Psi_{1}+\Psi_{2} \quad \Psi_{1}=\sum_{n} c_{n} e^{-\mathrm{i} E_{n} t} \psi_{n}(\vec{r}) \quad \Psi_{2}=\sum_{n} d_{n} e^{\mathrm{i} E_{n} t} \psi_{n}(\vec{r})
$$

where the integrated square magnitudes of $\Psi_{1}$ and $\Psi_{2}$ are constant.
Next it will be shown that the rearranged Klein-Gordon equation

$$
\frac{1}{c^{2}} \frac{\partial^{2} \Psi}{\partial t^{2}}-\sum_{i} \Psi_{i i}+\left(\frac{m c^{2}}{\hbar c}\right)^{2} \Psi=0
$$

preserves the sum of integrals

$$
\int\left|\frac{1}{c} \frac{\partial \Psi}{\partial t}\right|^{2}+\int \sum_{i}\left|\Psi_{i}\right|^{2}+\int\left|\frac{m c^{2}}{\hbar c} \Psi\right|^{2}
$$

To do so it suffices to show that the sum of the time derivatives of the three integrals is zero. That can be done by multiplying the Klein-Gordon equation by $\partial \Psi^{*} / \partial t$, adding the complex conjugate of the obtained equation, and integrating over all space. Each of the three terms in the Klein-Gordon equation will then give one of the three needed time derivatives. So their sum will indeed be zero.

To check that, look at what each term in the Klein-Gordon equation produces separately. The first term gives

$$
\int \frac{1}{c^{2}}\left(\frac{\partial \Psi^{*}}{\partial t} \frac{\partial^{2} \Psi}{\partial t^{2}}+\frac{\partial \Psi}{\partial t} \frac{\partial^{2} \Psi^{*}}{\partial t^{2}}\right)
$$

or taking one time derivative outside the integral, that is

$$
\frac{1}{c^{2}} \frac{\mathrm{~d}}{\mathrm{~d} t} \int \frac{\partial \Psi^{*}}{\partial t} \frac{\partial \Psi}{\partial t}
$$

That is the first needed time derivative, since a number times its complex conjugate is the square magnitude of that number.

The second term in the Klein-Gordon equation produces

$$
-\sum_{i} \int\left(\frac{\partial \Psi^{*}}{\partial t} \Psi_{i i}+\frac{\partial \Psi}{\partial t} \Psi_{i i}^{*}\right)
$$

That equals

$$
-\sum_{i} \int\left(\frac{\partial \Psi^{*}}{\partial t} \Psi_{i}+\frac{\partial \Psi}{\partial t} \Psi_{i}^{*}\right)_{i}+\sum_{i} \frac{\mathrm{~d}}{\mathrm{~d} t} \int \Psi_{i}^{*} \Psi_{i}
$$

as can be seen by differentiating out the parenthetical expression in the first integral with respect to $r_{i}$ and bringing the time derivative in the second term inside the integral. The first integral above is zero for a periodic box, for an impenetrable container, and for infinite space for the same reasons as given in the derivation for the Schrödinger equation. The second term above is the needed second time derivative.

The final of the three terms in the Klein-Gordon equation produces

$$
\left(\frac{m c^{2}}{\hbar c}\right)^{2} \int\left(\frac{\partial \Psi^{*}}{\partial t} \Psi+\frac{\partial \Psi}{\partial t} \Psi^{*}\right)
$$

That equals

$$
\left(\frac{m c^{2}}{\hbar c}\right)^{2} \frac{\mathrm{~d}}{\mathrm{~d} t} \int \Psi^{*} \Psi
$$

as can be seen by bringing the time derivative inside the integral. This is the last of the three needed time derivatives.

## D. 33 Quantum field derivations

This derivation will find the properties of a system described by a Hamiltonian of the form:

$$
\begin{equation*}
H=E^{\mathrm{p}}\left(\widehat{P}^{2}+\widehat{Q}^{2}\right)+E_{\mathrm{ref}} \tag{1}
\end{equation*}
$$

Here $\widehat{P}$ and $\widehat{Q}$ are Hermitian operators with commutator

$$
\begin{equation*}
[\widehat{P}, \widehat{Q}]=-\frac{1}{2} \mathrm{i} \tag{2}
\end{equation*}
$$

and $E^{\mathrm{p}}$ and $E_{\text {ref }}$ are constants with units of energy.
First note that the commutator (2) directly implies the uncertainty relationship, chapter 4.5.2 (4.46):

$$
\begin{equation*}
\sigma_{P} \sigma_{Q} \geqslant \frac{1}{4} \tag{3}
\end{equation*}
$$

Also note that the evolution equations for the expectation values of $P$ and $Q$ follow directly from chapter 7.2 (7.4). The commutator appearing in it is readily worked out using the commutator (2) and the rules of chapter 4.5.4. Since energy eigenstates are stationary, according to the evolution equations in such states the expectation values of $P$ and $Q$ will have to be zero.

The equality of the $\widehat{P}$ and $\widehat{Q}$ terms in the Hamiltonian is a simple matter of symmetry. Nothing changes if you swap $\widehat{P}$ and $\widehat{Q}$, adding a minus sign for one. Then unavoidably the two terms in the Hamiltonian must be equal; it is shown below that the eigenfunctions are unique.

The commutator (2) also implies that $\widehat{P}, \widehat{Q}$, and all their combinations, do not commute with the Hamiltonian. So they are not conserved quantities of the system. However, there are two combinations,

$$
\begin{equation*}
\widehat{a} \equiv \widehat{P}-\mathrm{i} \widehat{Q} \quad \widehat{a}^{\dagger} \equiv \widehat{P}+\mathrm{i} \widehat{Q} \tag{4}
\end{equation*}
$$

whose commutator with the Hamiltonian gives back a multiple of the same thing:

$$
[H, \widehat{a}]=-E^{\mathrm{p}} \widehat{a} \quad\left[H, \widehat{a}^{\dagger}\right]=E^{\mathrm{p}} \widehat{a}^{\dagger}
$$

In other words, $\widehat{a}$ and $\widehat{a}^{\dagger}$ are commutator eigenoperators of the Hamiltonian. The above relations are readily checked using the given commutator (2) and the rules of chapter 4.5.4.

To see why that is important, multiply both sides of the eigenvalue problems above with a system energy eigenfunction of energy $E$ :

$$
[H, \widehat{a}] \psi_{E}=-E^{\mathrm{p}} \widehat{a} \psi_{E} \quad\left[H, \widehat{a}^{\dagger}\right] \psi_{E}=E^{\mathrm{p}} \widehat{a}^{\dagger} \psi_{E}
$$

After writing out the definitions of the commutators, recognizing $H \psi_{E}$ as $E \psi_{E}$, and rearranging, that gives

$$
H\left(\widehat{a} \psi_{E}\right)=\left(E-E^{\mathrm{p}}\right)\left(\widehat{a} \psi_{E}\right) \quad H\left(\widehat{a}^{\dagger} \psi_{E}\right)=\left(E+E^{\mathrm{p}}\right)\left(\widehat{a}^{\dagger} \psi_{E}\right)
$$

These results can be compared to the definition of an energy eigenfunction. Then it is seen that $\widehat{a} \psi_{E}$ is an energy eigenfunction with one unit $E^{\mathrm{p}}$ less energy than $\psi_{E}$. And $\widehat{a}^{\dagger} \psi_{E}$ is an energy eigenfunction with one unit $E^{\mathrm{p}}$ more energy than $\psi_{E}$. So apparently $\widehat{a}$ and $\widehat{a}^{\dagger}$ act as annihilation and creation operators of quanta of energy $E^{\mathrm{p}}$. They act as shown to the left in figure A.6.

There are however two important caveats for these statements. If $\widehat{a} \psi_{E}$ or $\widehat{a}^{\dagger} \psi_{E}$ is zero, it is not an energy eigenfunction. Eigenfunctions must be nonzero. Also, even if the states $\widehat{a} \psi_{E}$ or $\widehat{a}^{\dagger} \psi_{E}$ are not zero, they will not normally be normalized states.

To get a better understanding of these issues, it is helpful to first find the Hamiltonian in terms of $\widehat{a}$ and $\widehat{a}^{\dagger}$. There are two equivalent forms,

$$
\begin{equation*}
H=E^{\mathrm{p}} \widehat{a} \widehat{a}^{\dagger}-\frac{1}{2} E^{\mathrm{p}}+E_{\text {ref }} \quad H=E^{\mathrm{p}} \widehat{a}^{\dagger} \widehat{a}+\frac{1}{2} E^{\mathrm{p}}+E_{\text {ref }} \tag{5}
\end{equation*}
$$

These expressions can be verified by plugging in the definitions (4) of $\widehat{a}$ and $\widehat{a}^{\dagger}$ and using the commutator (2). (Note that subtracting the two expressions gives the commutator of $\widehat{a}$ and $\widehat{a}^{\dagger}$ to be 1.)

Now look at the first Hamiltonian first. If $\widehat{a}^{\dagger} \psi_{E}$ would be zero for some state $\psi_{E}$, then that state would have energy $E_{\text {ref }}-\frac{1}{2} E^{\mathrm{p}}$. But that is not possible. If you look at the original Hamiltonian (1), the energy must at least be $E_{\text {ref }}$; square Hermitian operators are nonnegative.
(To be more precise, if you square a Hermitian operator, you square the eigenvalues, making them nonnegative. It is said that the square operator is "positive definite," or, if there are zero eigenvalues, positive semi-definite. And such an operator produces nonnegative expectation values. And the expectation values of the operators in the Hamiltonian do add up to the total energy; just take an inner product of the Hamiltonian eigenvalue problem with the wave function. See chapter 4.4 for more information on expectation values.)

It follows that $\widehat{a}^{\dagger} \psi_{E}$ is never zero. This operator can be applied indefinitely to find states of higher and higher energy. So there is no maximum energy.

But there is a possibility that $\widehat{a} \psi_{E}$ is zero. As the second form of the Hamiltonian in (5) shows, that requires that the energy of state $\psi_{E}$ equals

$$
E_{0}=\frac{1}{2} E^{\mathrm{p}}+E_{\mathrm{ref}}
$$

Now if you start from any energy state $\psi_{E}$ and apply $\widehat{a}$ sufficiently many times, you must eventually end up at this energy level. If not, you could go on lowering the energy forever. That would be inconsistent with the fact that the energy cannot be lower than $E_{\text {ref }}$. It follows that the above energy is the lowest energy that a state can have. So it is the ground state energy.

And any other energy must be a whole multiple of $E^{\mathrm{p}}$ higher than the ground state energy. Otherwise you could not end up at the ground state energy by applying $\widehat{a}$. Therefore, the energy eigenstates can be denoted more meaningfully by $|i\rangle$ rather than $\psi_{E}$. Here $i$ is the number of quanta $E^{\text {p }}$ that the energy is above the ground state level.

Now assume that the ground state is unique. In that case, there is one unique energy eigenfunction at each energy level. That is a consequence of the fact that if you go down a unit in energy with $\widehat{a}$ and then up a unit again with $\widehat{a}^{\dagger}$, (or vice versa), you must end up not just at the same energy, but at the same state. Otherwise the state would not be an eigenfunction of the Hamiltonian in one of the forms given in (5). Repeated application shows that if you go down any number of steps, and then up the same number of steps, you end up at the same state. Since every state must end up at the unique ground state, every state must be the result of applying $\widehat{a}^{\dagger}$ to the ground state sufficiently many times. There is just one such state for each energy level.

If there are two independent ground states, applying $\widehat{a}^{\dagger}$ on each gives two separate sets of energy eigenstates. And similar if there are still more ground states. Additional symbols will need to be added to the kets to keep the different families apart.

It was already mentioned that the states produced by the operators $\widehat{a}$ and $\widehat{a}^{\dagger}$ are usually not normalized. For example, the state $\widehat{a}|i\rangle$ will have a square magnitude given by the inner product

$$
\left.\left.|\widehat{a}| i\rangle\left.\right|^{2}=\langle\widehat{a} \mid i\rangle|\widehat{a}| i\right\rangle\right\rangle
$$

Now if you take $\widehat{a}$ or $\widehat{a}^{\dagger}$ to the other side of an inner product, it will change into the other one; the i in the definitions (4) will change sign. So the square magnitude of $\widehat{a}|i\rangle$ becomes

$$
\left.\left.|\widehat{a}| i\rangle\left.\right|^{2}=\langle\mid i\rangle\left|\widehat{a}^{\dagger} \widehat{a}\right| i\right\rangle\right\rangle
$$

From the second form of the Hamiltonian in (5), it is seen that $\widehat{a}^{\dagger} \widehat{a}$ gives the number of energy quanta $i$. And since the state $|i\rangle$ is normalized, the square magnitude of $\widehat{a}|i\rangle$ is therefore $i$. That means that

$$
\widehat{a}|i\rangle=c \sqrt{i}|i-1\rangle
$$

where $c$ is some number of magnitude 1 . Similarly

$$
\widehat{a}^{\dagger}|i\rangle=d \sqrt{i+1}|i-1\rangle
$$

But note that you can always change the definition of an energy eigenfunction by a constant of magnitude 1 . That allows you, while going up from $|0\rangle$ using $\widehat{a}^{\dagger}$, to redefine each state so that $d$ is 1 . And if $d$ is always one, then so is $c$. Otherwise $\widehat{a}^{\dagger} \widehat{a}$ would not be $i$.

In the ground state, the expectation values of $P$ and $Q$ are zero, while the expectation values of $P^{2}$ and $Q^{2}$ are equal to the minimum $\frac{1}{4}$ allowed by the uncertainty relation (3). The derivations of these statements are the same as those for the harmonic oscillator ground state in $\{\mathrm{D} .13\}$.

## D. 34 The adiabatic theorem

Consider the Schrödinger equation

$$
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=H \Psi
$$

If the Hamiltonian is independent of time, the solution can be written in terms of the Hamiltonian energy eigenvalues $E_{\vec{n}}$ and eigenfunctions $\psi_{\vec{n}}$ as

$$
\Psi=\sum_{\vec{n}} c_{\vec{n}}(0) e^{\mathrm{i} \theta_{\vec{n}}} \psi_{\vec{n}} \quad \theta_{\vec{n}}=-\frac{1}{\hbar} E_{\vec{n}} t
$$

Here $\vec{n}$ stands for the quantum numbers of the eigenfunctions and the $c_{\vec{n}}(0)$ are arbitrary constants.

However, the Hamiltonian varies with time for the systems of interest here. Still, at any given time its eigenfunctions form a complete set. So it is still possible to write the wave function as a sum of them, say like

$$
\begin{equation*}
\Psi=\sum_{\vec{n}} \bar{c}_{\vec{n}} e^{\mathrm{i} \theta_{\vec{n}}} \psi_{\vec{n}} \quad \theta_{\vec{n}}=-\frac{1}{\hbar} \int E_{\vec{n}} \mathrm{~d} t \tag{D.18}
\end{equation*}
$$

But the coefficients $\bar{c}_{\vec{n}}$ can no longer be assumed to be constant like the $c_{\vec{n}}(0)$. They may be different at different times.

To get an equation for their variation, plug the expression for $\Psi$ in the Schrödinger equation. That gives:

$$
\mathrm{i} \hbar \sum_{\vec{n}} \bar{c}_{\vec{n}}^{\prime} e^{\mathrm{i} \theta_{\vec{n}}} \psi_{\vec{n}}-\mathrm{i} \hbar \sum_{\vec{n}} \bar{c}_{\vec{n}} \frac{\mathrm{i}}{\hbar} E_{\vec{n}} e^{\mathrm{i} \theta_{\vec{n}}} \psi_{\vec{n}}+\mathrm{i} \hbar \sum_{\vec{n}} \bar{c}_{\vec{n}} e^{\mathrm{i} \theta_{\vec{n}}} \psi_{\vec{n}}^{\prime}=H \sum_{\vec{n}} \bar{c}_{\vec{n}} e^{\mathrm{i} \theta_{\vec{n}}} \psi_{\vec{n}}
$$

where the primes indicate time derivatives. The middle sum in the left hand side and the right hand side cancel against each other since by definition $\psi_{\vec{n}}$ is an eigenfunction of the Hamiltonian with eigenvalue $E_{\vec{n}}$. For the remaining two sums, take an inner product with an arbitrary eigenfunction $\left\langle\psi_{\overrightarrow{\underline{n}}}\right|$ :

$$
\mathrm{i} \hbar \bar{c}_{\overrightarrow{\underline{n}}}^{\prime} e^{\mathrm{i} \theta_{\overrightarrow{\underline{n}}}}+\mathrm{i} \hbar \sum_{\vec{n}} \bar{c}_{\vec{n}} e^{\mathrm{i} \theta_{\vec{n}}}\left\langle\psi_{\overrightarrow{\underline{\rightharpoonup}}} \mid \psi_{\vec{n}}^{\prime}\right\rangle=0
$$

In the first sum only the term $\vec{n}=\underline{\vec{n}}$ survived because of the orthonormality of the eigenfunctions. Divide by $\mathrm{i} \hbar e^{\mathrm{i} \theta_{\overrightarrow{\underline{n}}}}$ and rearrange to get

$$
\begin{equation*}
\bar{c}_{\underline{\underline{r}}}^{\prime}=-\sum_{\vec{n}} e^{\mathrm{i}\left(\theta_{\vec{n}}-\theta_{\vec{n}}\right)}\left\langle\psi_{\overrightarrow{\vec{n}}} \mid \psi_{\vec{n}}^{\prime}\right\rangle \bar{c}_{\vec{n}} \tag{D.19}
\end{equation*}
$$

This is still exact.
However, the purpose of the current derivation is to address the adiabatic approximation. The adiabatic approximation assumes that the entire evolution takes place very slowly over a large time interval $T$. For such an evolution, it helps to consider all quantities to be functions of the scaled time variable $t / T$. Variables change by a finite amount when $t$ changes by a finite fraction of $T$, so when $t / T$ changes by a finite amount. This implies that the time derivatives of the slowly varying quantities are normally small, of order $1 / T$.

Consider now first the case that there is no degeneracy, in other words, that there is only one eigenfunction $\psi_{\vec{n}}$ for each energy $E_{\vec{n}}$. If the Hamiltonian changes slowly and regularly in time, then so do the energy eigenvalues and eigenfunctions. In particular, the time derivatives of the eigenfunctions in (D.19) are small of order $1 / T$. It then follows from the entire equation that the time derivatives of the coefficients are small of order $1 / T$ too.
(Recall that the square magnitudes of the coefficients give the probability for the corresponding energy. So the magnitude of the coefficients is bounded by 1 . Also, for simplicity it will be assumed that the number of eigenfunctions in the system is finite. Otherwise the sums over $\vec{n}$ might explode. This book routinely assumes that it is "good enough" to approximate an infinite system by a large-enough finite one. That makes life a lot easier, not just here but also in other derivations like \{D.18\}.)

It is convenient to split up the sum in (D.19):

$$
\begin{equation*}
\bar{c}_{\underline{\vec{n}}}^{\prime}=-\left\langle\psi_{\overrightarrow{\underline{r}}} \mid \psi_{\underline{\underline{r}}}^{\prime}\right\rangle \bar{c}_{\underline{\vec{n}}}-\sum_{\overrightarrow{\vec{n}} \neq \underline{\vec{n}}} e^{\mathrm{i}\left(\theta_{\vec{n}}-\theta_{\overrightarrow{\underline{n}}}\right)}\left\langle\psi_{\overrightarrow{\underline{r}}} \mid \psi_{\vec{n}}^{\prime}\right\rangle \bar{c}_{\vec{n}} \tag{D.20}
\end{equation*}
$$

Under the stated conditions, the final sum can be ignored.
However, that is not because it is small due to the time derivative in it, as one reference claims. While the time derivative of $\psi_{\vec{n}}$ is indeed small of order $1 / T$, it acts over a time that is large of order $T$. The sum can be ignored because of the exponential in it. As the definition of $\theta_{\vec{n}}$ shows, it varies on the normal time scale, rather than on the long time scale $T$. Therefore it oscillates many times on the long time scale; that causes opposite values of the exponential to largely cancel each other.

To show that more precisely, note that the formal solution of the full equation (D.20) is, [41, 19.2]:

$$
\begin{equation*}
\bar{c}_{\underline{\underline{n}}}(t)=e^{\mathrm{i} \gamma_{\overline{\underline{n}}}}\left[\bar{c}_{\underline{\underline{n}}}(0)-\sum_{\vec{n} \neq \underline{\vec{n}}} \int_{\bar{t}=0}^{t} e^{\mathrm{i}\left(\theta_{\vec{n}}-\theta_{\overrightarrow{\underline{n}}}\right)} e^{-\mathrm{i} \gamma_{\overline{\underline{\rightharpoonup}}}}\left\langle\psi_{\underline{\vec{n}}} \mid \psi_{\vec{n}}^{\prime}\right\rangle \bar{c}_{\vec{n}} \mathrm{~d} \bar{t}\right] \quad \gamma_{\underline{\vec{n}}}^{\prime}=\mathrm{i}\left\langle\psi_{\overrightarrow{\underline{r}}} \mid \psi_{\overrightarrow{\underline{n}}}^{\prime}\right\rangle \tag{D.21}
\end{equation*}
$$

To check this solution, you can just plug it in. Note in doing so that the integrands are taken to be functions of $\bar{t}$, not $t$.

All the integrals are negligibly small because of the rapid variation of the first exponential in them. To verify that, rewrite them a bit and then perform an integration by parts:

$$
\begin{aligned}
& \int_{\bar{t}=0}^{t}-\frac{\mathrm{i}}{\hbar}\left(E_{\vec{n}}-E_{\overrightarrow{\vec{n}}}\right) e^{\mathrm{i}\left(\theta_{\vec{n}}-\theta_{\vec{n}}\right)} \frac{\hbar e^{-\mathrm{i} \gamma_{\vec{n}}}\left\langle\psi_{\overrightarrow{\vec{n}}} \mid \psi_{\vec{n}}^{\prime}\right\rangle \bar{c}_{\vec{n}}}{\mathrm{i}\left(E_{\vec{n}}-E_{\vec{n}}\right)} \mathrm{d} \bar{t}= \\
& \left.\quad e^{\mathrm{i}\left(\theta_{\vec{n}}-\theta_{\overrightarrow{\vec{n}}}\right.} \frac{\left.\hbar e^{-\mathrm{i} \gamma_{\vec{n}}}\left\langle\psi_{\vec{n}}\right| \psi_{\vec{n}}^{\prime}\right) \bar{c}_{\vec{n}}}{\mathrm{i}\left(E_{\vec{n}}-E_{\overrightarrow{\vec{n}}}\right)}\right|_{\bar{t}=0} ^{t}-\int_{\bar{t}=0}^{t} e^{\mathrm{i}\left(\theta_{\vec{n}}-\theta_{\vec{n}}\right)}\left(\frac{\hbar e^{-\mathrm{i} \gamma_{\underline{\underline{n}}}}\left\langle\psi_{\vec{n}} \mid \psi_{\vec{n}}^{\prime}\right\rangle \bar{c}_{\vec{n}}}{\mathrm{i}\left(E_{\vec{n}}-E_{\overrightarrow{\vec{n}}}\right)}\right)^{\prime} \mathrm{d} \bar{t}
\end{aligned}
$$

The first term in the right hand side is small of order $1 / T$ because the time derivative of the wave function is. The integrand in the second term is small of order $1 / T^{2}$ because of the two time derivatives. So integrated over an order $T$ time range, it is small of order $1 / T$ like the first term. It follows that the integrals in (D.21) become zero in the limit $T \rightarrow \infty$.

And that means that in the adiabatic approximation

$$
\bar{c}_{\vec{n}}=c_{\vec{n}}(0) e^{\mathrm{i} \gamma_{\vec{n}}} \quad \gamma_{\vec{n}}=\mathrm{i} \int\left\langle\psi_{\vec{n}} \mid \psi_{\vec{n}}^{\prime}\right\rangle \mathrm{d} t
$$

The underbar used to keep $\underline{\vec{n}}$ and $\vec{n}$ apart is no longer needed here since only one set of quantum numbers appears. This expression for the coefficients can be plugged in (D.18) to find the wave function $\Psi$. The constants $c_{\vec{n}}(0)$ depend on the initial condition for $\Psi$. (They also depend on the choice of integration constants for $\theta_{\vec{n}}$ and $\gamma_{\vec{n}}$, but normally you take the phases zero at the initial time).

Note that $\gamma_{\vec{n}}$ is real. To verify that, differentiate the normalization requirement to get

$$
\left\langle\psi_{\vec{n}} \mid \psi_{\vec{n}}\right\rangle=1 \quad \Longrightarrow \quad\left\langle\psi_{\vec{n}}^{\prime} \mid \psi_{\vec{n}}\right\rangle+\left\langle\psi_{\vec{n}} \mid \psi_{\vec{n}}^{\prime}\right\rangle=0
$$

So the sum of the inner product plus its complex conjugate are zero. That makes it purely imaginary, so $\gamma_{\vec{n}}$ is real.

Since both $\gamma_{\vec{n}}$ and $\theta_{\vec{n}}$ are real, it follows that the magnitudes of the coefficients of the eigenfunctions do not change in time. In particular, if the system starts out in a single eigenfunction, then it stays in that eigenfunction.

So far it has been assumed that there is no degeneracy, at least not for the considered state. However it is no problem if at a finite number of times, the energy of the considered state crosses some other energy. For example, consider a three-dimensional harmonic oscillator with three time varying spring stiffnesses. Whenever any two stiffnesses become equal, there is significant degeneracy. Despite that, the given adiabatic solution still applies. (This does assume that you have chosen the eigenfunctions to change smoothly through degeneracy, as perturbation theory says you can, \{D.79\}.)

To verify that the solution is indeed still valid, cut out a time interval of size $\delta T$ around each crossing time. Here $\delta$ is some number still to be chosen. The parts of the integrals in (D.21) outside of these intervals have magnitudes $\varepsilon(T, \delta)$ that become zero when $T \rightarrow \infty$ for the same reasons as before. The parts of the integrals corresponding to the intervals can be estimated as no more than some finite multiple of $\delta$. The reason is that the integrands are of order $1 / T$ and they are integrated over ranges of size $\delta T$. All together, that is enough to show that the complete integrals are less than say $1 \%$; just take $\delta$ small enough that the intervals contribute no more than $0.5 \%$ and then take $T$ large enough that the remaining integration range contributes no more than $0.5 \%$ too. Since you can play the same game for $0.1 \%, 0.01 \%$ or any arbitrarily small amount, the conclusion is that for infinite $T$, the contribution of the integrals becomes zero. So in the limit $T \rightarrow \infty$, the adiabatic solution applies.

Things change if some energy levels are permanently degenerate. Consider an harmonic oscillator for which at least two spring stiffnesses are permanently equal. In that case, you need to solve for all coefficients at a given energy
level $E_{\vec{n}}$ together. To figure out how to do that, you will need to consult a book on mathematics that covers systems of ordinary differential equations. In particular, the coefficient $\bar{c}_{\underline{\underline{n}}}$ in (D.21) gets replaced by a vector of coefficients with the same energy. The scalar $\gamma_{\underline{\underline{n}}}$ becomes a matrix with indices ranging over the set of coefficients in the vector. Also, $e^{i \gamma_{\vec{\pi}}}$ gets replaced by a "fundamental solution matrix," a matrix consisting of independent solution vectors. And $e^{-\mathrm{i} \gamma_{\overrightarrow{\underline{n}}}}$ is the inverse matrix. The sum no longer includes any of the coefficients of the considered energy.

More recent derivations allow the spectrum to be continuous, in which case the nonzero energy gaps $E_{\overrightarrow{\underline{n}}}-E_{\vec{n}}$ can no longer be assumed to be larger than some nonzero amount. And unfortunately, assuming the system to be approximated by a finite one helps only partially here; an accurate approximation will produce very closely spaced energies. Such problems are well outside the scope of this book.

## D. 35 The evolution of expectation values

To verify the stated formulae for the evolution of expectation values, just write the definition of expectation value, $\langle\Psi \mid A \Psi\rangle$, differentiate to get

$$
\left\langle\Psi_{t} \mid A \Psi\right\rangle+\left\langle\Psi \mid A \Psi_{t}\right\rangle+\left\langle\Psi \mid A_{t} \Psi\right\rangle
$$

and replace $\Psi_{t}$ by $H \Psi / \mathrm{i} \hbar$ on account of the Schrödinger equation. Note that in the first inner product, the i appears in the left part, hence comes out as its complex conjugate -i.

## D. 36 Photon wave function derivations

The rules of engagement are as follows:

- The Cartesian axes are numbered using an index $i$, with $i=1,2$, and 3 for $x, y$, and $z$ respectively.
- Also, $r_{i}$ indicates the coordinate in the $i$ direction, $x, y$, or $z$.
- Derivatives with respect to a coordinate $r_{i}$ are indicated by a simple subscript $i$.
- If the quantity being differentiated is a vector, a comma is used to separate the vector index from differentiation ones.
- Index $\bar{\imath}$ is the number immediately following $i$ in the cyclic sequence $\ldots$...123123... and $\overline{\bar{i}}$ is the number immediately preceding $i$.
- Time derivatives are indicated by a subscript t.
- A bare $\int$ integral sign is assumed to be an integration over all space, or over the entire box for particles in a box. The $\mathrm{d}^{3} \vec{r}$ is normally omitted for brevity and to be understood.
- A superscript * indicates a complex conjugate.

## D.36.1 Rewriting the energy integral

As given in the text, the energy in an electromagnetic field in free space that satisfies the Coulomb-Lorenz gauge is, writing out the square magnitudes and individual components,

$$
E=\frac{1}{2} \epsilon_{0} \int\left(\left|\frac{\partial \vec{A}}{\partial t}\right|^{2}+c^{2}|\nabla \vec{A}|^{2}\right)=\frac{1}{2} \epsilon_{0} \sum_{i} \int\left(A_{i, t}^{*} A_{i, t}+c^{2} \sum_{j=1}^{3} A_{i, j}^{*} A_{i, j}\right)
$$

However, a bit more general expression is desirable. If only the Lorenz condition is satisfied, there may also be an electrostatic potential $\varphi$. In that case, a more general expression for the energy is:

$$
\begin{equation*}
E=\frac{1}{2} \epsilon_{0}\left[\sum_{i=1}^{3} \int\left(A_{i, t}^{*} A_{i, t}+c^{2} \sum_{j=1}^{3} A_{i, j}^{*} A_{i, j}\right)-\int\left(\frac{1}{c^{2}} \varphi_{t}^{*} \varphi_{t}+\sum_{j=1}^{3} \varphi_{j}^{*} \varphi_{j}\right)\right] \tag{1}
\end{equation*}
$$

The minus sign for the $\varphi$ terms appears because this is really a dot product of relativistic four-vectors. The zeroth components in such a dot product acquire a minus sign, chapter 1.2.4 and 1.3.2. In derivation $\{D .32\}$ it was shown that each of the four integrals is constant. That is because each component satisfies the Klein-Gordon equation. So their sum is constant too.

The claim to verify now is that the same energy can be obtained from integrating the electric and magnetic fields as

$$
\begin{equation*}
E=\frac{1}{2} \epsilon_{0} \int\left(|\overrightarrow{\mathcal{E}}|^{2}+c^{2}|\overrightarrow{\mathcal{B}}|^{2}\right)=\frac{1}{2} \epsilon_{0} \sum_{i} \int\left(\mathcal{E}_{i}^{*} \mathcal{E}_{i}+c^{2} \mathcal{B}_{i}^{*} \mathcal{B}_{i}\right) \tag{2}
\end{equation*}
$$

Since $\overrightarrow{\mathcal{E}}=-\partial \vec{A} / \partial t-\nabla \varphi$ and $\overrightarrow{\mathcal{B}}=\nabla \times \vec{A}$ :

$$
\mathcal{E}_{i}=-A_{i, t}-\varphi_{i} \quad \mathcal{B}_{i}=A_{\overline{\bar{i}, \bar{\imath}}}-A_{\bar{i}, \bar{i}}
$$

From now on, it will be understood that there is a summation over $i$ and $j$ and that everything has a $\frac{1}{2} \epsilon_{0}$. Therefore these will no longer be shown.

Start with the electric field integral. It is, using the above expressions and multiplying out,

$$
\int A_{i, t}^{*} A_{i, t}+A_{i, t}^{*} \varphi_{i}+\varphi_{i}^{*} A_{i, t}+\varphi_{i}^{*} \varphi_{i}
$$

The first term already gives the vector-potential time derivatives in (1). That leaves the final three terms. Perform an integration by parts on the first two. It will always be assumed that the potentials vanish at infinity or that the system is in a periodic box. In that case there are no boundary terms in an integration by parts. So the three terms become

$$
\int-A_{i, i t}^{*} \varphi-\varphi^{*} A_{i, i t}+\varphi_{i}^{*} \varphi_{i}
$$

However, the divergence $A_{i, i}$ is according to the Lorenz condition equal to $-\varphi_{t} / c^{2}$, so

$$
\int \frac{1}{c^{2}} \varphi_{t t}^{*} \varphi+\frac{1}{c^{2}} \varphi^{*} \varphi_{t t}+\varphi_{i}^{*} \varphi_{i}
$$

Using the Klein-Gordon equation, $\varphi_{t t} / c^{2}=\varphi_{i i}$, and then another integration by parts on the first two terms and renotating $i$ by $j$ gives the $\varphi_{j}^{*} \varphi_{j}$ terms in (1).

Now consider the integral of $|\overrightarrow{\mathcal{B}}|^{2}$ in (2). You get, multiplying out,

Now the first and last terms in the right hand side summed over $i$ produce all terms $A_{i, j}^{*} A_{i, j}$ in (1) in which $i$ and $j$ are different. That leaves the middle terms. An integration by parts yields

$$
c^{2} \int\left(A_{\bar{i}, \overline{\bar{l}}}^{*} A_{\bar{\imath}}+A_{\bar{i}, \overline{\bar{u}}}^{*} A_{\overline{\bar{\imath}}}\right)
$$

Renotate the indices cyclically to get

$$
c^{2} \int\left(A_{\bar{i}, \bar{i} i}^{*} A_{i}+A_{\overline{\bar{i}, \bar{i} i}}^{*} A_{i}\right)
$$

(If you want, you can check that this is the same by writing out all three terms in the sum.) This is equivalent to

$$
c^{2} \int\left(A_{i, i}^{*}+A_{\bar{i}, \bar{i}}^{*}+A_{\overline{\bar{i}, \bar{\imath}}}^{*}\right)_{i} A_{i}-A_{i, i i}^{*} A_{i}
$$

as you can see from differentiating and multiplying out. The final term gives after integration by parts the $A_{i, j}^{*} A_{i, j}$ terms in (1) in which $i$ and $j$ are equal. That leaves the first part. The term in parentheses is the divergence $-\varphi_{t} / c^{2}$, so the first part is

$$
\int-\varphi_{i t}^{*} A_{i}
$$

Perform an integration by parts

$$
\int \varphi_{t}^{*} A_{i, i}
$$

Recognizing once more the divergence, this gives the final $-\varphi_{t}^{*} \varphi_{t} / c^{2}$ term in (1)

## D.36.2 Angular momentum states

The rules of engagement listed at the start of this section apply. In addition:

- The quantum numbers $\ell$ and $m_{\ell}$ will be renotated by $l$ and $m$, while $k$ stays $k$. That is easier to type.
- The quantum numbers are not shown unless needed. For example, $j$ stands for $j_{l}$.
- A bar on a quantity, like in $\bar{Y} Y$, means the complex conjugate. In addition, the (unlisted) quantum numbers of spherical harmonic $\bar{Y}$ may in general be different from those of $Y$ and are indicated by bars too.
- The symbols $f$ and $g$ are used as generic scalar functions. They often stand in particular for the $j Y$ scalar modes.
- An integral in spherical coordinates takes the form $\int \ldots r^{2} \mathrm{~d} r \mathrm{~d} \Omega$ where $\mathrm{d} \Omega=\sin \theta \mathrm{d} \theta \mathrm{d} \phi$.

## D.36.2.1 About the scalar modes

The scalar modes are the $j Y$.
It will be assumed that the $j$ are zero at the large radius $r_{\max }$ at which the domain is assumed to terminate. That makes the scalar modes a complete set; any scalar function $f$ can be written as a combination of them. (That is because they are the eigenfunctions of the Laplacian inside the sphere, and the zero boundary condition on the sphere surface $r=r_{\text {max }}$ makes the Laplacian Hermitian. This will not be explicitly proved since it is very standard.)

The Bessel function $j$ of the scalar modes satisfy the ordinary differential equation, $\{\mathrm{A} .6\}$

$$
\begin{equation*}
r^{2} j^{\prime \prime}+2 r j^{\prime}=l(l+1) j-k^{2} r^{2} j \tag{3}
\end{equation*}
$$

The following integral is needed (note that $j$ is real):

$$
\begin{equation*}
\int_{0}^{r_{\max }} j^{2} r^{2} \mathrm{~d} r \sim \frac{r_{\max }}{2 k^{2}} \tag{4}
\end{equation*}
$$

This is valid for large $k r_{\text {max }}$, which applies since $r_{\text {max }}$ is large and the $k$ values of interest are finite. The above result comes from the integral of the square twodimensional Bessel functions $J$, and a recurrence relation, [41, 27.18,88], using $j_{l}(k r)=J_{l+\frac{1}{2}}(k r) \sqrt{\pi / 2 k r},[1, \mathrm{p} 437,10.1 .1]$, and the asymptotic behavior of the Bessel function you get from \{A.6\} (A.19). To get the leading asymptotic term, each time you have to differentiate the trigonometric function. And where the trigonometric function in $j_{l}$ is zero at $r_{\text {max }}$ because of the boundary condition, the one in $j_{l+1}$ has magnitude 1 .

The spherical harmonics are orthonormal on the unit sphere, $\{$ D.14.4 $\}$

$$
\begin{equation*}
\int \bar{Y} Y \mathrm{~d} \Omega=\delta_{\bar{l}} \delta_{\bar{m} m} \tag{5}
\end{equation*}
$$

In other words, the integral is only 1 if $l=\bar{l}$ and $m=\bar{m}$ and otherwise it is zero. Further

$$
\begin{equation*}
\int\left(\bar{Y}_{\theta} Y_{\theta}+\frac{1}{\sin ^{2} \theta} \bar{Y}_{\phi} Y_{\phi}\right) \mathrm{d} \Omega=l(l+1) \delta_{\bar{l}} \delta_{\bar{m} m} \tag{6}
\end{equation*}
$$

## D.36.2.2 Basic observations and eigenvalue problem

For any function $f$

$$
\begin{equation*}
\vec{r} \times \nabla f=-\nabla \times(\vec{r} f) \tag{7}
\end{equation*}
$$

This follows from writing out the right hand side

$$
-\left(r_{\bar{\imath}} f\right)_{\bar{\imath}}+\left(r_{\bar{\imath}} f\right)_{\overline{\bar{\imath}}}=-r_{\overline{\bar{\imath}}} f_{\bar{\imath}}+r_{\bar{\imath}} f_{\overline{\bar{\imath}}}
$$

the latter since $\bar{\imath}$ and $\overline{\bar{\imath}}$ are different indices.
The electric modes

$$
\nabla \times \vec{r} \times \nabla f
$$

are solenoidal because $\nabla \cdot \nabla \times \ldots$ gives zero. The magnetic modes

$$
\vec{r} \times \nabla f
$$

are solenoidal for the same reason, after noting (7) above.
The Laplacian commutes with the operators in front of the scalar functions in the electric and magnetic modes. That can be seen for the magnetic ones from

$$
\left(r_{\bar{\imath}} f_{\overline{\bar{\imath}}}-r_{\bar{\imath}} f_{\bar{\imath}}\right)_{j j}=r_{\bar{\imath}} f_{j j \bar{\imath}}-r_{\bar{\imath}} f_{j j \bar{\imath}}+2 r_{\bar{\imath}, j} f_{j \bar{\imath}}-2 r_{\overline{\bar{\imath}}, j} f_{j \bar{\imath}}=r_{\bar{\imath}} f_{j j \bar{\imath}}-r_{\bar{\imath}} f_{j j \bar{\imath}}+2 f_{\overline{\bar{\imath}}}-2 f_{\overline{\bar{\imath}}}
$$

and the final two terms cancel. And the Laplacian also commutes with the additional $\nabla \times$ in the electric modes since differentiations commute.

From this it follows that the energy eigenvalue problem is satisfied because by definition of the scalar modes $-\nabla^{2} j Y=k^{2} j Y$. In addition,

$$
\begin{equation*}
\nabla \times \nabla \times \vec{r} \times \nabla f=k^{2} \vec{r} \times \nabla f \tag{8}
\end{equation*}
$$

because $\nabla \times \nabla \times=-\nabla^{2}$ for a solenoidal function, (D.1).

## D.36.2.3 Spherical form and net angular momentum

In spherical coordinates, the magnetic mode is

$$
\begin{equation*}
\vec{A}^{\mathrm{M}}=\vec{r} \times \nabla j Y=j\left[\hat{\imath}_{\phi} Y_{\theta}-\hat{\imath}_{\theta} \frac{1}{\sin \theta} Y_{\phi}\right] \tag{9}
\end{equation*}
$$

and then the electric mode is

$$
\begin{equation*}
\vec{A}^{\mathrm{E}}=\nabla \times \vec{r} \times \nabla j Y=-\hat{\imath}_{r} l(l+1) \frac{j}{r} Y-\frac{(r j)^{\prime}}{r}\left[\hat{\imath}_{\theta} Y_{\theta}+\hat{\imath}_{\phi} \frac{1}{\sin \theta} Y_{\phi}\right] \tag{10}
\end{equation*}
$$

from [41, 20.74,76,82] and for the $r$ component of $\vec{A}^{\mathrm{E}}$ the eigenvalue problem of chapter 4.2.3.

Now note that the $\phi$ dependence of $Y$ is through a simple factor $e^{\mathrm{im} \phi}$, chapter 4.2.3. Therefore it is seen that if the coordinate system is rotated over an angle $\gamma$ around the $z$-axis, it produces a factor $e^{\mathrm{i} m \gamma}$ in the vectors. First of all that means that the azimuthal quantum number of net angular momentum is $m$, \{A.19\}. But it also means that, $\{\mathrm{A} .19\}$,

$$
\widehat{J}_{z} \vec{r} \times \nabla f=\vec{r} \times \nabla L_{z} f \quad \widehat{J}_{z} \nabla \times \vec{r} \times \nabla f=\nabla \times \vec{r} \times \nabla L_{z} f
$$

because either way the vector gets multiplied by $m \hbar$ for the modes. And if it is true for all the modes, then it is true for any function $f$. Since the $z$-axis is not special for general $f$, the same must hold for the $x$ and $y$ angular momentum operators. From that it follows that the modes are also eigenfunctions of net square angular momentum, with azimuthal quantum number $l$.

At the cut-off $r=r_{\text {max }}, j=0$, which gives:

$$
\begin{equation*}
\text { At } r_{\max }: \quad \vec{A}^{\mathrm{M}}=0 \quad \vec{A}^{\mathrm{E}}=-j^{\prime}\left[\hat{\imath}_{\theta} Y_{\theta}+\hat{\imath}_{\phi} \frac{1}{\sin \theta} Y_{\phi}\right] \tag{11}
\end{equation*}
$$

Also needed is, differentiating (10):

$$
\begin{equation*}
\text { At } r_{\max }: \quad \frac{\partial \vec{A}^{\mathrm{E}}}{\partial r}=-\hat{\imath}_{r} l(l+1) \frac{j^{\prime}}{r} Y+\frac{j^{\prime}}{r}\left[\hat{\imath}_{\theta} Y_{\theta}+\hat{\imath}_{\phi} \frac{1}{\sin \theta} Y_{\phi}\right] \tag{12}
\end{equation*}
$$

which used (3) to get rid of the second order derivative of $j$.

## D.36.2.4 Orthogonality and normalization

Whether the modes are orthogonal, and whether the Laplacian is Hermitian, is not obvious because of the weird boundary conditions at $r_{\text {max }}$.

In general the important relations here

$$
\begin{align*}
& \int\left(\bar{k}^{2}-k^{2}\right) A_{i} A_{i} \\
&=\int \bar{A}_{i, j j} A_{i}-\bar{A}_{i} A_{i, j j} \\
&=\int\left(\bar{A}_{i, j} A_{i}-\bar{A}_{i} A_{i, j}\right)_{j}  \tag{13}\\
&=\int_{S}\left(\bar{A}_{i, j} A_{i}-\bar{A}_{i} A_{i, j}\right) \frac{\partial r_{j}}{\partial r} \mathrm{~d} S
\end{align*}
$$

where $S$ is the surface of the sphere $r=r_{\max }$. The second last line can be verified by differentiating out and the last line is the divergence theorem.

The first and second line in (13) show that the Laplacian is Hermitian if all unequal modes are orthogonal (or have equal $k$ values, but orthogonality should be shown anyway.). For unequal $k$ values orthogonality may be shown by showing that the final surface integral is zero.

It is convenient to show right away that the electric and magnetic modes are always mutually orthogonal:

$$
\int\left(r_{\bar{\imath}} \bar{f}_{\overline{\bar{\imath}}}-r_{\overline{\bar{\imath}}} \bar{f}_{\bar{\imath}}\right) A_{i}^{\mathrm{E}}=\int\left(r_{\bar{\imath}} \bar{f} A_{i}^{\mathrm{E}}\right)_{\overline{\bar{\imath}}}-\left(r_{\overline{\bar{\imath}}} \bar{f} A_{i}^{\mathrm{E}}\right)_{\bar{\imath}}-r_{\bar{\imath}} \bar{f} A_{i, \overline{\bar{\imath}}}^{\mathrm{E}}+r_{\overline{\bar{\imath}}} \bar{f} A_{i, \bar{\imath}}^{\mathrm{E}}
$$

The first two terms in the right hand side can be integrated in the $\overline{\bar{\imath}}$, respectively $\bar{\imath}$ direction and are then zero because $\bar{f}$ is zero on the spherical surface $r=r_{\text {max }}$. The final two terms summed over $i$ can be renotated by shifting the summation index one unit down, respectively up in the cyclic sequence to give

$$
\sum_{i}-\int \bar{f} r_{i}\left(A_{\bar{i}, \bar{i}}^{\mathrm{E}}-A_{\bar{i}, \overline{\bar{l}}}^{\mathrm{E}}\right)=\sum_{i}-\int \bar{f} \vec{r} \cdot \nabla \times \vec{A}^{\mathrm{E}}=-k^{2} \int \bar{f} \vec{r} \cdot \vec{r} \times \nabla f
$$

the latter because of the form of $\vec{A}^{\mathrm{E}}$, the fact that $\nabla \times \nabla \times=-\nabla^{2}$ for a solenoidal vector, and the energy eigenvalue problem established for $\vec{A}^{\mathrm{M}}$. The final term is zero because $\vec{r} \cdot \vec{r} \times$ is.

Next consider the orthogonality of the magnetic modes for different quantum numbers. For $\bar{l} \neq l$ or $\bar{m} \neq m$, the orthogonality follows from (9) and (6). For $\bar{k} \neq k$, the orthogonality follows from the final line in (13) since the magnetic modes are zero at $r_{\text {max }}$, (11).

Finally the electric modes. For $\bar{l} \neq l$ or $\bar{m} \neq m$, the orthogonality follows from (10), (5), and (6). For $\bar{k} \neq k$, the orthogonality follows from the final line in (13). To see that, recognize that $A_{i, j} \partial r_{j} / \partial r$ is the radial derivative of $\vec{A}$; therefore using (11) and (12), the integrand vanishes.

The integral of the absolute square integral of a magnetic mode is, using (9), (6), and (4),

$$
\int \vec{A}^{\mathrm{M} *} \cdot \vec{A}^{\mathrm{M}}=l(l+1) \frac{r_{\max }}{2 k^{2}}
$$

The integral of the absolute square integral of an electric mode is, using (10), (5), and (6),

$$
l^{2}(l+1)^{2} \int_{0}^{r_{\max }} j^{2} \mathrm{~d} r+l(l+1) \int_{0}^{r_{\max }}(r j)^{\prime}(r j)^{\prime} \mathrm{d} r
$$

Apply an integration by parts on the second integral,

$$
l^{2}(l+1)^{2} \int_{0}^{r_{\max }} j^{2} \mathrm{~d} r-l(l+1) \int_{0}^{r_{\max }} j r(r j)^{\prime \prime} \mathrm{d} r
$$

and then use (3) to get

$$
\int \vec{A}^{\mathrm{M} *} \cdot \vec{A}^{\mathrm{M}}=k^{2} l(l+1) \frac{r_{\max }}{2 k^{2}}
$$

The normalizations given in the text follow.

## D.36.2.5 Completeness

Because of the condition $\nabla \cdot \vec{A}=0$, you would generally speaking expect two different types of modes described by scalar functions. The electric and magnetic modes seem to fit that bill. But that does not mean that there could not be say a few more special modes. What is needed is to show completeness. That means to show that any smooth vector field satisfying $\nabla \cdot \vec{A}=0$ can be written as a sum of the electric and magnetic modes, and nothing else.

This author does not know any simple way to do that. It would be automatic without the solenoidal condition; you would just take each Cartesian component to be a combination of the scalar modes $j Y$ satisfying a zero boundary condition at $r_{\text {max }}$. Then completeness would follow from the fact that they are eigenfunctions of the Hermitian Laplacian. Or from more rigorous arguments that you can find in mathematical books on partial differential equations. But how to do something similar here is not obvious, at least not to this author.

What will be done is show that any reasonable solenoidal vector can be written in the form

$$
\vec{A}=\vec{r} \times \nabla f+\nabla \times \vec{r} \times \nabla g
$$

where $f$ and $g$ are scalar functions. Completeness then follows since the modes $j Y$ provide a complete description of any arbitrary function $f$ and $g$.

But to show the above does not seem easy either, so what will be actually shown is that any vector without radial component can be written in the form

$$
\vec{v}=\vec{r} \times \nabla f+\hat{\imath}_{r} \times \vec{r} \times \nabla g
$$

That is sufficient because the Fourier transform of $\vec{A}$ does not have a radial component, so it will be of this form. And the inverse Fourier transform of $\vec{v}$ is of the form $\vec{A}$, compare any book on Fourier transforms and (7).

The proof that $\vec{v}$ must be of the stated form is by construction. Note that automatically, the radial component of the two terms is zero. Writing out the gradients in spherical coordinates, [41, 20.74,82], multiplying out the cross products and equating components gives at any arbitrary radius $r$

$$
-\frac{\partial f}{\partial \phi}-\sin \theta \frac{\partial g}{\partial \theta}=v_{\theta} \sin \theta \quad \sin \theta \frac{\partial f}{\partial \theta}-\frac{\partial g}{\partial \phi}=v_{\phi} \sin \theta
$$

Now decompose this in Fourier modes $e^{\text {im } \phi}$ in the $\phi$ direction:

$$
-\mathrm{i} m f_{m}-\sin \theta \frac{\partial g_{m}}{\partial \theta}=v_{\theta m} \sin \theta \quad \sin \theta \frac{\partial f_{m}}{\partial \theta}-\mathrm{i} m g_{m}=v_{\phi m} \sin \theta
$$

For $m=0, f_{0}$ and $g_{0}$ follow by integration. Note that the integrands are periodic of period $2 \pi$ and antisymmetric about the $z$-axis. That makes $f$ and $g$ periodic of period $2 \pi$ too,

For $m \neq 0$ make a coordinate transform from $\theta$ to

$$
t=\int \mathrm{d} \theta / \sin \theta=\ln \tan \frac{1}{2} \theta
$$

Note that $-\infty<t<\infty$. If anybody is actually reading this, send me an email. The system becomes after cleaning up

$$
-\mathrm{i} m f_{m}-\frac{\partial g_{m}}{\partial t}=v_{\theta m} / \cosh t \quad \frac{\partial f_{m}}{\partial t}-\mathrm{i} m g_{m}=v_{\phi m} / \cosh t
$$

It is now easiest to solve the above equations for each of the two right hand sides separately. Here the first right hand side will be done, the second right hand side goes similarly.

From the two equations it is seen that $f_{m}$ must satisfy

$$
\frac{\partial^{2} f_{m}}{\partial t^{2}}-m^{2} f_{m}=\frac{-2 m i v_{\theta m}}{e^{t}+e^{-t}}
$$

and $\mathrm{i} m g_{m}$ must the derivative of $f_{m}$. The solution satisfying the required regularity at $\pm \infty$ is, [41, 19.8],

$$
f_{m}=\int_{t}^{\infty} \mathrm{i} v_{\theta m} \frac{e^{-m(\tau-t)}}{e^{\tau}+e^{-\tau}} \mathrm{d} \tau+\int_{-\infty}^{t} \mathrm{i} v_{\theta m} \frac{e^{m(\tau-t)}}{e^{\tau}+e^{-\tau}} \mathrm{d} \tau
$$

That finishes the construction, but you may wonder about potential nonexponential terms in the first integral at $-\infty$ and the second integral at $\infty$. Those would produce weak logarithmic singularities in the physical $f$ and $g$. You could simply guess that the two right hand sides will combine so that these terms drop out. After all, there is nothing special about the chosen direction of the $z$-axis. If you choose a different axis, it will show no singularities at the old $z$-axis, and the solution is unique.

For more confidence, you can check the cancellation explicitly for the leading order, $m=1$ terms. But there is a better way. If the right hand sides are zero within a nonzero angular distance $\Delta \theta_{1}$ from the $z$-axis, there are no singularities. And it is easy to split off a part of $\vec{v}$ that is zero within $\Delta \theta_{1}$ of the axis and then changes smoothly to the correct $\vec{v}$ in an angular range from $\Delta \theta_{1}$ to $\Delta \theta_{2}$ from the axis. The remainder of $\vec{v}$ can than be handled by using say the $x$-axis as the axis of the spherical coordinate system.

## D.36.2.6 Density of states

The spherical Bessel function is for large arguments proportional to $\sin (k r) / r$ or $\cos (k r) / r$. Either way, the zeros are spaced $\Delta k r_{\max }=\pi$ apart. So there is one state $\Delta N=1$ in an interval $\Delta E=\hbar \Delta k c=\hbar \pi c / r_{\max }$. The ratio gives the stated density of states.

## D.36.2.7 Parity

Parity is what happens to the sign of the wave function under a parity transformation. A parity transformation inverts the positive direction of all three Cartesian axes, replacing any position vector $\vec{r}$ by $-\vec{r}$. The parity of something is 1 or even if it does not change, and -1 or odd if it changes sign. Under a parity transformation, the operators $\vec{r} \times$ and $\nabla \times$ flip over the parity of what they act on. On the other hand, $\nabla j_{j} Y_{j}^{m_{j}}$ has the same parity as $j_{j} Y_{j}^{m_{j}}$; the spatial components flip over, but so do the unit vectors that multiply them. And the parity of $j_{j} Y_{j}^{m_{j}}$ is even if $j$ is even and odd if $j$ is odd. The stated parities follow.

## D.36.2.8 Orbital angular momentum of the states

In principle a state of definite net angular momentum $j$ and definite spin 1 may involve orbital angular momentum $l=j-1, l=j$ and $l=j-1$, chapter 7.4.2. But states of definite parity restrict that to either only odd values or only even values, $\{$ A. 20$\}$. To get the stated parities, $l=j$ for magnetic states and $l=$ $j-1$ or $l=j+1$ for electric ones.
woof.

## D. 37 Forces by particle exchange derivations

## D.37.1 Classical energy minimization

The energy minimization including a selecton is essentially the same as the one for only spoton and foton field. That one has been discussed in chapter A.22.1 and in detail in $\{\mathrm{A} .2\}$. So only the key differences will be listed here.

The energy to minimize is now

$$
\frac{\epsilon_{1}}{2} \int(\nabla \varphi)^{2} \mathrm{~d}^{3} \vec{r}-\int \varphi(\vec{r})\left(s_{\mathrm{p}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right)+s_{2} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{e}}\right)\right) \mathrm{d}^{3} \vec{r}
$$

So the only real difference in the variational analysis is

$$
s_{\mathrm{p}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right) \quad \rightarrow \quad s_{\mathrm{p}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right)+s_{\mathrm{e}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right)
$$

That means that the Poisson equation now becomes

$$
-\nabla^{2} \varphi(\vec{r})=\frac{s_{\mathrm{p}}}{\epsilon_{1}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right)+\frac{s_{\mathrm{e}}}{\epsilon_{1}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{e}}\right)
$$

Since the Poisson equation is linear, the solution is $\varphi=\varphi^{\mathrm{p}}+\varphi^{\mathrm{e}}$. Here $\varphi^{\mathrm{p}}$ is the foton field (A.107) produced by the spoton as before, and $\varphi^{e}$ is a similar expression, but using the selecton sarge and distance from the selecton:

$$
\varphi^{\mathrm{p}}=\frac{s_{\mathrm{p}}}{4 \pi \epsilon_{1}\left|\vec{r}-\vec{r}_{\mathrm{p}}\right|} \quad \varphi^{\mathrm{e}}=\frac{s_{\mathrm{e}}}{4 \pi \epsilon_{1}\left|\vec{r}-\vec{r}_{\mathrm{e}}\right|}
$$

The energy lowering is now

$$
-\frac{1}{2} \int\left(\varphi^{\mathrm{p}}(\vec{r})+\varphi^{\mathrm{e}}(\vec{r})\right)\left(s_{\mathrm{p}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{p}}\right)+s_{\mathrm{e}} \delta_{\varepsilon}^{3}\left(\vec{r}-\vec{r}_{\mathrm{e}}\right)\right) \mathrm{d}^{3} \vec{r}
$$

Multiplying out, you get, of course, the energy lowerings for the spoton and selecton in isolation. But you also get two additional interaction terms between these sarges. These two terms are equal; the selecton field $\varphi^{e}$ evaluated at the position of the spoton times spoton sarge is the same as the spoton field $\varphi^{\mathrm{p}}$ at the selecton times selecton sarge. So it is seen that each term contributes half to the Koulomb energy as claimed in the text.

The foton field energy is still half of the particle-field interaction energies and of opposite sign. That is why the energy change is half of what you would expect from the interaction of the particles with each other's field: the other half is offset by changes in field energy.

## D.37.2 Quantum energy minimization

This derivation includes the selecton in the spoton-fotons system analyzed in \{A.22.3\}. Since the analysis is essentially unchanged, only the key differences will be highlighted.

If an selecton is added to the system, the system wave function becomes

$$
\psi_{\varphi \mathrm{pe}}=C_{0} \psi_{\mathrm{p}} \psi_{\mathrm{e}}|0\rangle+C_{1} \psi_{\mathrm{p}} \psi_{\mathrm{e}}|1\rangle+\ldots \quad\left|C_{0}\right|^{2}+\left|C_{1}\right|^{2}+\ldots=1
$$

The demon can hold the selecton in its other hand. The Hamiltonian will now of course include a term for the selecton in isolation, as well as an interaction with the foton field. These are completely analogous to the corresponding spoton terms.

So the energy to be minimized for the ground state becomes
$E=E_{\mathrm{p}}+E_{\mathrm{e}}+\left|C_{1}\right|^{2} \hbar \omega-2 \frac{\varepsilon_{k}}{\sqrt{2} k}\left|s_{\mathrm{p}}\left\langle\psi_{\mathrm{p}} \mid e^{\mathrm{i} \vec{k} \cdot \overrightarrow{\mathrm{r}}_{\mathrm{p}}} \psi_{\mathrm{p}}\right\rangle+s_{\mathrm{e}}\left\langle\psi_{\mathrm{e}} \mid e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{e}}} \psi_{\mathrm{e}}\right\rangle\right|\left|C_{1}\right| \cos (\alpha+\beta)$
If this is minimized as in $\{\mathrm{A} .22 .3\}$, the energy is

$$
\left.E=E_{\mathrm{p}}+E_{\mathrm{e}}-\frac{1}{2 \epsilon_{1} \mathcal{V} k^{2}}\left|s_{\mathrm{p}}\left\langle\psi_{\mathrm{p}}\right| e^{\mathrm{i} \vec{k} \cdot \overrightarrow{\mathrm{p}}_{\mathrm{p}}}\right| \psi_{\mathrm{p}}\right\rangle+\left.s_{\mathrm{e}}\left\langle\psi_{\mathrm{e}}\right| e^{\mathrm{ik} \cdot \vec{r}_{\mathrm{e}}}\left|\psi_{\mathrm{e}}\right\rangle\right|^{2}
$$

The square absolute value of a quantity can be found as the product of that quantity times its complex conjugate. That gives the same energy lowering as for the lone spoton, and a similar term for a lone selecton. However, there is an additional term

$$
-\frac{s_{\mathrm{p}} s_{\mathrm{e}}}{2 \epsilon_{1} \mathcal{V} k^{2}}\left(\left\langle\psi_{\mathrm{p}}\right| e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}}\left|\psi_{\mathrm{p}}\right\rangle\left\langle\psi_{\mathrm{e}}\right| e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{e}}}\left|\psi_{\mathrm{e}}\right\rangle+\left\langle\psi_{\mathrm{e}}\right| e^{-\mathrm{i} \vec{k} \cdot \overrightarrow{r_{\mathrm{e}}}}\left|\psi_{\mathrm{e}}\right\rangle\left\langle\psi_{\mathrm{p}}\right| e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}}\left|\psi_{\mathrm{p}}\right\rangle\right)
$$

If you write out the inner product integrals over the selecton coordinates explicitly, this becomes

$$
-\int s_{\mathrm{e}} \psi_{\mathrm{e}}^{*}\left(\vec{r}_{\mathrm{e}}\right) \frac{s_{\mathrm{p}}}{2 \epsilon_{1} \mathcal{V} k^{2}}\left[\left\langle\psi_{\mathrm{p}}\right| e^{-\mathrm{i} \cdot \vec{k} \cdot \vec{r}_{\mathrm{p}}}\left|\psi_{\mathrm{p}}\right\rangle e^{\mathrm{i} \cdot \overrightarrow{r_{\mathrm{e}}}}+\left\langle\psi_{\mathrm{p}}\right| e^{\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{p}}}\left|\psi_{\mathrm{p}}\right\rangle e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{\mathrm{e}}}\right] \psi_{\mathrm{e}}\left(\vec{r}_{\mathrm{e}}\right) \mathrm{d}^{3} \vec{r}_{\mathrm{e}}
$$

Summed over all $\vec{k}$, the second term inside the square brackets gives the same answer as the first; that is because opposite $\vec{k}$ values appear equally in the summation. Looking at the first term, the summation over $\vec{k}$ produces again the spoton potential $\varphi_{\mathrm{cl}}^{\mathrm{p}}$, but now evaluated at the position of the selecton. That then shows the additional energy lowering to be

$$
-\int s_{\mathrm{e}} \psi_{\mathrm{e}}^{*}\left(\vec{r}_{\mathrm{e}}\right) \varphi_{\mathrm{cl}}^{\mathrm{p}}\left(\vec{r}_{\mathrm{e}}\right) \psi_{\mathrm{e}}\left(\vec{r}_{\mathrm{e}}\right) \mathrm{d}^{3} \vec{r}
$$

Except for the differences in notation, that is the same selecton-spoton interaction energy as found in $\{\mathrm{A} .22 .1\}$.

## D.37.3 Rewriting the Lagrangian

The rules of engagement are as follows:

- The Cartesian axes are numbered using an index $i$, with $i=1,2$, and 3 for $x, y$, and $z$ respectively.
- Also, $r_{i}$ indicates the coordinate in the $i$ direction, $x, y$, or $z$.
- Derivatives with respect to a coordinate $r_{i}$ are indicated by a simple subscript $i$.
- If the quantity being differentiated is a vector, a comma is used to separate the vector index from differentiation ones.
- Index $\bar{\imath}$ is the number immediately following $i$ in the cyclic sequence $\ldots 123123 \ldots$ and $\overline{\bar{\imath}}$ is the number immediately preceding $i$.
- If $i$ is already been used for something else, $j$ can be used the same way.
- Time derivatives are indicated by a subscript t .

Consider first the square magnetic field:

$$
\mathcal{B}^{2}=\sum_{i}\left(A_{\bar{i}, \bar{i}}-A_{\bar{i}, \overline{\bar{\imath}}}\right)^{2}
$$

Expanding out the square, that is equivalent to

$$
\mathcal{B}^{2}=\sum_{i}\left(A_{\overline{\bar{i}, \bar{\imath}}}^{2}+A_{\bar{\tau}, \overline{\bar{\imath}}}^{2}+A_{i, i}^{2}-A_{i, i} A_{i, i}-A_{\bar{i}, \overline{\bar{\imath}}} A_{\overline{\bar{\imath}}, \bar{i}}-A_{\overline{\bar{\imath}}, \bar{\imath}} A_{\bar{i}, \overline{\bar{\imath}}}\right)
$$

The summation indices can now be cyclically redefined to give an equivalent sum over $i$ equal to

$$
\mathcal{B}^{2}=\sum_{i}\left(A_{i, \bar{\imath}}^{2}+A_{i, \bar{\imath}}^{2}+A_{i, i}^{2}-A_{i, i} A_{i, i}-A_{i, \bar{\imath}} A_{\bar{\imath}, i}-A_{i, \bar{\imath}} A_{\overline{\bar{\imath}}, i}\right)
$$

The terms can be combined in sets of three as

$$
\mathcal{B}^{2}=A_{i, j}^{2}-A_{i, j} A_{j, i}
$$

Here summation over $i$ and $j$ is now understood.
The square electric field is

$$
\mathcal{E}^{2}=\left(-\varphi_{i}-A_{i, t}\right)^{2}=A_{i, t}^{2}+2 A_{i, t} \varphi_{i}+\varphi_{i}^{2}
$$

All together, that gives

$$
\begin{aligned}
\mathcal{E}^{2}-c^{2} \mathcal{B}^{2}= & A_{i, t}^{2}-c^{2} A_{i, j}^{2}-\frac{1}{c^{2}} \varphi_{t}^{2}+\varphi_{i}^{2} \\
& +\frac{1}{c^{2}}\left(\varphi_{t}+c^{2} A_{i, i}\right)\left(\varphi_{t}+c^{2} A_{j, j}\right) \\
& +2 A_{i, t} \varphi_{i}-2 A_{i, i} \varphi_{t}+c^{2} A_{i, j} A_{j, i}-c^{2} A_{i, i} A_{j, j}
\end{aligned}
$$

as can be verified by multiplying out and simplifying. The right hand side in the first line is the self-evident electromagnetic Lagrangian density, except for the factor $\epsilon_{0} / 2$. The second line is the square of the Lorentz condition quantity. The final line can be written as a sum of pure derivatives:

$$
2\left(A_{i} \varphi_{i}\right)_{t}-2\left(A_{i} \varphi_{t}\right)_{i}+c^{2}\left(A_{i} A_{j, i}\right)_{j}-c^{2}\left(A_{i} A_{j, j}\right)_{i}
$$

Pure derivatives do not produce changes in the action, as the changes in the potentials disappear on the boundaries of integration.

## D.37.4 Coulomb potential energy

The Coulomb potential energy between charged particles is typically derived in basic physics. But it can also easily be verified from the conventional electromagnetic energy (A.143). In the steady case, there is only the electric field, due to the Coulomb potential. The energy may then be written as
$\frac{\epsilon_{0}}{2} \int \mathcal{E}_{\mathrm{C}}^{2} \mathrm{~d}^{3} \vec{r}=\frac{\epsilon_{0}}{2} \int\left(\nabla \varphi_{\mathrm{C}}\right)^{2} \mathrm{~d}^{3} \vec{r}=-\frac{\epsilon_{0}}{2} \int \varphi_{\mathrm{C}} \nabla^{2} \varphi_{\mathrm{C}} \mathrm{d}^{3} \vec{r}=\frac{1}{2} \int \varphi_{\mathrm{C}}(\vec{r} ; t) \rho(\vec{r} ; t) \mathrm{d}^{3} \vec{r}$ where the first equality comes from the definition of the electric field, the second from integration by parts and the third one from the first Maxwell equation. Substitution of the Coulomb potential in terms of the charge distribution as given in $\{\mathrm{A} .22 .8\}$,

$$
\varphi_{\mathrm{C}}(\vec{r} ; t)=\int_{\text {all } \underline{\underline{r}}} \frac{\rho(\overrightarrow{\underline{r}} ; t)}{4 \pi \epsilon_{0}|\vec{r}-\underline{\vec{r}}|} \mathrm{d}^{3} \underline{\vec{r}}
$$

now gives the Koulomb potential energy $V_{\mathrm{C}}$ for a continuous charge distribution:

$$
V_{\mathrm{C}}=\frac{1}{2} \int_{\text {all } \vec{r}} \int_{\text {all }} \frac{\rho(\vec{r} ; t) \rho(\vec{r} ; t)}{4 \pi \epsilon_{0}|\vec{r}-\overrightarrow{\underline{r}}|} \mathrm{d}^{3} \vec{r} \mathrm{~d}^{3} \overrightarrow{\underline{r}}
$$

For point charges, the charge distribution is by definition

$$
\rho(\vec{r} ; t)=\sum_{i=1}^{I} q_{i} \delta^{3}\left(\vec{r}-\vec{r}_{i}\right)
$$

Here $\delta^{3}$ is the three-dimensional delta function, $\vec{r}_{i}=\vec{r}_{i}(t)$ the position of point charge $i$, and $q_{i}$ its charge.

Recall that the delta function picks out the value at $\vec{r}_{i}$ from whatever it is integrated against. Using this twice on the Coulomb potential energy above,

$$
V_{\mathrm{C}}=\frac{1}{2} \sum_{i=1}^{I} \int_{\text {all } \overrightarrow{\underline{r}}} \frac{q_{i} \rho(\overrightarrow{\vec{r}} ; t)}{4 \pi \epsilon_{0}\left|\vec{r}_{i}-\overrightarrow{\vec{r}}\right|} \mathrm{d}^{3} \overrightarrow{\vec{r}}=\frac{1}{2} \sum_{i=1}^{I} \sum_{\substack{i=1 \\ \underline{i} \neq i}}^{I} \frac{q_{i} q_{\underline{i}}}{4 \pi \epsilon_{0}\left|\vec{r}_{i}-\vec{r}_{\underline{r}}\right|}
$$

That is the Coulomb potential energy $V_{\mathrm{C}}$ for point charges.
Note again that physically all the energy is inside the electromagnetic field. There is no energy of interaction of the charged particles with the field. If equal charges move closer together, they increase the energy in the electromagnetic field. That requires work.

## D. 38 Time-dependent perturbation theory

The equations to be solved are

$$
\mathrm{i} \hbar \dot{c}_{1}=\left\langle E_{1}\right\rangle c_{1}+H_{12} c_{2} \quad \mathrm{i} \hbar \dot{c}_{2}=H_{21} c_{1}+\left\langle E_{2}\right\rangle c_{2}
$$

To simplify the use of perturbation theory, it is convenient to use a trick that gets rid of half the terms in these equations. The trick is to define new coefficients $\bar{c}_{1}$ and $\bar{c}_{2}$ by

$$
\begin{equation*}
\bar{c}_{1}=c_{1} e^{\mathrm{i} \int\left\langle E_{1}\right\rangle \mathrm{d} t / \hbar} \quad \bar{c}_{2}=c_{2} e^{\mathrm{i} \int\left\langle E_{2}\right\rangle \mathrm{d} t / \hbar} \tag{D.22}
\end{equation*}
$$

The new coefficients $\bar{c}_{1}$ and $\bar{c}_{2}$ are physically just as good as $c_{1}$ and $c_{2}$. For one, the probabilities are given by the square magnitudes of the coefficients, and the square magnitudes of $\bar{c}_{1}$ and $\bar{c}_{2}$ are exactly the same as those of $c_{1}$ and $c_{2}$. That is because the exponentials have magnitude one. Also, the initial conditions are unchanged, assuming that you choose the integration constants so that the integrals are initially zero.

The evolution equations for $\bar{c}_{1}$ and $\bar{c}_{2}$ are

$$
\begin{equation*}
\mathrm{i} \hbar \dot{\bar{c}}_{1}=H_{12} e^{-\mathrm{i} \int E_{21} \mathrm{~d} t / \hbar} \bar{c}_{2} \quad \mathrm{i} \hbar \dot{\bar{c}}_{2}=H_{21} e^{\mathrm{i} \int E_{21} \mathrm{~d} t / \hbar} \bar{c}_{1} \tag{D.23}
\end{equation*}
$$

with $E_{21}=\left\langle E_{2}\right\rangle-\left\langle E_{1}\right\rangle$. Effectively, the two energy expectation values have been turned into zero. However, the matrix element is now time-dependent, if
it was not already. To check the above evolution equations, just plug in the definition of the coefficients.

It will from now on be assumed that the original Hamiltonian coefficients are independent of time. That makes the difference in expectation energies $E_{21}$ constant too.

Now the formal way to perform time-dependent perturbation theory is to assume that the matrix element $H_{21}$ is small. Write $H_{21}$ as $\varepsilon H_{21}^{0}$ where $\varepsilon$ is a scale factor. Then you can find the behavior of the solution in the limiting process $\varepsilon \rightarrow 0$ by expanding the solution in powers of $\varepsilon$. The definition of the scale factor $\varepsilon$ is not important. You might identify it with a small physical parameter in the matrix element. But in fact you can take $H_{21}^{0}$ the same as $H_{21}$ and $\varepsilon$ as an additional mathematical parameter with no meaning for the physical problem. In that approach, $\varepsilon$ disappears when you take it to be 1 in the final answer.

But because the problem here is so trivial, there is really no need for a formal time-dependent perturbation expansion. In particular, by assumption the system stays close to state $\psi_{1}$, so the coefficient $\bar{c}_{2}$ must remain small. Then the evolution equations above show that $\bar{c}_{1}$ will hardly change. That allows it to be treated as a constant in the evolution equation for $\bar{c}_{2}$. That then allows $\bar{c}_{2}$ to be found by simple integration. The integration constant follows from the condition that $c_{2}$ is zero at the initial time. That then gives the result cited in the text.

It may be noted that for the analysis to be valid, $H_{21} t / \hbar$ must be small. That ensures that $\bar{c}_{2}$ is correspondingly small according to its evolution equation. And then the change in $\bar{c}_{1}$ from its original value is small of order $\left(H_{21} t / \hbar\right)^{2}$ according to its evolution equation. So the assumption that it is about constant in the equation for $\bar{c}_{2}$ is verified. The error will be of order $\left(H_{21} t / \hbar\right)^{3}$.

To be sure, this does not verify that this error in $\bar{c}_{2}$ decays to zero when $E_{21} t / 2 \hbar$ tends to infinity. But it does, as can be seen from the exact solution,

$$
\left|c_{2}\right|^{2}=\left(\frac{\left|H_{21}\right| t}{\hbar}\right)^{2} \frac{\sin ^{2}\left(\tilde{E}_{21} t / 2 \hbar\right)}{\left(\tilde{E}_{21} t / 2 \hbar\right)^{2}} \quad \tilde{E}_{21} \equiv \sqrt{E_{21}^{2}+\left|H_{21}\right|^{2}}
$$

By splitting it up into ranges $\left|E_{21}\right| t / \hbar$ no larger than $\left|H_{21}\right| t / \hbar$ and $\left|E_{21}\right| t / \hbar$ no larger than 1, you can see that the error is never larger than order $\left(H_{21} t / \hbar\right)^{2}$ for $\left|E_{21}\right| t / \hbar$ no larger than 1. And it is of order $\left(H_{21} t / \hbar\right)^{2} /\left(\left|E_{21}\right| t / \hbar\right)^{2}$ outside that range.

Finally, consider the case that the state cannot just transition to one state $\psi_{2}$ but to a large number $N$ of them, each with its own coefficient $\bar{c}_{2}$. In that case, the individual contributions of all these states add up to change $\bar{c}_{1}$. And $\bar{c}_{1}$ must definitely stay approximately constant for the above analysis to be valid. Fortunately, if you plug the approximate expressions for the $\bar{c}_{2}$ into the evolution equation for $\bar{c}_{1}$, you can see that $\bar{c}_{1}$ stays approximately constant as
long as the sum of all the transition probabilities does. So as long as there is little probability of any transition at time $t$, time-dependent perturbation theory should be OK.

## D. 39 Selection rules

This note derives the selection rules for electric dipole transitions between two hydrogen states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$. Some selection rules for forbidden transitions are also derived. The derivations for forbidden transitions use some more advanced results from later chapters. It may be noted that in any case, the Hamiltonian assumes that the velocity of the electrons is small compared to the speed of light.

According to chapter 4.3, the hydrogen states take the form $\psi_{\mathrm{L}}=\psi_{n_{\mathrm{L}} l_{\mathrm{L}} m_{\mathrm{L}}} \uparrow$
 numbers. The final $\downarrow$ represents the electron spin state, up or down.

As noted in the text, allowed electric dipole transitions must respond to at least one component of a constant ambient electric field. That means that they must have a nonzero value for at least one electrical dipole moment,

$$
\left\langle\psi_{\mathrm{L}}\right| r_{i}\left|\psi_{\mathrm{H}}\right\rangle \neq 0
$$

where $r_{i}$ can be one of $r_{1}=x, r_{2}=y$, or $r_{3}=z$ for the three different components of the electric field.

The trick in identifying when these inner products are zero is based on taking inner products with cleverly chosen commutators. Since the hydrogen states are eigenfunctions of $\widehat{L}_{z}$, the following commutator is useful

$$
\left\langle\psi_{\mathrm{L}}\right|\left[r_{i}, \widehat{L}_{z}\right]\left|\psi_{\mathrm{H}}\right\rangle=\left\langle\psi_{\mathrm{L}}\right| r_{i} \widehat{L}_{z}-\widehat{L}_{z} r_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

For the $r_{i} \widehat{L}_{z}$ term in the right hand side, the operator $\widehat{L}_{z}$ acts on $\psi_{\mathrm{H}}$ and produces a factor $m_{\mathrm{H}} \hbar$, while for the $\widehat{L}_{z} r_{i}$ term, $\widehat{L}_{z}$ can be taken to the other side of the inner product and then acts on $\psi_{\mathrm{L}}$, producing a factor $m_{\mathrm{L}} \hbar$. So:

$$
\begin{equation*}
\left\langle\psi_{\mathrm{L}}\right|\left[r_{i}, \widehat{L}_{z}\right]\left|\psi_{\mathrm{H}}\right\rangle=\left(m_{\mathrm{H}}-m_{\mathrm{L}}\right) \hbar\left\langle\psi_{\mathrm{L}}\right| r_{i}\left|\psi_{\mathrm{H}}\right\rangle \tag{D.24}
\end{equation*}
$$

The final inner product is the dipole moment of interest. Therefore, if a suitable expression for the commutator in the left hand side can be found, it will fix the dipole moment.

In particular, according to chapter 4.5.4 $\left[z, \widehat{L}_{z}\right]$ is zero. That means according to equation (D.24) above that the dipole moment $\left\langle\psi_{\mathrm{L}}\right| z\left|\psi_{\mathrm{H}}\right\rangle$ in the right hand side will have to be zero too, unless $m_{\mathrm{H}}=m_{\mathrm{L}}$. So the first conclusion is that the $z$-component of the electric field does not do anything unless $m_{\mathrm{H}}=m_{\mathrm{L}}$. One down, two to go.

For the $x$ and $y$ components, from chapter 4.5.4

$$
\left[x, \widehat{L}_{z}\right]=-\mathrm{i} \hbar y \quad\left[y, \widehat{L}_{z}\right]=\mathrm{i} \hbar x
$$

Plugging that into (D.24) produces

$$
-\mathrm{i} \hbar\left\langle\psi_{\mathrm{L}}\right| y\left|\psi_{\mathrm{H}}\right\rangle=\left(m_{\mathrm{H}}-m_{\mathrm{L}}\right) \hbar\left\langle\psi_{\mathrm{L}}\right| x\left|\psi_{\mathrm{H}}\right\rangle \quad \mathrm{i} \hbar\left\langle\psi_{\mathrm{L}}\right| x\left|\psi_{\mathrm{H}}\right\rangle=\left(m_{\mathrm{H}}-m_{\mathrm{L}}\right) \hbar\left\langle\psi_{\mathrm{L}}\right| y\left|\psi_{\mathrm{H}}\right\rangle
$$

From these equations it is seen that the $y$ dipole moment is zero if the $x$ one is, and vice-versa. Further, plugging the $y$ dipole moment from the first equation into the second produces

$$
\mathrm{i} \hbar\left\langle\psi_{\mathrm{L}}\right| x\left|\psi_{\mathrm{H}}\right\rangle=\frac{\left(m_{\mathrm{H}}-m_{\mathrm{L}}\right)^{2} \hbar^{2}}{-\mathrm{i} \hbar}\left\langle\psi_{\mathrm{L}}\right| x\left|\psi_{\mathrm{H}}\right\rangle
$$

and if the $x$ dipole moment is nonzero, that requires that $\left(m_{\mathrm{H}}-m_{\mathrm{L}}\right)^{2}$ is one, so $m_{\mathrm{H}}=m_{\mathrm{L}} \pm 1$. It follows that dipole transitions can only occur if $m_{\mathrm{H}}=m_{\mathrm{L}}$, through the $z$ component of the electric field, or if $m_{\mathrm{H}}=m_{\mathrm{L}} \pm 1$, through the $x$ and $y$ components.

To derive selection rules involving the azimuthal quantum numbers $l_{\mathrm{H}}$ and $l_{\mathrm{L}}$, the obvious approach would be to try the commutator $\left[r_{i}, \widehat{L}^{2}\right]$ since $\widehat{L}^{2}$ produces $l(l+1) \hbar^{2}$. However, according to chapter 4.5.4, (4.68), this commutator will bring in the $\widehat{\vec{r}} \times \widehat{\vec{L}}$ operator, which cannot be handled. The commutator that works is the second of (4.73):

$$
\left[\left[r_{i}, \widehat{L}^{2}\right], \widehat{L}^{2}\right]=2 \hbar^{2}\left(r_{i} \widehat{L}^{2}+\widehat{L}^{2} r_{i}\right)
$$

where by the definition of the commutator

$$
\left[\left[r_{i}, \widehat{L}^{2}\right], \widehat{L}^{2}\right]=\left(r_{i} \widehat{L}^{2}-\widehat{L}^{2} r_{i}\right) \widehat{L}^{2}-\widehat{L}^{2}\left(r_{i} \widehat{L}^{2}-\widehat{L}^{2} r_{i}\right)=r_{i} \widehat{L}^{2} \widehat{L}^{2}-2 \widehat{L}^{2} r_{i} \widehat{L}^{2}+\widehat{L}^{2} \widehat{L}^{2} r_{i}
$$

Evaluating $\left\langle\psi_{\mathrm{L}}\right|\left[\left[r_{i}, \widehat{L}^{2}\right], \widehat{L}^{2}\right]\left|\psi_{\mathrm{H}}\right\rangle$ according to each of the two equations above and equating the results gives

$$
2 \hbar^{2}\left[l_{\mathrm{H}}\left(l_{\mathrm{H}}+1\right)+l_{\mathrm{L}}\left(l_{\mathrm{L}}+1\right)\right]\left\langle\psi_{\mathrm{L}}\right| r_{i}\left|\psi_{\mathrm{H}}\right\rangle=\hbar^{2}\left[l_{\mathrm{H}}\left(l_{\mathrm{H}}+1\right)-l_{\mathrm{L}}\left(l_{\mathrm{L}}+1\right)\right]^{2}\left\langle\psi_{\mathrm{L}}\right| r_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

For $\left\langle\psi_{\mathrm{L}}\right| r_{i}\left|\psi_{\mathrm{H}}\right\rangle$ to be nonzero, the numerical factors in the left and right hand sides must be equal,

$$
2\left[l_{\mathrm{H}}\left(l_{\mathrm{H}}+1\right)+l_{\mathrm{L}}\left(l_{\mathrm{L}}+1\right)\right]=\left[l_{\mathrm{H}}\left(l_{\mathrm{H}}+1\right)-l_{\mathrm{L}}\left(l_{\mathrm{L}}+1\right)\right]^{2}
$$

The right hand side is obviously zero for $l_{\mathrm{H}}=l_{\mathrm{L}}$, so $l_{\mathrm{H}}-l_{\mathrm{L}}$ can be factored out of it as

$$
\left[l_{\mathrm{H}}\left(l_{\mathrm{H}}+1\right)-l_{\mathrm{L}}\left(l_{\mathrm{L}}+1\right)\right]^{2}=\left(l_{\mathrm{H}}-l_{\mathrm{L}}\right)^{2}\left(l_{\mathrm{H}}+l_{\mathrm{L}}+1\right)^{2}
$$

and the left hand side can be written in terms of these same factors as

$$
2\left[l_{\mathrm{H}}\left(l_{\mathrm{H}}+1\right)+l_{\mathrm{L}}\left(l_{\mathrm{L}}+1\right)\right]=\left(l_{\mathrm{H}}-l_{\mathrm{L}}\right)^{2}+\left(l_{\mathrm{H}}+l_{\mathrm{L}}+1\right)^{2}-1
$$

Equating the two results and simplifying gives

$$
\left[\left(l_{\mathrm{H}}-l_{\mathrm{L}}\right)^{2}-1\right]\left[\left(l_{\mathrm{H}}+l_{\mathrm{L}}+1\right)^{2}-1\right]=0
$$

The second factor is only zero if $l_{\mathrm{H}}=l_{\mathrm{L}}=0$, but then $\left\langle\psi_{\mathrm{L}}\right| r_{i}\left|\psi_{\mathrm{H}}\right\rangle$ is still zero because both states are spherically symmetric. It follows that the first factor will have to be zero for dipole transitions to be possible, and that means that $l_{\mathrm{H}}=l_{\mathrm{L}} \pm 1$.

The spin is not affected by the perturbation Hamiltonian, so the dipole moment inner products are still zero unless the spin magnetic quantum numbers $m_{s}$ are the same, both spin-up or both spin-down. Indeed, if the electron spin is not affected by the electric field to the approximations made, then obviously it cannot change. That completes the selection rules as given in chapter 7.4.4 for electric dipole transitions.

Now consider the effect of the magnetic field on transitions. For such transitions to be possible, the matrix element formed with the magnetic field must be nonzero. Like the electric field, the magnetic field can be approximated as spatially constant and quasi-steady. The perturbation Hamiltonian of a constant magnetic field is according to chapter 13.4

$$
H_{1}=\frac{e}{2 m_{\mathrm{e}}} \overrightarrow{\mathcal{B}} \cdot(\widehat{\hat{L}}+2 \hat{\widehat{S}})
$$

Note that now electron spin must be included in the discussion.
According to this perturbation Hamiltonian, the perturbation coefficient $H_{\mathrm{HL}}$ for the $z$-component of the magnetic field is proportional to

$$
\left\langle\psi_{\mathrm{L}}\right| \widehat{L}_{z}+2 \widehat{S}_{z}\left|\psi_{\mathrm{H}}\right\rangle
$$

and that is zero because $\psi_{\mathrm{H}} \hat{\downarrow}$ is an eigenfunction of both operators and orthogonal to $\psi_{\mathrm{L}} \uparrow$. So the $z$-component of the magnetic field does not produce transitions to different states.

However, the $x$-component (and similarly the $y$-component) produces a perturbation coefficient proportional to

$$
\left\langle\psi_{\mathrm{L}}\right| \widehat{L}_{x}\left|\psi_{\mathrm{H}}\right\rangle+2\left\langle\psi_{\mathrm{L}}\right| \widehat{S}_{x}\left|\psi_{\mathrm{H}}\right\rangle
$$

According to chapter 12.11, the effect of $\widehat{L}_{x}$ on a state with magnetic quantum number $m_{\mathrm{H}}$ is to turn it into a linear combination of two similar states with magnetic quantum numbers $m_{\mathrm{H}}+1$ and $m_{\mathrm{H}}-1$. Therefore, for the first inner product above to be nonzero, $m_{\mathrm{L}}$ will have to be either $m_{\mathrm{H}}+1$ or $m_{\mathrm{H}}-1$. Also the orbital azimuthal momentum numbers $l$ will need to be the same, and so will the spin magnetic quantum numbers $m_{s}$. And the principal quantum numbers $n$, for that matter; otherwise the radial parts of the wave fuctions are orthogonal.

The magnetic field simply wants to rotate the orbital angular momentum vector in the hydrogen atom. That does not change the energy, in the absence of an average ambient magnetic field. For the second inner product, the spin magnetic quantum numbers have to be different by one unit, while the orbital magnetic quantum numbers must now be equal. So, all together

$$
l_{\mathrm{H}}=l_{\mathrm{L}} \quad m_{\mathrm{H}}=m_{\mathrm{L}} \text { or } m_{\mathrm{L}} \pm 1 \quad m_{s, \mathrm{H}}=m_{s, \mathrm{~L}} \text { or } m_{s, \mathrm{~L}} \pm 1
$$

and either the orbital or the spin magnetic quantum numbers must be unequal. That are the selection rules as given in chapter 7.4.4 for magnetic dipole transitions. Since the energy does not change in these transitions, Fermi's golden rule would have the decay rate zero. Fermi's analysis is not exact, but such transitions should be very rare.

The logical way to proceed to electric quadrupole transitions would be to expand the electric field in a Taylor series in terms of $y$ :

$$
\overrightarrow{\mathcal{E}}=\hat{k} \mathcal{E}_{\mathrm{f}} \cos (\omega(t-y / c)-\alpha) \approx \hat{k} \mathcal{E}_{\mathrm{f}} \cos (\omega t-\alpha)+\hat{k} \frac{\omega}{c} \mathcal{E}_{\mathrm{f}} \sin (\omega t-\alpha) y
$$

The first term is the constant electric field of the electric dipole approximation, and the second would then give the electric quadrupole approximation. However, an electric field in which $\mathcal{E}_{z}$ is a multiple of $y$ is not conservative, so the electrostatic potential does no longer exist.

It is necessary to retreat to the so-called vector potential $\vec{A}$. It is then simplest to chose this potential to get rid of the electrostatic potential altogether. In that case the typical electromagnetic wave is described by the vector potential

$$
\vec{A}=-\hat{k} \frac{1}{\omega} \mathcal{E}_{\mathrm{f}} \sin (\omega(t-y / c)-\alpha) \quad \overrightarrow{\mathcal{E}}=-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A}
$$

In terms of the vector potential, the perturbation Hamiltonian is, chapter 13.1 and 13.4, and assuming a weak field,

$$
H_{1}=\frac{e}{2 m_{\mathrm{e}}}(\vec{A} \cdot \widehat{\vec{p}}+\widehat{\vec{p}} \vec{A})+\frac{e}{m_{\mathrm{e}}} \widehat{\vec{S}} \cdot \overrightarrow{\mathcal{B}}
$$

Ignoring the spatial variation of $\vec{A}$, this expression produces an Hamiltonian coefficient

$$
H_{\mathrm{HL}}=-\frac{e}{m_{\mathrm{e}} \omega} \mathcal{E}_{\mathrm{f}} \sin (\omega t-\alpha)\left\langle\psi_{\mathrm{L}}\right| \widehat{p}_{z}\left|\psi_{\mathrm{H}}\right\rangle
$$

That should be same as for the electric dipole approximation, since the field is now completely described by $\vec{A}$, but it is not quite. The earlier derivation assumed that the electric field is quasi-steady. However, $\widehat{p}_{z}$ is equal to the commutator $\mathrm{i}_{\mathrm{e}}\left[H_{0}, z\right] / \hbar$ where $H_{0}$ is the unperturbed hydrogen atom Hamiltonian. If that is plugged in and expanded, it is found that the expressions are equivalent, provided that the perturbation frequency is close to the frequency of the
photon released in the transition, and that that frequency is sufficiently rapid that the phase shift from sine to cosine can be ignored. Those are in fact the normal conditions.

Now consider the second term in the Taylor series of $\vec{A}$ with respect to $y$. It produces a perturbation Hamiltonian

$$
\frac{e}{m_{\mathrm{e}}} \frac{1}{c} \mathcal{E}_{\mathrm{f}} \cos (\omega t-\alpha) y \widehat{y}_{z}
$$

The factor $y \widehat{p}_{z}$ can be trivially rewritten to give

$$
\frac{e}{2 m_{\mathrm{e}}} \frac{1}{c} \mathcal{E}_{\mathrm{f}} \cos (\omega t-\alpha)\left(y \widehat{p}_{z}-z \widehat{p}_{y}\right)+\frac{e}{2 m_{\mathrm{e}}} \frac{1}{c} \mathcal{E}_{\mathrm{f}} \cos (\omega t-\alpha)\left(y \widehat{p}_{z}+z \widehat{p}_{y}\right)
$$

The first term has already been accounted for in the magnetic dipole transitions discussed above, because the factor within parentheses is $\widehat{L}_{x}$. The second term is the electric quadrupole Hamiltonian for the considered wave.

As second terms in the Taylor series, both Hamiltonians will be much smaller than the electric dipole one. The factor that they are smaller can be estimated from comparing the first and second term in the Taylor series. Note that $c / \omega$ is proportional to the wave length $\lambda$ of the electromagnetic wave. Also, the additional position coordinate in the operator scales with the atom size, call it $R$. So the factor that the magnetic dipole and electric quadrupole matrix elements are smaller than the electric dipole one is $R / \lambda$. Since transition probabilities are proportional to the square of the corresponding matrix element, it follows that, all else being the same, magnetic dipole and electric quadrupole transitions are slower than electric dipole ones by a factor $(R / \lambda)^{2}$. (But note the earlier remark on the problem for the hydrogen atom that the energy does not change in magnetic dipole transitions.)

The selection rules for the electric quadrupole Hamiltonian can be narrowed down with a bit of simple reasoning. First, since the hydrogen eigenfunctions are complete, applying any operator on an eigenfunction will always produce a linear combination of eigenfunctions. Now reconsider the derivation of the electric dipole selection rules above from that point of view. It is then seen that $z$ only produces eigenfunctions with the same values of $m$ and the values of $l$ exactly one unit different. The operators $x$ and $y$ change both $m$ and $l$ by exactly one unit. And the components of linear momentum do the same as the corresponding components of position, since $\widehat{p}_{i}=\mathrm{i} m_{\mathrm{e}}\left[H_{0}, r_{i}\right] / \hbar$ and $H_{0}$ does not change the eigenfunctions, just their coefficients. Therefore $y \widehat{p}_{z}+z \widehat{p}_{y}$ produces only eigenfunctions with azimuthal quantum number $l$ either equal to $l_{\mathrm{H}}$ or to $l_{\mathrm{H}} \pm 2$, depending on whether the two unit changes reinforce or cancel each other. Furthermore, it produces only eigenfunctions with $m$ equal to $m_{\mathrm{H}} \pm 1$. However, $x \widehat{p}_{y}+y \widehat{p}_{x}$, corresponding to a wave along another axis, will produce values of $m$ equal to $m_{\mathrm{H}}$ or to $m_{\mathrm{H}} \pm 2$. Therefore the selection rules become:

$$
l_{\mathrm{H}}=l_{\mathrm{L}} \text { or } l_{\mathrm{L}} \pm 2 \quad m_{\mathrm{H}}=m_{\mathrm{L}} \text { or } m_{\mathrm{L}} \pm 1 \text { or } m_{\mathrm{L}} \pm 2 \quad m_{s, \mathrm{H}}=m_{s, \mathrm{~L}}
$$

That are the selection rules as given in chapter 7.4.4 for electric quadrupole transitions. These arguments apply equally well to the magnetic dipole transition, but there the possibilities are narrowed down much further because the angular momentum operators only produce a couple of eigenfunctions. It may be noted that in addition, electric quadrupole transitions from $l_{\mathrm{H}}=0$ to $l_{\mathrm{L}}=0$ are not possible because of spherical symmetry.

## D. 40 Quantization of radiation derivations

This gives various derivations for the addendum of the same name.
It is to be shown first that

$$
\begin{equation*}
\int_{\text {all }} c^{2}\left(\overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}\right)^{2} \mathrm{~d}^{3} \vec{r}=-\int_{\text {all }}\left(\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right)^{2} \mathrm{~d}^{3} \vec{r} \tag{1}
\end{equation*}
$$

To see that, note from (A.157) that

$$
c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}=\frac{1}{\mathrm{i} k} \nabla \times \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}
$$

so the left-hand integral becomes

$$
\int_{\text {all }} c^{2}\left(\overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}\right)^{2} \mathrm{~d}^{3} \vec{r}=-\frac{1}{k^{2}} \int_{\text {all }}\left(\nabla \times \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right) \cdot\left(\nabla \times \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}\right) \mathrm{d}^{3} \vec{r}
$$

Now the curl, $\nabla \times$, is Hermitian, $\{D .10\}$, so the second curl can be pushed in front of the first curl. Then curl curl acts as $-\nabla^{2}$ because $\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}$ is solenoidal and the standard vector identity (D.1). And the eigenvalue problem turns $-\nabla^{2}$ into $k^{2}$.

Note incidentally that the additional surface integral in $\{$ D. 10$\}$ is zero even for the photon modes of definite angular momentum, $\{\mathrm{A} .21 .7\}$, because for them either $\overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}$ is zero on the surface or $\nabla \times \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}$ is. Also note that the integrals become equal instead of opposite if you push complex conjugates on the first factors in the integrands.

Now the Hamiltonian can be worked out. Using Using (A.152) and (A.162), it is

$$
H=\frac{1}{4} \epsilon_{0} \int_{\text {all }}\left[\left(\widehat{a} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n}}+\widehat{a} \overrightarrow{\mathcal{E}}_{\gamma}^{\mathrm{n} *}\right)^{2}+\left(\widehat{a} c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n}}+\widehat{a}^{\dagger} c \overrightarrow{\mathcal{B}}_{\gamma}^{\mathrm{n} *}\right)^{2}\right] \mathrm{d}^{3} \vec{r}
$$

When that is multiplied out and integrated, the $(\widehat{a})^{2}$ and $\left(\widehat{a}^{\dagger}\right)^{2}$ terms drop out because of (1). The remaining multiplied-out terms in the Hamiltonian produce the stated Hamiltonian after noting the wave function normalization (A.158).

The final issue is to identify the relationships between the coefficients $D_{0}$, $D_{1}$ and $C$ as given in the text. The most important question is here under what circumstances $2\left|D_{1}\right|$ and $4|C|^{2}$ can get very close to the larger value $2 D_{0}$.

The coefficient $D_{1}$ was defined as

$$
2 D_{1}=\sum_{i} c_{i-1}^{*} c_{i+1} \sqrt{i} \sqrt{i+1}
$$

To estimate this, consider the infinite-dimensional vectors $\vec{a}$ and $\vec{b}$ with coefficients

$$
a_{i} \equiv c_{i-1} \sqrt{i} \quad b_{i} \equiv c_{i+1} \sqrt{i+1}
$$

Note that $2 D_{1}$ above is the inner product of these two vectors. And an inner product is less in magnitude than the product of the lengths of the vectors involved.

$$
\left|2 D_{1}\right|=|\langle\vec{a} \mid \vec{b}\rangle| \leqslant|\vec{a}||\vec{b}|=\sqrt{\left[\sum_{i}\left|c_{i-1}\right|^{2} i\right]\left[\sum_{i}\left|c_{i+1}\right|^{2}(i+1)\right]}
$$

By changing the notations for the summation indices, (letting $i-1 \rightarrow i$ and $i+1 \rightarrow i$ ), the sums become the expectation values of $i+1$, respectively $i$. So

$$
\left|2 D_{1}\right| \leqslant \sqrt{(\langle i\rangle+1)(\langle i\rangle)}=\sqrt{\langle i\rangle^{2}+\langle i\rangle}<\sqrt{\langle i\rangle^{2}+\langle i\rangle+\frac{1}{4}}=\sqrt{\left(\langle i\rangle+\frac{1}{2}\right)^{2}}=2 D_{0}
$$

The final equality is by the definition of $D_{0}$. The second inequality already implies that $\left|D_{1}\right|$ is always smaller than $D_{0}$. However, if the expectation value of $i$ is large, it does not make much of a difference.

In that case, the bigger problem is the inner product between the vectors $\vec{a}$ and $\vec{b}$. Normally it is smaller than the product of the lengths of the vectors. For it to become equal, the two vectors have to be proportional. The coefficients of $\vec{b}$ must be some multiple, call it $B^{2} e^{2 i \beta}$, of those of $\vec{a}$ :

$$
c_{i+1} \sqrt{i+1} \approx B^{2} e^{2 \mathrm{i} \beta} c_{i-1} \sqrt{i}
$$

For larger values of $i$ the square roots are about the same. Then the above relationship requires an exponential decay of the coefficients. For small values of $i$, obviously the above relation cannot be satisfied. The needed values of $c_{i}$ for negative $i$ do not exist. To reduce the effect of this "start-up" problem, significant coefficients will have to exist for a considerable range of $i$ values.

In addition to the above conditions, the coefficient $4|C|^{2}$ has to be close to $2 D_{0}$. Here the coefficient $C$ was defined as

$$
\sqrt{2} C=\sum_{i} c_{i-1}^{*} c_{i} \sqrt{i}
$$

Using the same manipulations as for $D_{1}$, but with

$$
a_{i} \equiv c_{i-1} \sqrt{\sqrt{i}} \quad b_{i} \equiv c_{i+1} \sqrt{\sqrt{i}}
$$

gives

$$
2|C|^{2} \leqslant\left[\sum_{i}\left|c_{i-1}\right|^{2} \sqrt{i}\right]\left[\sum_{i}\left|c_{i}\right|^{2} \sqrt{i}\right]=\langle\sqrt{i+1}\rangle\langle\sqrt{i}\rangle
$$

To bound this further, define

$$
f(x)=\left\langle\sqrt{i+\frac{1}{2}+x}\right\rangle
$$

By expanding the square root in a Taylor series,

$$
f\left(-\frac{1}{2}\right)<f(0)-\Delta f \quad f\left(\frac{1}{2}\right)<f(0)+\Delta f
$$

where $\Delta f$ is the expectation value of the linear term in the Taylor series; the inequalities express that a square root function has a negative second order derivative. Multiplying these two expressions shows that

$$
f\left(-\frac{1}{2}\right) f\left(\frac{1}{2}\right)<f^{2}(0) \quad \Longrightarrow \quad\langle\sqrt{i+1}\rangle\langle\sqrt{i}\rangle<\left\langle\sqrt{i+\frac{1}{2}}\right\rangle^{2}
$$

Since it has already been shown that the expectation value of $i$ must be large, this inequality will be almost an equality, anyway.

In any case,

$$
2|C|^{2}<\left\langle\sqrt{i+\frac{1}{2}}\right\rangle^{2}
$$

This is less than

$$
\left\langle\sqrt{i+\frac{1}{2}}^{2}\right\rangle=2 D_{0}
$$

The big question is now how much it is smaller. To answer that, use the shorthand

$$
\sqrt{i+\frac{1}{2}} \equiv x_{i}=x+x_{i}^{\prime}
$$

where $x$ is the expectation value of the square root and $x_{i}^{\prime}$ is the deviation from the average. Then, noting that the expectation value of $x_{i}^{\prime}$ is zero,

$$
2 D_{0}=\left\langle\left(x+x_{i}^{\prime}\right)^{2}\right\rangle=\langle x\rangle^{2}+\left\langle\left(x_{i}^{\prime}\right)^{2}\right\rangle
$$

The second-last term is the bound for $2|C|^{2}$ as obtained above. So, the only way that $2|C|^{2}$ can be close to $2 D_{0}$ is if the final term is relatively small. That means that the deviation from the expectation square root must be relatively small. So the coefficients $c_{i}$ can only be significant in some limited range around an average value of $i$. In addition, for the vectors $\vec{a}$ and $\vec{b}$ in the earlier estimate for $C$ to be almost proportional,

$$
c_{i-1} \sqrt{\sqrt{i}} \approx A e^{\mathrm{i} \alpha} c_{i} \sqrt{\sqrt{i}}
$$

where $A e^{\mathrm{i} \alpha}$ is some constant. That again means an exponential dependence, like for the condition on $D_{1}$. And $A e^{\mathrm{i} \alpha}$ will have to be approximately $B e^{\mathrm{i} \beta}$. And $A$ will have to be about 1, because otherwise start and end effects will dominate the exponential part. That gives the situation as described in the text.

## D. 41 Derivation of the Einstein B coefficients

The purpose of this note is to derive the Einstein $B$ coefficients of chapter 7.8. They determine the transition rates between the energy states of atoms. For simplicity it will be assumed that there are just two atomic energy eigenstates involved, a lower energy one $\psi_{\mathrm{L}}$ and an higher energy one $\psi_{\mathrm{H}}$. It is further assumed that the atoms are subject to incoherent ambient electromagnetic radiation. The energy in the ambient radiation is $\rho(\omega)$ per unit volume and unit frequency range. Finally it is assumed that the atoms suffer frequent collisions with other atoms. The typical time between collisions will be indicated by $t_{\mathrm{c}}$. It is small compared to the typical decay time of the states, but large compared to the frequency of the relevant electromagnetic field.

Unlike what you may find elsewhere, it will not be assumed that the atoms are either fully in the high or fully in the low energy state. That is a highly unsatisfactory assumption for many reasons. For one thing it assumes that the atoms know what you have selected as $z$-axis. In the derivation below, the atoms are allowed to be in a linear combination of the states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$, with coefficients $c_{\mathrm{L}}$ and $c_{\mathrm{H}}$.

Since both the electromagnetic field and the collisions are random, a statistical rather than a determinate treatment is needed. In it, the probability that a randomly chosen atom can be found in the lower energy state $\psi_{\mathrm{L}}$ will be indicated by $P_{\mathrm{L}}$. Similarly, the probability that an atom can be found in the higher energy state $\psi_{\mathrm{H}}$ will be indicated by $P_{\mathrm{H}}$. For a single atom, these probabilities are given by the square magnitudes of the coefficients $c_{\mathrm{L}}$ and $c_{\mathrm{H}}$ of the energy states. Therefore, $P_{\mathrm{L}}$ and $P_{\mathrm{H}}$ will be defined as the averages of $\left|c_{\mathrm{L}}\right|^{2}$ respectively $\left|c_{\mathrm{H}}\right|^{2}$ over all atoms.

It is assumed that the collisions are globally elastic in the sense that they do not change the average energy picture of the atoms. In other words, they do not affect the average probabilities of the eigenfunctions $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$. However, they are assumed to leave the wave function of an individual atom immediately after a collision in some state $c_{\mathrm{L}, 0} \psi_{\mathrm{L}}+c_{\mathrm{H}, 0} \psi_{\mathrm{H}}$ in which $c_{\mathrm{L}, 0}$ and $c_{\mathrm{H}, 0}$ are quite random, especially with respect to their phase. What is now to be determined in this note is how, until the next collision, the wave function of the atom will develop under the influence of the electromagnetic field and how that changes the average probabilities $\left|c_{\mathrm{L}}\right|^{2}$ and $\left|c_{\mathrm{H}}\right|^{2}$.

The evolution equations of the coefficients $\bar{c}_{\mathrm{L}}$ and $\bar{c}_{\mathrm{H}}$, in between collisions, were given in chapter 7.7.2 (7.42). They are in terms of modified variables $\bar{c}_{\mathrm{L}}$ and $\bar{c}_{\mathrm{H}}$. However, these variables have the same square magnitudes and initial conditions as $c_{\mathrm{L}}$ and $c_{\mathrm{H}}$. So it really does not make a difference.

Further, because the equations are linear, the solution for the coefficients $\bar{c}_{\mathrm{L}}$ and $\bar{c}_{\mathrm{H}}$ can be written as a sum of two contributions, one proportional to the initial value $\bar{c}_{\mathrm{L}, 0}$ and the other to $\bar{c}_{\mathrm{H}, 0}$ :

$$
\bar{c}_{\mathrm{L}}=\bar{c}_{\mathrm{L}, 0} \bar{c}_{\mathrm{L}}^{\mathrm{L}}+\bar{c}_{\mathrm{H}, 0} \bar{c}_{\mathrm{L}}^{\mathrm{H}} \quad \bar{c}_{\mathrm{H}}=\bar{c}_{\mathrm{L}, 0} \bar{c}_{\mathrm{H}}^{\mathrm{L}}+\bar{c}_{\mathrm{H}, 0} \bar{c}_{\mathrm{H}}^{\mathrm{H}}
$$

Here $\left(\bar{c}_{\mathrm{L}}^{\mathrm{L}}, \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right)$ is the solution that starts out from the lower energy state ( $\bar{c}_{\mathrm{L}}^{\mathrm{L}}, \bar{c}_{\mathrm{H}}^{\mathrm{L}}$ ) $=(1,0)$ while $\left(\bar{c}_{\mathrm{L}}^{\mathrm{H}}, \bar{c}_{\mathrm{H}}^{\mathrm{H}}\right)$ is the solution that starts out from the higher energy state $\left(\bar{c}_{\mathrm{L}}^{\mathrm{H}}, \bar{c}_{\mathrm{H}}^{\mathrm{H}}\right)=(0,1)$.

Now consider what happens to the probability of an atom to be in the excited state in the time interval between collisions:
$\left|\bar{c}_{\mathrm{H}}\right|^{2}-\left|\bar{c}_{\mathrm{H}, 0}\right|^{2}=\left(\bar{c}_{\mathrm{H}, 0}+\bar{c}_{\mathrm{L}, 0} \Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}+\bar{c}_{\mathrm{H}, 0} \Delta \bar{c}_{\mathrm{H}}^{\mathrm{H}}\right)^{*}\left(\bar{c}_{\mathrm{H}, 0}+\bar{c}_{\mathrm{L}, 0} \Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}+\bar{c}_{\mathrm{H}, 0} \Delta \bar{c}_{\mathrm{H}}^{\mathrm{H}}\right)-\bar{c}_{\mathrm{H}, 0}^{*} \bar{c}_{\mathrm{H}, 0}$
Here $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}$ indicates the change in $\bar{c}_{\mathrm{H}}^{\mathrm{L}}$ in the time interval between collisions; in particular $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}=\bar{c}_{\mathrm{H}}^{\mathrm{L}}$ since this solution starts from the ground state with $\bar{c}_{\mathrm{H}}^{\mathrm{L}}=$ 0 . Similarly, the change $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{H}}$ equals $\bar{c}_{\mathrm{H}}^{\mathrm{H}}-1$ since this solution starts out from the excited state with $\bar{c}_{\mathrm{H}}^{\mathrm{H}}=1$.

Because the typical time between collisions $t_{\mathrm{c}}$ is assumed small, so will be the changes $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}$ and $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{H}}$ as given by the evolution equations (7.42). Note also that $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{H}}$ will be quadratically small, since the corresponding solution starts out from $\bar{c}_{\mathrm{L}}^{\mathrm{H}}=0$, so $\bar{c}_{\mathrm{L}}^{\mathrm{H}}$ is an additional small factor in the equation (7.42) for $\bar{c}_{\mathrm{H}}^{\mathrm{H}}$.

Therefore, if the change in probability $\left|\bar{c}_{\mathrm{H}}\right|^{2}$ above is multiplied out, ignoring terms that are cubically small or less, the result is, (remember that for a complex number $c, c+c^{*}$ is twice its real part):

$$
\left|\bar{c}_{\mathrm{H}}\right|^{2}-\left|\bar{c}_{\mathrm{H}, 0}\right|^{2}=2 \Re\left(\bar{c}_{\mathrm{H}, 0}^{*} \bar{c}_{\mathrm{L}, 0} \Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right)+\left|\bar{c}_{\mathrm{L}, 0}\right|^{2}\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}+\left|\bar{c}_{\mathrm{H}, 0}\right|^{2} 2 \Re\left(\Delta \bar{c}_{\mathrm{H}}^{\mathrm{H}}\right)
$$

Now if this is averaged over all atoms and time intervals between collisions, the first term in the right hand side will average away. The reason is that it has a random phase angle, for one since those of $\bar{c}_{\mathrm{L}, 0}$ and $\bar{c}_{\mathrm{H}, 0}$ are assumed to be random after a collision. For a number with a random phase angle, the real part is just as likely to be positive as negative, so it averages away. Also, for the final term, $2 \Re\left(\Delta \bar{c}_{\mathrm{H}}^{\mathrm{H}}\right)$ is the approximate change in $\left|\bar{c}_{\mathrm{H}}^{\mathrm{H}}\right|^{2}$ in the time interval, and that equals $-\left|\Delta \bar{c}_{\mathrm{L}}^{\mathrm{H}}\right|^{2}$ because of the normalization condition $\left|\bar{c}_{\mathrm{L}}^{\mathrm{H}}\right|^{2}+\left|\bar{c}_{\mathrm{H}}^{\mathrm{H}}\right|^{2}=$ 1. So the relevant expression for the average change in probability becomes

$$
\left|\bar{c}_{\mathrm{H}}\right|^{2}-\left|\bar{c}_{\mathrm{H}, 0}\right|^{2}=\left|\bar{c}_{\mathrm{L}, 0}\right|^{2}\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}-\left|\bar{c}_{\mathrm{H}, 0}\right|^{2}\left|\Delta \bar{c}_{\mathrm{L}}^{\mathrm{H}}\right|^{2}
$$

Summing the changes in the probabilities therefore means summing the changes in the square magnitudes of $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}$ and $\Delta \bar{c}_{\mathrm{L}}^{\mathrm{H}}$.

If the above expression for the average change in the probability of the high energy state is compared to (7.46), it is seen that the Einstein coefficient $B_{\mathrm{L} \rightarrow \mathrm{H}}$ is the average change $\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}$ per unit time. This is admittedly the same answer you would get if you assumed that the atoms are either in the low energy state or in the high energy state immediately after each collision. But as noted, that assumption is simply not reasonable.

Now the needed $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}=\bar{c}_{\mathrm{H}}^{\mathrm{L}}$ may be found from the second evolution equation (7.42). To do so, you can consider $\bar{c}_{\mathrm{L}}^{\mathrm{L}}$ to be 1 . The reason is that it starts out as 1 , and it never changes much because of the assumed short evolution time $t_{c}$
compared to the typical transition time between states. That allows $\bar{c}_{\mathrm{H}}^{\mathrm{L}}$ to be found from a simple integration. And the second term in the modified Hamiltonian coefficient (7.44) can be ignored because of the additional assumption that $t_{\mathrm{c}}$ is still large compared to the frequency of the electromagnetic wave. That causes the exponential in the second term to oscillate rapidly and it does not integrate to a sizable contribution.

What is left is

$$
\begin{equation*}
\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}=\frac{\mathcal{E}_{\mathrm{f}}}{\hbar}\left\langle\psi_{\mathrm{L}}\right| e z\left|\psi_{\mathrm{H}}\right\rangle e^{\mathrm{i} \alpha} \frac{e^{-\mathrm{i}\left(\omega-\omega_{0}\right) t}-1}{2\left(\omega-\omega_{0}\right)} \tag{D.25}
\end{equation*}
$$

and $\Delta \bar{c}_{\mathrm{L}}^{\mathrm{H}}$ is given by a virtually identical expression. However, since it is assumed that the atoms are subject to incoherent radiation of all wave numbers $\vec{k}$ and polarizations $p$, the complete $\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}$ will consist of the sum of all their contributions:

$$
\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}=\sum_{\vec{k}, p} \Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}(\vec{k}, p)
$$

(This really assumes that the particles are in a very large periodic box so that the electromagnetic field is given by a Fourier series; in free space you would need to integrate over the wave numbers instead of sum over them.) The square magnitude is then

$$
\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}=\sum_{\vec{k}, p} \sum_{\overrightarrow{\vec{k}}, \underline{p}} \Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}, *}(\vec{k}, p) \Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}(\underline{\vec{k}}, \underline{p})=\sum_{\vec{k}, p}\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}(\vec{k}, p)\right|^{2}
$$

where the final equality comes from the assumption that the radiation is incoherent, so that the phases of different waves are uncorrelated and the corresponding products average to zero.

The bottom line is that square magnitudes must be summed together to find the total contribution of all waves. And the square magnitude of the contribution of a single wave is, according to (D.25) above,

$$
\left.\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}(\vec{k}, p)\right|^{2}=\left|\frac{\mathcal{E}_{\mathrm{f}}}{2 \hbar}\left\langle\psi_{\mathrm{L}}\right| e z\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2} t^{2}\left(\frac{\sin \left(\frac{1}{2}\left(\omega-\omega_{0}\right) t\right)}{\frac{1}{2}\left(\omega-\omega_{0}\right) t}\right)^{2}
$$

Now broadband radiation is described in terms of an electromagnetic energy density $\rho(\omega)$; in particular $\rho(\omega) \mathrm{d} \omega$ gives the energy per unit volume due to the electromagnetic waves in an infinitesimal frequency range $\mathrm{d} \omega$ around a frequency $\omega$. For a single wave, this energy equals $\frac{1}{2} \epsilon_{0} \mathcal{E}_{f}^{2}$, chapter 13.2 (13.11). And the square amplitudes of different waves simply add up to the total energy; that is the so-called Parseval equality of Fourier analysis. So to sum the expression above over all the frequencies $\omega$ of the broadband radiation, make the substitution $\mathcal{E}_{\mathrm{f}}^{2}=2 \rho(\omega) \mathrm{d} \omega / \epsilon_{0}$ and integrate:

$$
\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}=\frac{\left.\left|\left\langle\psi_{\mathrm{L}}\right| e z\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}}{2 \hbar^{2} \epsilon_{0}} t_{\mathrm{c}}^{2} \int_{\omega=0}^{\infty} \rho(\omega)\left(\frac{\sin \left(\frac{1}{2}\left(\omega-\omega_{0}\right) t_{\mathrm{c}}\right)}{\frac{1}{2}\left(\omega-\omega_{0}\right) t_{\mathrm{c}}}\right)^{2} \mathrm{~d} \omega
$$

If a change of integration variable is made to $u=\frac{1}{2}\left(\omega-\omega_{0}\right) t_{\mathrm{c}}$, the integral becomes

$$
\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}=\frac{\left.\left|\left\langle\psi_{\mathrm{L}}\right| e z\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}}{\hbar^{2} \epsilon_{0}} t \int_{u=-\frac{1}{2} \omega_{0} t_{\mathrm{c}}}^{\infty} \rho\left(\omega_{0}+2\left(u / t_{\mathrm{c}}\right)\right)\left(\frac{\sin u}{u}\right)^{2} \mathrm{~d} u
$$

Recall that a starting assumption underlying these derivations was that $\omega_{0} t_{c}$ was large. So the lower limit of integration can be approximated as $-\infty$.

Note that this is essentially the same analysis as the one for Fermi's golden rule, except for the presence of the given field strength $\rho$. However, here the mathematics can be performed more straightforwardly, using integration rather than summation.

Consider for a second the limiting process that the field strength $\rho$ goes to zero, and that the atom is kept isolated enough that the collision time $t_{\mathrm{c}}$ can increase correspondingly. Then the term $2 u / t_{\mathrm{c}}$ in the argument of $\rho$ will tend to zero. So only waves with the exact frequency $\omega=\omega_{0}$ will produce transitions in the limit of zero field strength. That confirms the basic claim of quantum mechanics that only the energy eigenvalues are measurable. In the absence of an electromagnetic field and other disturbances, the energy eigenvalues are purely the atomic ones. (Also recall that relativistic quantum mechanics adds that in reality, the electric field is never zero.)

In any case, while the term $2 u / t_{\mathrm{c}}$ may not be exactly zero, it is certainly small compared to $\omega_{0}$ because of the assumption that $\omega_{0} t_{\mathrm{c}}$ is large. So the term may be ignored anyway. Then $\rho\left(\omega_{0}\right)$ is a constant in the integration and can be taken out. The remaining integral is in table books, [41, 18.36], and the result is

$$
\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}=\frac{\left.\pi\left|\left\langle\psi_{\mathrm{L}}\right| e z\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}}{\hbar^{2} \epsilon_{0}} \rho\left(\omega_{0}\right) t
$$

This must still be averaged over all directions of wave propagation and polarization. That gives:

$$
\left|\Delta \bar{c}_{\mathrm{H}}^{\mathrm{L}}\right|^{2}=\frac{\left.\pi\left|\left\langle\psi_{\mathrm{L}}\right| e \vec{r}\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}}{3 \hbar^{2} \epsilon_{0}} \rho\left(\omega_{0}\right) t_{\mathrm{c}}
$$

where

$$
\left.\left.\left.\left.\left|\left\langle\psi_{\mathrm{L}}\right| e \vec{r}\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}=\left|\left\langle\psi_{\mathrm{L}}\right| e x\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}+\left|\left\langle\psi_{\mathrm{L}}\right| e y\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}+\left|\left\langle\psi_{\mathrm{L}}\right| e z\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2} .
$$

To see why, consider the electromagnetic waves propagating along any axis, not just the $y$-axis, and polarized in either of the other two axial directions. These waves will include $e x$ and $e y$ as well as $e z$ in the transition probability, making the average as shown above. And of course, waves propagating in an oblique rather than axial direction are simply axial waves when seen in a rotated coordinate system and produce the same average.

The Einstein coefficient $B_{\mathrm{L} \rightarrow \mathrm{H}}$ is the average change per unit time, so the claimed (7.47) results from dividing by the time $t_{\mathrm{c}}$ between collisions. There is no need to do $B_{\mathrm{H} \rightarrow \mathrm{L}}$ separately from $\Delta \bar{c}_{\mathrm{L}}^{\mathrm{L}}$; it follows immediately from the symmetry property mentioned at the end of chapter 7.7.2 that it is the same.

## D. 42 Derivation of the Einstein A coefficients

Einstein did not really derive the spontaneous emission rate from relativistic quantum mechanics. That did not exist at the time. Instead Einstein used a dirty trick; he peeked at the solution.

To see how, consider a system of identical atoms that can be in a low energy state $\psi_{\mathrm{L}}$ or in an excited energy state $\psi_{\mathrm{H}}$. The fraction of atoms in the low energy state is $P_{\mathrm{L}}$ and the fraction in the excited energy state is $P_{\mathrm{H}}$. Einstein assumed that the fraction $P_{\mathrm{H}}$ of excited atoms would evolve according to the equation

$$
\frac{\mathrm{d} P_{\mathrm{H}}}{\mathrm{~d} t}=B_{\mathrm{L} \rightarrow \mathrm{H}} \rho\left(\omega_{0}\right) P_{\mathrm{L}}-B_{\mathrm{H} \rightarrow \mathrm{~L}} \rho\left(\omega_{0}\right) P_{\mathrm{H}}-A_{\mathrm{H} \rightarrow \mathrm{~L}} P_{\mathrm{H}}
$$

where $\rho(\omega)$ is the ambient electromagnetic field energy density, $\omega_{0}$ the frequency of the photon emitted in a transition from the high to the low energy state, and the $A$ and $B$ values are constants. This assumption agrees with the expression (7.46) given in chapter 7.8.

Then Einstein demanded that in an equilibrium situation, in which $P_{\mathrm{H}}$ is independent of time, the formula must agree with Planck's formula for the blackbody electromagnetic radiation energy. The equilibrium version of the formula above gives the energy density as

$$
\rho\left(\omega_{0}\right)=\frac{A_{\mathrm{H} \rightarrow \mathrm{~L}} / B_{\mathrm{H} \rightarrow \mathrm{~L}}}{\left(B_{\mathrm{L} \rightarrow \mathrm{H}} P_{\mathrm{L}} / B_{\mathrm{H} \rightarrow \mathrm{~L}} P_{\mathrm{H}}\right)-1}
$$

Equating this to Planck's blackbody spectrum as derived in chapter 6.8 (6.11) gives

$$
\frac{A_{\mathrm{H} \rightarrow \mathrm{~L}} / B_{\mathrm{H} \rightarrow \mathrm{~L}}}{\left(B_{\mathrm{L} \rightarrow \mathrm{H}} P_{\mathrm{L}} / B_{\mathrm{H} \rightarrow \mathrm{~L}} P_{\mathrm{H}}\right)-1}=\frac{\hbar}{\pi^{2} c^{3}} \frac{\omega_{0}^{3}}{e^{\hbar \omega_{0} / k_{\mathrm{B}} T}-1}
$$

The atoms can be modeled as distinguishable particles. Therefore the ratio $P_{\mathrm{H}} / P_{\mathrm{L}}$ can be found from the Maxwell-Boltzmann formula of chapter 6.14; that gives the ratio as $e^{-\left(E_{\mathrm{H}}-E_{\mathrm{L}}\right) / k_{\mathrm{B}} T}$, or $e^{-\hbar \omega_{0} / k_{\mathrm{B}} T}$ in terms of the photon frequency. It then follows that for the two expressions for $\rho\left(\omega_{0}\right)$ to be equal,

$$
B_{\mathrm{L} \rightarrow \mathrm{H}}=B_{\mathrm{H} \rightarrow \mathrm{~L}} \quad \frac{A_{\mathrm{H} \rightarrow \mathrm{~L}}}{B_{\mathrm{H} \rightarrow \mathrm{~L}}}=\frac{\hbar \omega_{0}^{3}}{\pi^{2} c^{3}}
$$

That $B_{\mathrm{L} \rightarrow \mathrm{H}}$ must equal $B_{\mathrm{H} \rightarrow \mathrm{L}}$ is a consequence of the symmetry property mentioned at the end of chapter 7.7.2. But it was not self-evident when Einstein wrote the paper; Einstein really invented stimulated emission here.

The valuable result for this book is the formula for the spontaneous emission rate $A_{\mathrm{H} \rightarrow \mathrm{L}}$. With $B_{\mathrm{H} \rightarrow \mathrm{L}}$ given by (7.47), it determines the spontaneous emission rate. So it has been obtained without using relativistic quantum mechanics. (Or at least not explicitly; there simply are no nonrelativistic photons.)

## D. 43 Multipole derivations

This derives the multipole matrix elements corresponding to a single particle in an atom or nucleus. These will normally still need to be summed over all particles.

Both a basis of linear momentum photon wave functions and of angular momentum ones are covered. For the angular momentum wave functions, the long wave length approximation will be made that $k R$ is small. Here $k$ is the photon wave number and $R$ the typical size of atom or nucleus.

The derivations include a term due to an effect that was mentioned in the initial 1952 derivation by B. Stech, [44]. This effect is not mentioned in any textbook that the author is aware off. That seems to be unjustified. The term does not appear to be small for nuclei, but at the very least comparable to the usual electric multipole element given.

The rules of engagement are as follows:

- The considered particle will be indicated by a subscript $i$.
- The Cartesian axes are numbered using an index $j$, with $j=1,2$, and 3 for $x_{i}, y_{i}$, and $z_{i}$ respectively.
- Also, $r_{i, j}$ indicates the coordinate in the $j$ direction, $x_{i}, y_{i}$, or $z_{i}$.
- Derivatives with respect to a coordinate $r_{i, j}$ are indicated by a simple subscript $j$.
- If the quantity being differentiated is a vector, a comma is used to separate the vector index from differentiation ones.
- A bare $\int$ integral sign is assumed to be an integration over all nuclear coordinates.
- A superscript * indicates a complex conjugate.

The convoluted derivations in this note make use of a trick. Since "trick" sounds too tricky, it will be referred to as:
Lemma 1: This lemma allows you to get rid of derivatives on the wave function. The lemma assumes nonrelativistic particles. It is a generalization of a derivation of [16].

The lemma says that if $i$ is the number of a particle in the atom or nucleus, and if $F_{i}$ is any function of the position of that particle $i$, then

$$
\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} F_{i}\right) \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle=\frac{m_{i}}{\hbar^{2}}\left\langle\psi_{\mathrm{L}}\right|\left(E_{\mathrm{H}}-E_{\mathrm{L}}\right) F_{i}+\left[V, F_{i}\right]\left|\psi_{\mathrm{H}}\right\rangle-\frac{1}{2}\left\langle\psi_{\mathrm{L}}\right| \nabla_{i}^{2} F_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

Here $\nabla_{i}$ represents the vector of derivatives with respect to the coordinates of particle $i, V$ is the potential, and $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ are the final and initial atomic or nuclear wave functions.

The energy difference can be expressed in terms of the energy $\hbar \omega_{0}$ of the nominal photon emitted in the transition,
$\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} F_{i}\right) \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle=\frac{m_{i} \omega_{0}}{\hbar}\left\langle\psi_{\mathrm{L}}\right| \pm F_{i}+\left[V / \hbar \omega_{0}, F_{i}\right]\left|\psi_{\mathrm{H}}\right\rangle-\frac{1}{2}\left\langle\psi_{\mathrm{L}}\right| \nabla_{i}^{2} F_{i}\left|\psi_{\mathrm{H}}\right\rangle$
(D.27)

The $\pm$ allows for the possibility (in absorption) that $\psi_{\mathrm{L}}$ is actually the high energy state. The nominal photon frequency $\omega_{0}$ is normally taken equal to the actual photon frequency $\omega$.

Note that none of my sources includes the commutator in the first term, not even [16]. (The original 1952 derivation by [44] used a relativistic Dirac formulation, in which the term appears in a different place than here. The part in which it appears there is small without the term and is not worked out with it included.) The commutator is zero if the potential $V$ only depends on the position coordinates of the particles. However, nuclear potentials include substantial momentum terms.

To prove the lemma, start with the left hand side

$$
\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} F_{i}\right) \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle \equiv \int \psi_{\mathrm{L}}^{*} F_{i, j} \psi_{\mathbf{H}, j}
$$

where subscripts $j=1,2$, and 3 indicates the derivatives with respect to the three coordinates of particle $i$. Summation over $j$ is to be understood. Average the above expression with what you get from doing an integration by parts:

$$
\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} F_{i}\right) \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle=\frac{1}{2} \int \psi_{\mathrm{L}}^{*} F_{i, j} \psi_{\mathrm{H}, j}-\frac{1}{2} \int\left(\psi_{\mathrm{L}}^{*} F_{i, j}\right)_{j} \psi_{\mathrm{H}}
$$

or differentiating out

$$
\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} F_{i}\right) \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle=\frac{1}{2} \int \psi_{\mathrm{L}}^{*} F_{i, j} \psi_{\mathrm{H}, j}-\frac{1}{2} \int \psi_{\mathrm{L}, j}^{*} F_{i, j} \psi_{\mathrm{H}}-\frac{1}{2} \int \psi_{\mathrm{L}}^{*} F_{i, j j} \psi_{\mathrm{H}}
$$

Combine the first two integrals

$$
\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} F_{i}\right) \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle=\frac{1}{2} \int\left(\psi_{\mathrm{L}}^{*} \psi_{\mathrm{H}, j}-\psi_{\mathrm{L}, j}^{*} \psi_{\mathrm{H}}\right) F_{i, j}-\frac{1}{2} \int \psi_{\mathrm{L}}^{*} F_{i, j j} \psi_{\mathrm{H}}
$$

and do another integration by parts (I got this from [16], thanks):

$$
\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} F_{i}\right) \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle=-\frac{1}{2} \int\left(\psi_{\mathrm{L}}^{*} \psi_{\mathrm{H}, j j}-\psi_{\mathrm{L}, j j}^{*} \psi_{\mathrm{H}}\right) F_{i}-\frac{1}{2} \int \psi_{\mathrm{L}}^{*} F_{i, j j} \psi_{\mathrm{H}}
$$

Now note the nonrelativistic eigenvalue problems for the two states

$$
\begin{aligned}
& -\frac{\hbar^{2}}{2 m_{i}} \nabla_{i}^{2} \psi_{\mathrm{L}}-\sum_{\underline{i} \neq i} \frac{\hbar^{2}}{2 m_{\underline{i}}} \nabla_{\underline{i}}^{2} \psi_{\mathrm{L}}+V \psi_{\mathrm{L}}=E_{\mathrm{L}} \psi_{\mathrm{L}} \\
& -\frac{\hbar^{2}}{2 m_{i}} \nabla_{i}^{2} \psi_{\mathrm{H}}-\sum_{\underline{i} \neq i} \frac{\hbar^{2}}{2 m_{\underline{i}}} \nabla_{\underline{i}}^{2} \psi_{\mathrm{H}}+V \psi_{\mathrm{H}}=E_{\mathrm{H}} \psi_{\mathrm{H}}
\end{aligned}
$$

Here the sum is over the other particles in the nucleus. These two eigenvalue problems are used to eliminate the second order derivatives in the integral above. The terms involving the Laplacians with respect to the coordinates of the other particles then drop out. The reason is that $F_{i}$ is just a constant with respect to those coordinates, and that Laplacians are Hermitian. Assuming that $V$ is at least Hermitian, as it should, the $V$ terms produce the commutator in the lemma. And the right hand sides give the energy-difference term. The result is the lemma as stated.

## D.43.1 Matrix element for linear momentum modes

This requires in addition:
Lemma 2: This lemma allows you to express a certain combination of derivatives in terms of the angular momentum operator. It will be assumed that vector $\vec{A}_{0}$ is normal to vector $\vec{k}$.

In that case:

$$
\left(\vec{k} \cdot \vec{r}_{i}\right)\left(\vec{A}_{0} \cdot \nabla_{i}\right)-\left(\vec{A}_{0} \cdot \vec{r}_{i}\right)\left(\vec{k} \cdot \nabla_{i}\right)=\left(\vec{k} \times \vec{A}_{0}\right) \cdot\left(\vec{r}_{i} \times \nabla_{i}\right)=\frac{\mathrm{i}}{\hbar}\left(\vec{k} \times \vec{A}_{0}\right) \cdot \widehat{\vec{L}}_{i}
$$

The quickest way to prove this is to take the $x$-axis in the direction of $\vec{k}$, and the $y$-axis in the direction of $\vec{A}_{0}$. (The expression above is also true if the two vectors are nor orthogonal. You can see that using index notation. However, that will not be needed.) The final equality is just the definition of the angular momentum operator.

The objective is now to use these lemmas to work out the matrix element

$$
H_{21, i}=-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| \vec{A}_{0} e^{-\mathrm{i} \cdot \overrightarrow{r_{r}}} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

where $\vec{k}$ is the constant wave number vector and $\vec{A}_{0}$ is some other constant vector normal to $\vec{k}$. Also $\vec{r}_{i}$ is the position of the considered particle, and $\widehat{\vec{p}}_{i}$ is the momentum operator $\hbar \nabla_{i} / \mathrm{i}$ based on these coordinates.

To reduce this, take the factor $\hbar /$ i out of $\widehat{\vec{p}}_{i}$ and write the exponential in a Taylor series:

$$
H_{21, i}=\sum_{n=0}^{\infty} \frac{\mathrm{i} q_{i} \hbar}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| \frac{\left(-\mathrm{i} \vec{k} \cdot \vec{r}_{i}\right)^{n}}{n!} \vec{A}_{0} \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

Take another messy factor out of the inner product:

$$
H_{21, i}=\sum_{n=0}^{\infty} \frac{\mathrm{i}(-\mathrm{i})^{n} q_{i} \hbar}{m_{i}(n+1)!}\left\langle\psi_{\mathrm{L}}\right|(n+1)\left(\vec{k} \cdot \vec{r}_{i}\right)^{n} \vec{A}_{0} \cdot \nabla_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

For brevity, just consider the inner product by itself for now. It can trivially be rewritten as a sum of two terms, ([16], not me):

$$
\begin{align*}
& \left\langle\psi_{\mathrm{L}}\right|\left(\vec{k} \cdot \vec{r}_{i}\right)^{n-1}\left[\left(\vec{k} \cdot \vec{r}_{i}\right) \vec{A}_{0} \cdot \nabla_{i}+n\left(\vec{A}_{0} \cdot \vec{r}_{i}\right) \vec{k} \cdot \nabla_{i}\right]\left|\psi_{\mathrm{H}}\right\rangle  \tag{1}\\
& \quad+\left\langle\psi_{\mathrm{L}}\right|\left(\vec{k} \cdot \vec{r}_{i}\right)^{n-1} n\left[\left(\vec{k} \cdot \vec{r}_{i}\right) \vec{A}_{0} \cdot \nabla_{i}-\left(\vec{A}_{0} \cdot \vec{r}_{i}\right) \vec{k} \cdot \nabla_{i}\right]\left|\psi_{\mathrm{H}}\right\rangle \tag{2}
\end{align*}
$$

Now on the first inner product (1), lemma 1 can be applied with

$$
F_{i}=\left(\vec{k} \cdot \vec{r}_{i}\right)^{n}\left(\vec{A}_{0} \cdot \vec{r}_{i}\right) \quad \Longrightarrow \quad \nabla_{i}^{2} F_{i}=n(n-1) k^{2}\left(\vec{k} \cdot \vec{r}_{i}\right)^{n-2}\left(\vec{A}_{0} \cdot \vec{r}_{i}\right)
$$

(Recall that $\vec{A}_{0}$ and $\vec{k}$ are orthogonal. Also note that the Laplacian of $F_{i}$ is of essentially the same form as $F_{i}$, just for a different value of $n$.) On the second inner product (2), lemma 2 can be applied.

Plugging these results back into the expression for the matrix element, renotating $n$ into $\ell-1$ for the first part of (1), into $\ell+1$ for the second part, which can then be combined with the first part, and into $\ell$ for (2), and cleaning up gives the final result:

$$
H_{21, i}=-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| \vec{A}_{0} e^{-\mathrm{i} \vec{k} \cdot \vec{r}_{i}} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle \equiv \sum_{\ell=1}^{\infty} H_{21, i}^{\mathrm{E} \ell}+H_{21, i}^{\mathrm{M} \ell 1}
$$

where

$$
H_{21, i}^{\mathrm{E} \ell}=\mathrm{i} q_{i} k c A_{0} \frac{(-\mathrm{i} k)^{\ell-1}}{\ell!}\left\langle\psi_{\mathrm{L}}\right| f r_{i, k}^{\ell-1} r_{i, \mathcal{E}}+\left[V / \hbar \omega, r_{i, k}^{\ell-1} r_{i, \mathcal{E}}\right]\left|\psi_{\mathrm{H}}\right\rangle
$$

and

$$
H_{21, i}^{\mathrm{M} \ell 1}=\mathrm{i} \frac{q_{i}}{m_{i} c} k c A_{0} \frac{\ell(-\mathrm{i} k)^{\ell-1}}{(\ell+1)!}\left\langle\psi_{\mathrm{L}}\right| r_{i, k}^{\ell-1} \widehat{L}_{i, \mathcal{B}}\left|\psi_{\mathrm{H}}\right\rangle
$$

Here $A_{0}$ is the magnitude of $\vec{A}_{0}$. Also $r_{i, k}$ is the component of the position $\vec{r}_{i}$ of particle $i$ in the direction of motion of the electromagnetic wave. The direction of motion is the direction of $\vec{k}$. Similarly $r_{i, \mathcal{E}}$ is the component of $\vec{r}_{i}$ in the direction of the electric field. The electric field has the same direction as $\vec{A}_{0}$. Further, $L_{i, \mathcal{B}}$ is the component of the orbital angular momentum operator of particle $i$ in the direction of the magnetic field. The magnetic field is in the same direction as $\vec{k} \times \vec{A}_{0}$. Finally, the factor $f$ is

$$
f= \pm 1+\frac{\hbar \omega}{2 m_{i} c^{2}} \frac{\ell}{\ell+2} \approx \pm 1
$$

The approximation applies because normally the energy release in a transition is small compared to the rest mass energy of the particle. (And if it was not, the nonrelativistic electromagnetic interaction used here would not be valid in the first place.) For the emission process covered in $\{$ A. 25$\}$, the plus sign applies, $f=1$.

The commutator is zero if the potential depends only on position. That is a valid approximation for electrons in atoms, but surely not for nuclei. For these it is a real problem, $\{\mathrm{N} .14\}$.

For addendum $\{\mathrm{A} .25\}$, the constant $A_{0}$ should be taken equal to $-\mathcal{E}_{0} / \sqrt{2} \mathrm{i} k c$. Note also that the interaction of the particle spin with the magnetic field still needs to be added to $H_{21, i}^{\mathrm{M} \ell 1}$. This interaction is unchanged from the naive approximation.

## D.43.2 Matrix element for angular momentum modes

This subsection works out the details of the matrix element when angular momentum modes are used for the photon wave function.

The first matrix element to find is

$$
H_{21, i}^{\mathrm{E} 1}=-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| A_{0} \vec{A}_{\gamma i}^{\mathrm{E} *} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

where, $\{\mathrm{A} .21 .7\}$,

$$
\vec{A}_{\gamma i}^{\mathrm{E}}=\nabla_{i} \times \vec{r}_{i} \times \nabla_{i} j_{\ell i} Y_{\ell i}^{m}
$$

is the electric multipole vector potential at the location of particle $i$. This uses the short hand

$$
j_{\ell i} \equiv j_{\ell}\left(k r_{i}\right) \quad Y_{\ell i}^{m} \equiv Y_{\ell}^{m}\left(\theta_{i}, \phi_{i}\right)
$$

where $\ell$ is the multipole order or photon angular momentum, $k$ the photon wave number, $j_{\ell}$ a spherical Bessel function, and $Y_{\ell}^{m}$ a spherical harmonic.

Note that the electric multipole vector potential is closely related to the magnetic one:

$$
\vec{A}_{\gamma i}^{\mathrm{E}}=\nabla_{i} \times \vec{A}_{\gamma i}^{\mathrm{M}} \quad \vec{A}_{\gamma i}^{\mathrm{M}}=\vec{r}_{i} \times \nabla_{i} j_{\ell i} Y_{\ell i}^{m}=-\nabla_{i} \times j_{\ell i} Y_{\ell i}^{m} \vec{r}_{i}
$$

The expression for the electric potential can be simplified for long photon wave lengths. Note first that

$$
\nabla_{i} \times \vec{A}_{\gamma i}^{\mathrm{E}}=\nabla_{i} \times \nabla_{i} \times \vec{A}_{\gamma i}^{\mathrm{M}}=-\nabla_{i}^{2} \vec{A}_{\gamma i}^{\mathrm{M}}=k^{2} \vec{A}_{\gamma i}^{\mathrm{M}}=-k^{2} \nabla_{i} \times j_{\ell i} Y_{\ell i}^{m} \vec{r}_{i}
$$

where the second equality applied because the vector potentials are solenoidal and the standard vector identity (D.1), while the third equality is the energy eigenvalue problem, $\{\mathrm{A} .21\}$. It follows that the electric vector potential is of the form

$$
\vec{A}_{\gamma i}^{\mathrm{E}}=-k^{2} j_{\ell i} Y_{\ell i}^{m} \vec{r}_{i}+\nabla_{i} F_{i}
$$

because vector calculus says that if the curl of something is zero, it is the gradient of some scalar function $F_{i}$. Here

$$
F_{i}=\int_{\overrightarrow{\underline{r}}_{i}=0}^{\vec{r}_{i}}\left[\vec{A}_{\gamma i}^{\mathrm{E}}+k^{2} j_{\ell i} Y_{\ell i}^{m} \vec{r}_{i}\right] \cdot \mathrm{d} \overrightarrow{\underline{r}}_{i}
$$

The direction of integration in the expression for $F_{i}$ does not make a difference, so the simplest is to integrate radially outwards. The expression for $\vec{A}_{\gamma i}^{\mathrm{E}}$ was given in $\{\mathrm{D} .36 .2\}$. That gives

$$
F_{i}=\int_{{\underline{r_{i}}}=0}^{r_{i}}\left[-l(l+1)+k^{2} r^{2}\right] j_{\ell i} \frac{\mathrm{~d} r}{r} Y_{\ell i}^{m}
$$

Long photon wave length corresponds to small photon wave number $k$. All $k^{2}$ terms above can then be ignored and in addition the following approximation for the Bessel function applies, $\{\mathrm{A} .6\}$,

$$
j_{\ell i} \approx \frac{\left(k r_{i}\right)^{\ell}}{(2 \ell+1)!!}
$$

This is readily integrated to find

$$
F_{i} \approx-(\ell+1) \frac{\left(k r_{i}\right)^{\ell}}{(2 \ell+1)!!} Y_{\ell i}^{m}
$$

and $\vec{A}_{\gamma i}^{\mathrm{E}}$ is the gradient.
That allows lemma 1 to be used to find the electric matrix element.

$$
\begin{aligned}
H_{21, i}^{\mathrm{E} 1} & =-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| A_{0} \vec{A}_{\gamma i}^{\mathrm{E} *} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle \\
& \approx-\mathrm{i} q_{i} k c A_{0} \frac{(\ell+1) k^{\ell}}{(2 \ell+1)!!}\left\langle\psi_{\mathrm{L}}\right| r_{i}^{\ell} Y_{\ell i}^{m *}+\left[V / \hbar \omega, r_{i}^{\ell} Y_{\ell i}^{m *}\right]\left|\psi_{\mathrm{H}}\right\rangle
\end{aligned}
$$

This assumes $\psi_{\mathrm{L}}$ is indeed the lower-energy state. The value of $A_{0}$ (as defined here) to use in addendum $\{\mathrm{A} .25\}$ is $-\varepsilon_{k}^{\mathrm{E}} / \sqrt{2} \mathrm{i} k c$.

The commutator is again negligible for atoms, but a big problem for nuclei, \{N.14\}.

There is also a term due to the interaction of the spin with the magnetic field, given by the curl of $\vec{A}_{\gamma i}^{\mathrm{E}}$ as already found above,
$H_{21, i}^{\mathrm{E} \ell 2}=-\frac{q_{i}}{m_{i}} \frac{g_{i}}{2}\left\langle\psi_{\mathrm{L}}\right| k^{2} A_{0} \vec{A}_{\gamma i}^{\mathrm{M} *} \cdot \hat{\vec{S}}_{i}\left|\psi_{\mathrm{H}}\right\rangle=-\frac{q_{i}}{m_{i}} \frac{g_{i}}{2}\left\langle\psi_{\mathrm{L}}\right| k^{2} A_{0}\left(\vec{r}_{i} \times \nabla_{i} j_{\ell i} Y_{\ell i}^{m *}\right) \cdot \widehat{\vec{S}}_{i}\left|\psi_{\mathrm{H}}\right\rangle$
Using the property of the scalar triple product that the factors can be interchanged if a minus sign is added, the matrix element becomes

$$
H_{21, i}^{\mathrm{E} \ell 2}=\frac{q_{i}}{m_{i}} \frac{g_{i}}{2} k^{2} A_{0}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} j_{\ell i} Y_{\ell i}^{m *}\right) \cdot\left(\vec{r}_{i} \times \widehat{\vec{S}}_{i}\right)\left|\psi_{\mathrm{H}}\right\rangle
$$

(Note that $\nabla_{i}$ only acts on the $j_{\ell i} Y_{\ell i}^{m *} ; \vec{A}_{\gamma i}^{\mathrm{M*}}$ is a function, not a differential operator.) In the long wave length approximation of the Bessel function, that becomes

$$
H_{21, i}^{\mathrm{E} 2} \approx q_{i} k c A_{0} \frac{(\ell+1) k^{\ell}}{(2 \ell+1)!!} \frac{\hbar \omega}{2(\ell+1) m_{i} c^{2}} \frac{g_{i}}{2}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} r_{i}^{\ell} Y_{\ell i}^{m *}\right) \cdot\left(\vec{r}_{i} \times \frac{2}{\hbar} \widehat{\vec{S}}_{i}\right)\left|\psi_{\mathrm{H}}\right\rangle
$$

The inner product should normally be of the same order as the one of $H_{21, i}^{\mathrm{E} 1}$. However, the second fraction above is normally small; usually the photon energy is small compared to the rest mass energy of the particles. (And if it was not, the nonrelativistic electromagnetic interaction used here would not be valid in the first place.) So this second term will be ignored in addendum $\{\mathrm{A} .25\}$.

The third matrix element to find is the magnetic multipole one

$$
H_{21, i}^{\mathrm{M} \ell 1}=-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| A_{0} \vec{A}_{\gamma i}^{\mathrm{M} *} \cdot \widehat{\vec{p}_{i}}\left|\psi_{\mathrm{H}}\right\rangle
$$

Note that in index notation

$$
\vec{A}_{\gamma i}^{\mathrm{M}} \cdot \widehat{\vec{p}}_{i}=\sum_{j} r_{i, \overline{\bar{\jmath}}}\left(j_{\ell i} Y_{\ell i}^{m}\right)_{\overline{\bar{\jmath}}} \widehat{p}_{i, j}-r_{i, \overline{\bar{\jmath}}}\left(j_{\ell i} Y_{\ell i}^{m}\right)_{\bar{\jmath}} \widehat{p}_{i, j}
$$

where $\bar{\jmath}$ follows $j$ in the cyclic sequence $\ldots 123123 \ldots$ and $\overline{\bar{\jmath}}$ precedes $j$. By a trivial renotation of the summation indices,

$$
\vec{A}_{\gamma i}^{\mathrm{M} *} \cdot \widehat{\vec{p}}_{i}=\sum_{j}\left(j_{\ell i} Y_{\ell i}^{m *}\right)_{j} r_{i, \overline{\bar{p}}} \widehat{p}_{i, \bar{\jmath}}-\left(j_{\ell i} Y_{\ell i}^{m *}\right)_{j} r_{i, \overline{\bar{p}}} \widehat{p}_{i, \bar{\jmath}}=-\left(\nabla_{i} j_{\ell i} Y_{\ell i}^{m *}\right) \cdot \widehat{\vec{L}}_{i}
$$

where $\widehat{\vec{L}}$ is the orbital angular momentum operator. Note that the parenthetical term commutes with this operator, something not mentioned in [33, p. 874].

It follows that

$$
H_{21, i}^{\mathrm{M} \ell 1}=-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| A_{0} \vec{A}_{\gamma i}^{\mathrm{M} *} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle=\frac{q_{i}}{m_{i}} A_{0}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} j_{\ell i} Y_{\ell i}^{m *}\right) \cdot \widehat{\vec{L}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

or in the long wave length approximation

$$
H_{21, i}^{\mathrm{M} \ell 1}=-\frac{q_{i}}{m_{i}}\left\langle\psi_{\mathrm{L}}\right| A_{0} \vec{A}_{\gamma i}^{\mathrm{M} *} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle \approx \frac{q_{i}}{m_{i}} A_{0} \frac{k^{\ell}}{(2 \ell+1)!!}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} r_{i}^{\ell} Y_{\ell i}^{m *}\right) \cdot \widehat{\vec{L}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

There is also a term due to the interaction of the spin with the magnetic field, given by the curl of $\vec{A}_{\gamma i}^{\mathrm{B}}$, which equals $\vec{A}_{\gamma i}^{\mathrm{E}}$,

$$
H_{21, i}^{\mathrm{M} \ell 2}=-\frac{q_{i}}{m_{i}} \frac{g_{i}}{2}\left\langle\psi_{\mathrm{L}}\right| A_{0} \vec{A}_{\gamma i}^{\mathrm{E} *} \cdot \widehat{\vec{S}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

Using the same long wave length approximation for $\vec{A}_{\gamma i}^{\mathrm{E}}$ as before, that becomes

$$
H_{21, i}^{\mathrm{M} \ell_{2}} \approx \frac{q_{i}}{m_{i}} A_{0} \frac{(\ell+1) k^{\ell}}{(2 \ell+1)!!} \frac{g_{i}}{2}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} r_{i}^{\ell} Y_{\ell i}^{m *}\right) \cdot \hat{\vec{S}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

The orbital and spin matrix elements may be combined into one as

$$
H_{21, i}^{\mathrm{M} \ell} \approx \frac{q_{i}}{2 m_{i}} A_{0} \frac{(\ell+1) k^{\ell}}{(2 \ell+1)!!}\left\langle\psi_{\mathrm{L}}\right|\left(\nabla_{i} r_{i}^{\ell} Y_{\ell i}^{m *}\right) \cdot\left(\frac{2}{\ell+1} \widehat{\vec{L}}_{i}+g_{i} \widehat{\vec{S}}_{i}\right)\left|\psi_{\mathrm{H}}\right\rangle
$$

The value of $A_{0}$ to use in addendum $\{\mathrm{A} .25\}$ is $-\varepsilon_{k}^{\mathrm{E}} / \sqrt{2} \mathrm{i} c$.

## D.43.3 Weisskopf and Moszkowski estimates

This subsection explains where the radial, angular, and momentum factors in the Weisskopf and Moszkowski estimates come from. These factors represent the nondimensionalized matrix elements.

The electric matrix element is simplest. It is, written out in spherical coordinates using the assumed wave functions,

$$
\left|h_{21}^{\mathrm{E} \ell}\right| \approx \int R_{\mathrm{L}}\left(r_{i}\right)^{*}\left(r_{i} / R\right)^{\ell} R_{\mathrm{H}}\left(r_{i}\right) r_{i}^{2} \mathrm{~d} r_{i} \sqrt{4 \pi} \int \Theta_{l_{\mathrm{L}} \mathrm{~J}_{\mathrm{L}} i}^{m_{j \mathrm{~L}}{ }^{*}} Y_{\ell i}^{m *} \Theta_{l_{\mathrm{H}} j_{\mathrm{H}} i}^{m_{j \mathrm{H}}} \sin ^{2} \theta_{i} \mathrm{~d} \theta_{i} \mathrm{~d} \phi_{i}
$$

The Weisskopf and Moszkowski estimates assume that the radial parts of wave functions equal a constant $C$ until the nuclear edge $R$ and are zero outside the nucleus. To perform the radial integral is then straightforward:

$$
\int R_{\mathrm{L}}\left(r_{i}\right)^{*}\left(r_{i} / R\right)^{\ell} R_{\mathrm{H}}\left(r_{i}\right) r_{i}^{2} \mathrm{~d} r_{i}=\frac{\int_{0}^{R} C^{2}\left(r_{i} / R\right)^{\ell} r_{i}^{2} \mathrm{~d} r_{i}}{\int_{0}^{R} C^{2} r_{i}^{2} \mathrm{~d} r_{i}}=\frac{3}{\ell+3}
$$

The first equality is true because the integral in the denominator is 1 on account of the normalization condition of wave functions. The second inequality follows from integrating.

The angular integral above is more tricky to ballpark. First of all, it will be assumed that the matrix element of interest is the lowest multipole order allowed by angular momentum conservation. That seems reasonable, given that normally higher multipole transitions will be very much slower. It follows that $\ell=\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right|$. (The possibility that the initial and final angular momenta are equal will be ignored.)

The change in orbital angular momenta could in principle be up to one unit different from the change in net angular momenta because of the spins. But parity conservation allows only $\left|l_{\mathrm{H}}-l_{\mathrm{L}}\right|=\ell$.

To simplify even further, assume the following specific angular states:

$$
\Theta_{l_{\mathrm{L}} j_{\mathrm{L}} i}^{m_{j \mathrm{~L}}}=Y_{0 i}^{0} \uparrow \quad \Theta_{l_{\mathrm{H}} j_{\mathrm{H}} i}^{m_{j \mathrm{H}}}=Y_{\ell i}^{\ell} \uparrow
$$

which have

$$
l_{\mathrm{L}}=0 \quad j_{\mathrm{L}}=\frac{1}{2} \quad m_{j \mathrm{~L}}=\frac{1}{2} \quad l_{\mathrm{H}}=\ell \quad j_{\mathrm{H}}=\ell+\frac{1}{2} \quad m_{j \mathrm{H}}=\ell+\frac{1}{2}
$$

If these states are substituted into the angular integral, the product of the spin states is 1 because spin states are orthonormal. What is left is

$$
\sqrt{4 \pi} \int Y_{0 i}^{0 *} Y_{\ell i}^{m *} Y_{\ell i}^{\ell} \sin ^{2} \theta_{i} \mathrm{~d} \theta_{i} \mathrm{~d} \phi_{i}
$$

Now $Y_{0}^{0}=1 / \sqrt{4 \pi}$ which is just a constant that can be taken out of the integral. There it cancels the corresponding square root in the definition of the matrix element. Then it is seen that the transition can only create a photon for which $m$ $=\ell$. The reason is that spherical harmonics are orthonormal; the inner product is only nonzero if the two spherical harmonics are equal, and then it is 1 . So the conclusion is that for the given states

$$
\sqrt{4 \pi} \int \Theta_{l_{\mathrm{L}} j_{\mathrm{L}} i}^{m_{j \mathrm{~L}} *} Y_{\ell i}^{m *} \Theta_{l_{\mathrm{H}} j_{\mathrm{H} i}}^{m_{j \mathrm{H}}} \sin ^{2} \theta_{i} \mathrm{~d} \theta_{i} \mathrm{~d} \phi_{i}=1
$$

The angular integral is 1 . That makes the decay rate exactly 1 Weisskopf unit.
One glaring deficiency in the above analysis was the assumption that the initial proton state was a $Y_{\ell}^{\ell} \uparrow$ one. It would certainly be reasonable to have an initial nuclear state that has orbital angular momentum $l_{\mathrm{H}}=\ell$ and total angular momentum $j_{\mathrm{H}}=\ell+\frac{1}{2}$. But a bunch of these nuclei would surely each be oriented in its own random direction. So they would have different magnetic quantum numbers $m_{j \mathrm{H}}$. They would not all have $m_{j \mathrm{H}}=\ell+\frac{1}{2}$.

Fortunately, it turns out that this makes no difference. For example, by symmetry the state $Y_{\ell}^{-\ell} \downarrow$ decays just as happily to $Y_{0}^{0} \downarrow$ as $Y_{\ell}^{\ell} \uparrow$ does to $Y_{0}^{0} \uparrow$. For other values of $m_{j \mathrm{H}}$ it is a bit more nuanced. They produce an initial state of the form:

$$
\Theta_{l_{\mathrm{H} j \mathrm{H} i} i}^{m_{j \mathrm{H}}}=\Theta_{\ell \ell+\frac{1}{2} i}^{m_{j}}=c_{1} Y_{\ell}^{m_{j \mathrm{H}}-\frac{1}{2}} \uparrow+c_{2} Y_{\ell}^{m_{j \mathrm{H}}+\frac{1}{2}} \downarrow
$$

Now the first term produces decays to $Y_{0}^{0} \uparrow$ by the emission of a photon with $m_{\ell}=\ell-\frac{1}{2}$. However, because of the factor $c_{1}$ the number of such decays that occur per second is a factor $c_{1}^{2}$ less than the Weisskopf unit. But the second term produces decays to $Y_{0}^{0} \downarrow$ by the emission of a photon with $m_{\ell}=\ell+\frac{1}{2}$. This decay rate is a factor $c_{2}^{2}$ less than the Weisskopf unit. Since $c_{1}^{2}+c_{2}^{2}=1$, (the normalization condition of the state), the total decay rate is still 1 Weisskopf unit.

So as long as the final state $\psi_{\mathrm{L}}$ has zero orbital angular momentum, the decay is at 1 Weisskopf unit. The orientation of the initial state makes no difference. That is reflected in table A.3. This table lists the angular factors to be applied to the Weisskopf unit to get the actual decay rate. The first row shows that, indeed, when the final angular momentum is $1 / 2$, as occurs for zero angular momentum, and the initial angular momentum is $\ell+\frac{1}{2}$, then no correction is needed. The correction factor is 1 .

More interesting is the possibility that the two states are swapped. Then the initial state is the one with zero orbital angular momentum. It might at first
seem that that will not make a difference either. After all, decay rates between specific states are exactly the same.

But there is in fact a difference. Previously, each initial nucleus had only two states to decay to: the spin-up and the spin-down version of the final state. Now however, each initial nucleus has $2 j_{\mathrm{L}}+1$, i.e. $2 \ell+2$ final states it can decay to, corresponding to the possible values of the final magnetic quantum number $m_{\mathrm{L}}$. That will increase the total decay rate correspondingly. In fact, suppose that the initial nuclei come in spin-up and spin-down pairs. Then each pair will decay at a rate of one Weisskopf unit to each possible final state. That is because this picture is the exact reverse of the decay of the final state. So the pairs would decay at a rate $2 \ell+2$ faster than the Weisskopf unit. So by symmetry each nucleus of the pair decays $\ell+1$ times faster than the Weisskopf unit. That is reflected in the first column of table A.3. (Recall that $\ell$ is the difference in the $j$ values.)

If neither the initial nor final state has zero orbital angular momentum, it gets more messy. Figuring out the correction factor in that case is something for those who love abstract mathematics.

Next consider magnetic multipole transitions. They are much messier to ballpark. It will again be assumed that the multipole order is the smallest possible. Unfortunately, now the final orbital angular momentum cannot be zero. Because of parity, that would require that the initial orbital angular momentum would be $\ell+1$. But that is too large because of the limitation (A.175) on the orbital angular momentum change in magnetic transitions. Therefore the simplest possible initial and final states have

$$
l_{\mathrm{L}}=1 \quad j_{\mathrm{L}}=\frac{1}{2} \quad m_{j \mathrm{~L}}=\frac{1}{2} \quad l_{\mathrm{H}}=\ell \quad j_{\mathrm{H}}=\ell+\frac{1}{2} \quad m_{j \mathrm{H}}=\ell+\frac{1}{2}
$$

For these quantum numbers, the initial and final states are

$$
\psi_{\mathrm{L}}=R_{\mathrm{L}, i} \Theta_{l_{\mathrm{L}} j_{\mathrm{L}} i}^{m_{j \mathrm{~L}}}=R_{\mathrm{L}, i}\left(\sqrt{\frac{2}{3}} Y_{1 i}^{1} \downarrow-\sqrt{\frac{1}{3}} Y_{1 i}^{0} \uparrow\right) \quad \psi_{\mathrm{H}}=R_{\mathrm{H}, i} \Theta_{l_{\mathrm{H}} j_{\mathrm{H}} i}^{m_{j \mathrm{H}}}=R_{\mathrm{H}, i} Y_{\ell i}^{\ell} \uparrow
$$

where the square roots come from figure 12.5 in the $j_{a}, j_{b}=1, \frac{1}{2}$ tabulation.
Now consider the form of the magnetic matrix element (A.181). First note, \{D.43.2\}, that the angular momentum and gradient factors commute. That helps because then the angular momentum operators, being Hermitian, can be applied on the easier state $\psi_{\mathrm{L}}$.

The $z$-component part of the dot product in the matrix element is then the easiest. The $z$ components of the angular momentum operators leave the state $\psi_{\mathrm{L}}$ essentially unchanged. They merely multiply the two terms by the eigenvalue $m_{l} \hbar$ respectively $m_{s} \hbar$.

Next, this gets multiplied by the $z$-component of the gradient. But multiplying by the gradient cannot change the spin. So the spin-down first term in $\psi_{\mathrm{L}}$ stays spin-down. That cannot match the spin-up of $\psi_{\mathrm{H}}$. So the first term does not produce a contribution.

The second term in $\psi_{\mathrm{L}}$ has the right spin. Since spin states are orthonormal, their inner product produces 1. But now there is a problem of matching the magnetic quantum number of $\psi_{\mathrm{H}}$. In particular, consider the harmonic polynomial $r^{\ell} Y_{\ell}^{m_{l}}$ in the gradient. The gradient reduces it to a combination of harmonic polynomials of one degree less, in other words, to $r^{\ell-1} Y_{\ell-1}^{m_{l}}$ polynomials. That limits $m_{l}$ to a value no larger than $\ell-1$, and since the second term in $\psi_{\mathrm{L}}$ has magnetic quantum number 0 , the value $\ell$ in $\psi_{\mathrm{H}}$ cannot be matched. The bottom line is that the $z$-component terms in the inner product of the matrix element do not produce a contribution.

However, the $x$ - and $y$-component terms are another story. The angular momentum operators in these directions change the corresponding magnetic quantum numbers, chapter 12.11. In general, their application produces a mixture of $m+1$ and $m-1$ states. In particular, the $x$ and $y$ components of spin will produce a spin-up version of the first term in $\psi_{\mathrm{L}}$. That now matches the spin in $\psi_{\mathrm{H}}$ and a nonzero contribution results. Similarly, the orbital angular momentum operators will produce an $m_{\mathrm{L}}=1$ version of the second term in $\psi_{\mathrm{L}}$. Combined with the $\ell-1$ units from the gradient, that is enough to match the magnetic quantum number of $\psi_{\mathrm{H}}$. So there is a total of four nonzero contributions to the matrix element.

Now it is just a matter of working out the details to get the complete matrix element. The information in chapter 12.11 can be used to find the exact states produced from $\Theta_{l_{\mathrm{H}} j_{\mathrm{H} i}}^{m_{j \mathrm{H}}}$ by the $x$ and $y$ angular momentum operators. Each state is a multiple of the $Y_{1}^{1} \uparrow$ state. As far as the gradient term is concerned, the harmonic polynomials are of the general form

$$
r^{\ell} Y_{\ell}^{\ell}=C(x+\mathrm{i} y)^{\ell} \quad r^{\ell} Y_{\ell}^{\ell-1}=D z(x+\mathrm{i} y)^{\ell-1}
$$

as seen in table 4.3 or $\{\mathrm{D} .64\}$. The constants $C, D, \ldots$ are of no importance here. The $x$ and $y$ derivatives of the first harmonic polynomial will give the needed $Y_{\ell-1}^{\ell-1}$ harmonic. (For values of $\ell$ greater than 1 , the third harmonic could also make a contribution. However, it turns out that here the $x$ and $y$ contributions cancel each other.) The effect of the $x$-derivative on the first harmonic is simply to add a factor $\ell /(x+\mathrm{i} y)$ to it. Similarly, the $y$-derivative simply adds a factor $\mathrm{i} \ell /(x+\mathrm{i} y)$. Now if you look up $Y_{1}^{1}$ in table 4.3, you see it is a multiple of $x+\mathrm{i} y$. So the product with the gradient term produces a simple multiple of $Y_{\ell}^{\ell} \uparrow$. The inner product with $\psi_{\mathrm{H}}$ then produces that multiple (which still depends on $r_{i}$ of course.) Identifying and adding the four multiples produces

$$
h_{21}^{\mathrm{M} \ell}=-\left(g_{i} \ell-\frac{2 \ell}{\ell+1}\right) \int R_{\mathrm{L}}\left(r_{i}\right)^{*}\left(r_{i} / R\right)^{\ell-1} R_{\mathrm{H}}\left(r_{i}\right) r_{i}^{2} \mathrm{~d} r_{i}
$$

The remaining radial integral may be ballparked exactly the same as for the electric case. The only difference is that the power of $r_{i}$ is one unit smaller.

A similar analysis shows that the given initial state cannot decay to the version of the final state with negative magnetic quantum number $m_{j \mathrm{~L}}=-\frac{1}{2}$.

And of course, if the initial and final states are swapped, there is again a factor $\ell+1$ increase in decay rate.

More interestingly, the same expression turns out to hold if neither the initial nor the final angular momentum equals $\frac{1}{2}$, using the correction factor of table A.3. But the obtained magnetic multipole decay rate is more limited than the electric one. It does require that $\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right|=\ell$ and that $\left|l_{\mathrm{H}}-l_{\mathrm{L}}\right|=\ell-1$

The momentum factors (A.189) were identified using a computer program. This program crunched out the complete matrix elements using procedures exactly like the ones above. This program was also used to create table A. 3 of angular factors. This guards against typos and provides an independent check on the Clebsch-Gordan values.

## D. 44 Derivation of group velocity

The objective of this note is to derive the wave function for a wave packet if time is large.

To shorten the writing, the Fourier integral (7.64) for $\Psi$ will be abbreviated as:

$$
\Psi=\int_{k_{1}}^{k_{2}} f(k) e^{\mathrm{i} \varphi t} \mathrm{~d} k \quad \varphi=k \frac{x}{t}-\omega \quad \varphi^{\prime}=\frac{x}{t}-v_{\mathrm{g}} \quad \varphi^{\prime \prime}=-v_{\mathrm{g}}^{\prime}
$$

where it will be assumed that $\varphi$ is a well behaved functions of $k$ and $f$ at least twice continuously differentiable. Note that the wave number $k_{0}$ at which the group velocity equals $x / t$ is a stationary point for $\varphi$. That is the key to the mathematical analysis.

The so-called "method of stationary phase" says that the integral is negligibly small as long as there are no stationary points $\varphi^{\prime}=0$ in the range of integration. Physically that means that the wave function is zero at large time positions that cannot be reached with any group velocity within the range of the packet. It therefore implies that the wave packet propagates with the group velocity, within the variation that it has.

To see why the integral is negligible if there are no stationary points, just integrate by parts:

$$
\Psi=\left.\frac{f(k)}{\mathrm{i} \varphi^{\prime} t} e^{\mathrm{i} \varphi t}\right|_{k_{1}} ^{k_{2}}-\int_{k_{1}}^{k_{2}}\left(\frac{f(k)}{\mathrm{i} \varphi^{\prime} t}\right)^{\prime} e^{\mathrm{i} \varphi t} \mathrm{~d} k
$$

This is small of order $1 / t$ for large times. And if $\bar{\Phi}_{0}(p)$ is chosen to smoothly become zero at the edges of the wave packet, rather than abruptly, you can keep integrating by parts to show that the wave function is much smaller still. That is important if you have to plot a wave packet for some book on quantum mechanics and want to have its surroundings free of visible perturbations.

For large time positions with $x / t$ values within the range of packet group velocities, there will be a stationary point to $\varphi$. The wave number at the stationary point will be indicated by $k_{0}$, and the value of $\varphi$ and its second derivative by $\varphi_{0}$ and $\varphi_{0}^{\prime \prime}$. (Note that the second derivative is minus the first derivative of the group velocity, and will be assumed to be nonzero in the analysis. If it would be zero, nontrivial modifications would be needed.)

Now split the exponential in the integral into two,

$$
\Psi=e^{\mathrm{i} \varphi_{0} t} \int_{k_{1}}^{k_{2}} f(k) e^{\mathrm{i}\left(\varphi-\varphi_{0}\right) t} \mathrm{~d} k
$$

It is convenient to write the difference in $\varphi$ in terms of a new variable $\bar{k}$ :

$$
\varphi-\varphi_{0}=\frac{1}{2} \varphi_{0}^{\prime \prime} \bar{k}^{2} \quad \bar{k} \sim k-k_{0} \quad \text { for } \quad k \rightarrow k_{0}
$$

By Taylor series expansion it can be seen that $\bar{k}$ is a well behaved monotonous function of $k$. The integral becomes in terms $\bar{k}$ :

$$
\Psi=e^{\mathrm{i} \varphi_{0} t} \int_{\bar{k}_{1}}^{\bar{k}_{2}} g(\bar{k}) e^{\mathrm{i} \frac{1}{2} \varphi_{0}^{\prime \bar{k}^{2}} t} \mathrm{~d} \bar{k} \quad g(\bar{k})=f(k) \frac{\mathrm{d} k}{\mathrm{~d} \bar{k}}
$$

Now split function $g$ apart as in

$$
g(\bar{k})=g(0)+[g(\bar{k})-g(0)]
$$

The part within brackets produces an integral

$$
e^{\mathrm{i} \varphi_{0} t} \int_{\bar{k}_{1}}^{\bar{k}_{2}} \frac{g(\bar{k})-g(0)}{\mathrm{i} \varphi_{0}^{\prime \prime} \bar{k} t} \quad \mathrm{i} \varphi_{0}^{\prime \prime} \bar{k} t e^{\mathrm{i} \frac{1}{2} \varphi_{0}^{\prime \prime} \bar{k}^{2} t} \mathrm{~d} \bar{k}
$$

and integration by parts shows that to be small of order $1 / t$.
That leaves the first part, $g(0)=f\left(k_{0}\right)$, which produces

$$
\Psi=e^{\mathrm{i} \varphi_{0} t} f\left(k_{0}\right) \int_{\bar{k}_{1}}^{\bar{k}_{2}} e^{\mathrm{i} \frac{1}{2} \varphi_{0}^{\prime \prime} \bar{k}^{2} t} \mathrm{~d} \bar{k}
$$

Change to a new integration variable

$$
u \equiv \sqrt{\frac{\left|\varphi_{0}^{\prime \prime}\right| t}{2}} \bar{k}
$$

Note that since time is large, the limits of integration will be approximately $u_{1}$ $=-\infty$ and $u_{2}=\infty$ unless the stationary point is right at an edge of the wave packet. The integral becomes

$$
\Psi=e^{\mathrm{i} \varphi_{0} t} f\left(k_{0}\right) \sqrt{\frac{2}{\left|\varphi_{0}^{\prime \prime}\right| t}} \int_{u_{1}}^{u_{2}} e^{ \pm \mathrm{i} u^{2}} \mathrm{~d} u
$$

where $\pm$ is the sign of $\varphi_{0}^{\prime \prime}$. The remaining integral is a "Fresnel integral" that can be looked up in a table book. Away from the edges of the wave packet, the integration range can be taken as all $u$, and then

$$
\Psi=e^{\mathrm{i} \varphi_{\rho} t} e^{ \pm \mathrm{i} \pi / 4} f\left(k_{0}\right) \sqrt{\frac{2 \pi}{\left|\varphi_{0}^{\prime \prime}\right| t}}
$$

Convert back to the original variables and there you have the claimed expression for the large time wave function.

Right at the edges of the wave packet, modified integration limits for $u$ must be used, and the result above is not valid. In particular it can be seen that the wave packet spreads out a distance of order $\sqrt{t}$ beyond the stated wave packet range; however, for large times $\sqrt{t}$ is small compared to the size of the wave packet, which is proportional to $t$.

For the mathematically picky: the treatment above assumes that the wave packet momentum range is not small in an asymptotic sense, (i.e. it does not go to zero when $t$ becomes infinite.) It is just small in the sense that the group velocity must be monotonous. However, Kaplun's extension theorem implies that the packet size can be allowed to become zero at least slowly. And the analysis is readily adjusted for faster convergence towards zero in any case.

## D. 45 Motion through crystals

This note derives the semi-classical motion of noninteracting electrons in crystals. The derivations will be one-dimensional, but the generalization to three dimensions is straightforward.

## D.45.1 Propagation speed

The first question is the speed with which a more or less localized electron moves. An electron in free space moves with a speed found by dividing its linear momentum by its mass. However, in a solid, the energy eigenfunctions are Bloch waves and these do not have definite momentum.

Fortunately, the analysis for the wave packet of a free particle is virtually unchanged for a particle whose energy eigenfunctions are Bloch waves instead of simple exponentials. In the Fourier integral (7.64), simply add the periodic factor $\psi_{\mathrm{p}, k}^{\mathrm{p}}(x)$. Since this factor is periodic, it is bounded, and it plays no part in limit process of infinite time. (You can restrict the times in the limit process to those at which $x$ is always at the same position in the period.)

As a result the group velocity is again $\mathrm{d} \omega / \mathrm{d} k$. Since the energy is $E^{\mathrm{p}}=\hbar \omega$ and the crystal momentum $p_{\mathrm{cm}}=\hbar k$, the velocity of a localized electron can be written as

$$
v=\frac{\mathrm{d} E^{\mathrm{p}}}{\mathrm{~d} p_{\mathrm{cm}}}
$$

In the absence of external forces, the electron will keep moving with the same velocity for all time. The large time wave function is

$$
\Psi(x, t) \sim \frac{e^{\mathrm{T} \mathrm{i} \pi / 4}}{\sqrt{\left|v_{\mathrm{g} 0}^{\prime}\right| t}} \bar{\Phi}_{0}\left(k_{0}\right) \psi_{\mathrm{p}, \mathrm{k}_{0}}^{\mathrm{p}}(x) e^{\mathrm{i}\left(k_{0} x-\omega_{0} t\right)} \quad v_{\mathrm{g} 0}=\frac{x}{t}
$$

where $k_{0}$ is the wave number at which the group speed equals $x / t$. Note that the wave function looks locally just like a single Bloch wave for large time.

## D.45.2 Motion under an external force

The acceleration due to an external force on an electrons is not that straightforward. First of all note that you cannot just add a constant external force. A constant force $F_{\text {ext }}$ would produce an external potential of the form $V_{\text {ext }}=$ $-F_{\text {ext }} x$ and that becomes infinite at infinite $x$. However, it can be assumed that the force is constant over the nonzero range of the wave packet.

Next there is a trick. Consider the expectation value $\left\langle\mathcal{T}_{d}\right\rangle$ of the translation operator $\mathcal{T}_{d}$ that translates the wave function over one atomic cell size $d$. If the wave packet consisted of just a single Bloch wave with wave number $k_{0}$, the expectation value of $\mathcal{T}_{d}$ would be $e^{\mathrm{i} k_{0} d}$. A wave packet must however include a small range of $k$ values. Then $\left\langle\mathcal{T}_{d}\right\rangle$ will be an average of $e^{\mathrm{i} k d}$ values over the $k$ values of the wave packet. Still, if the range of $k$ values is small enough, you can write

$$
\left\langle\mathcal{T}_{d}\right\rangle=A e^{\mathrm{i} k_{0} d}
$$

where $k_{0}$ is a $k$ value somewhere in the middle of the wave packet and $A$ is a real number close to one. So $\left\langle\mathcal{T}_{d}\right\rangle$ still gives the typical $k$ value in the wave packet.

Moreover, its magnitude $\left|\left\langle\mathcal{T}_{d}\right\rangle\right|=A$ is always less than one and the closer it is to one, the more compact the wave packet. That is because $\left\langle\mathcal{T}_{d}\right\rangle$ is an average of $e^{\text {ikd }}$ values. These are all located on the unit circle in the complex plane, the plane with $\cos (k d)$ as the horizontal axis and $\sin (k d)$ as the vertical axis. If the wave packet would consist of just a single $k$ value $k_{0}$, then the average of $e^{\mathrm{i} k d}$ would be exactly $e^{i k_{0} d}$, and be on the unit circle. If however the wave numbers spread out a bit around $k_{0}$, then the average moves inside the unit circle: if you average positions on a circle, the average is always inside the circle. In the extreme case that the $k$ values get uniformly distributed over the entire circle, the average position is at the origin. That would make $\left|\left\langle\mathcal{T}_{d}\right\rangle\right|$ zero. Conversely, as long as $\left|\left\langle\mathcal{T}_{d}\right\rangle\right|$ stays very close to one, the wave packet must be very compact in terms of $k$.

The time evolution of $\left\langle\mathcal{T}_{d}\right\rangle$ can be found using chapter 7.2:

$$
\begin{equation*}
\frac{\mathrm{d}\left\langle\mathcal{T}_{d}\right\rangle}{\mathrm{d} t}=\frac{\mathrm{i}}{\hbar}\left\langle\left[H_{0}+V_{\text {ext }}, \mathcal{T}_{d}\right]\right\rangle \tag{D.28}
\end{equation*}
$$

where $H_{0}$ is the Hamiltonian for the electron in the crystal, and $V_{\text {ext }}$ the additional external potential. Now the commutator of $H_{0}$ and $\mathcal{T}_{d}$ is zero; the crystal Hamiltonian acts exactly the same on the wave function whether it is shifted one cell over or not. The remainder of the commutator gives, when applied on an arbitrary wave function,

$$
\left[V_{\mathrm{ext}}, \mathcal{T}_{d}\right] \Psi \equiv V_{\mathrm{ext}} \mathcal{T}_{d} \Psi-\mathcal{T}_{d} V_{\mathrm{ext}} \Psi
$$

Writing this out with the arguments of the functions explicitly shown gives:

$$
V_{\text {ext }}(x) \Psi(x+d)-V_{\text {ext }}(x+d) \Psi(x+d)=\left(V_{\text {ext }}(x)-V_{\text {ext }}(x+d)\right) \mathcal{T}_{d} \Psi(x)
$$

Now assume that the external force $F_{\text {ext }}$ is constant over the extent of the wave packet. In that case the difference in the potentials is just $F_{\text {ext }} d$, and that is a constant that can be taken out of the expectation value of the commutator. So:

$$
\begin{equation*}
\frac{\mathrm{d}\left\langle\mathcal{T}_{d}\right\rangle}{\mathrm{d} t}=\frac{\mathrm{i}}{\hbar} F_{\text {ext }}\left\langle\left\langle\mathcal{T}_{d}\right\rangle\right. \tag{D.29}
\end{equation*}
$$

The solution to this equation is:

$$
\left\langle\mathcal{T}_{d}\right\rangle=\left\langle\mathcal{T}_{d}\right\rangle_{0} e^{\mathrm{i} F_{\text {ext }} d t / \hbar}
$$

where $\left\langle\mathcal{T}_{d}\right\rangle_{0}$ is the value of $\left\langle\mathcal{T}_{d}\right\rangle$ at the starting time $t=0$.
It follows that the magnitude of the $\left\langle\mathcal{T}_{d}\right\rangle$ does not change with time. In view of the earlier discussion, this means that the wave packet maintains its compactness in terms of $k$. (In physical space the wave packet will gradually spread out, as can be seen from the form of the large-time wave function given earlier.)

It further follows that the average wave number $k_{0}$ in the wave packet evolves as:

$$
\frac{\mathrm{d} h k_{0}}{\mathrm{~d} t}=F_{\mathrm{ext}}
$$

Since the packet remains compact, all wave numbers in the wave packet change the same way. This is Newton's second law in terms of crystal momentum.

## D.45.3 Free-electron gas with constant electric field

This book discussed the effect of an applied electric field on free electrons in a periodic box in chapter 6.20. The effect was described as a change of the velocity of the electrons. Since the velocity is proportional to the wave number for free electrons, the velocity change corresponds to a change in the wave number. In this subsection the effect of the electric field will be examined in more detail. The solution will again be taken to be one-dimensional, but the extension to three dimensions is trivial.

Assume that a constant electric field is applied, so that the electrons experience a constant force $F_{\text {ext }}$. The time-dependent Schrödinger equation is

$$
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \Psi}{\partial x^{2}}-F_{\mathrm{ext}} x \Psi
$$

Assume the initial condition to be

$$
\Psi_{0}=\sum_{k_{0}} c_{k_{0}} e^{\mathrm{i} k_{0} x}
$$

in which a subscript 0 indicates the initial time.
The exact solution to this problem is

$$
\Psi=\sum_{k_{0}} c\left(k_{0}, t\right) e^{\mathrm{i} k(t) x} \quad \frac{\mathrm{~d} \hbar k}{\mathrm{~d} t}=F_{\mathrm{ext}}
$$

where the magnitude of the coefficients $\left|c\left(k_{0}, t\right)\right|=\left|c_{k_{0}}\right|$ is independent of time. This exact solution is in terms of states $e^{i k(t) x}$ that change in time. The probability of the particle being in those states does not change.

Unfortunately, this solution is only periodic with period equal to the length of the box $\ell$ for times at which $F_{\text {ext }} t / \hbar$ happens to be a whole multiple of the wave number spacing. At those times the Fermi sphere of occupied states has shifted the same whole multiple of wave number spacings to the right.

At intermediate times, the solution is not periodic, so it cannot be correctly described using the periodic box modes. The magnitude of the wave function is still periodic. However, the momentum has values inconsistent with the periodic box. The problem is that even though a constant force is periodic, the corresponding potential is not. Since quantum mechanics uses the potential instead of the force, the quantum solution is no longer periodic.

The problem goes away by letting the periodic box size become infinite. But that brings back the ugly normalization problems. For a periodic box, the periodic boundary conditions will need to be relaxed during the application of the electric field. In particular, a factor $e^{i F_{\text {ext }} \ell t / \hbar}$ difference in wave function and its $x$-derivative must be allowed between the ends of the box. Since the periodic boundary conditions are artificial anyway for modeling a piece of electrical wire, this may not be a big concern. In any case, for a big-enough periodic box, the times at which the solution returns to its original periodicity become spaced very close together.

## D. 46 Derivation of the WKB approximation

The purpose in this note is to derive an approximate solution to the Hamiltonian eigenvalue problem

$$
\frac{\mathrm{d}^{2} \psi}{\mathrm{~d} x^{2}}=-\frac{p_{\mathrm{c}}^{2}}{\hbar^{2}} \psi
$$

where the classical momentum $p_{\mathrm{c}}=\sqrt{2 m(E-V)}$ is a known function for given energy. The approximation is to be valid when the values of $p_{c} / \hbar$ are large. In quantum terms, you can think of that as due to an energy that is macroscopically large. But to do the mathematics, it is easier to take a macroscopic point of view; in macroscopic terms, $p_{c} / \hbar$ is large because Planck's constant $\hbar$ is so small.

Since either way $p_{\mathrm{c}} / \hbar$ is a large quantity, for the left hand side of the Hamiltonian eigenvalue problem above to balance the right hand side, the wave function must vary rapidly with position. Something that varies rapidly and nontrivially with position tends to be hard to analyze, so it turns out to be a good idea to write the wave function as an exponential,

$$
\psi=e^{\mathrm{i} \tilde{\theta}}
$$

and then approximate the argument $\tilde{\theta}$ of that exponential.
To do so, first the equation for $\tilde{\theta}$ will be needed. Taking derivatives of $\psi$ using the chain rule gives in terms of $\tilde{\theta}$

$$
\frac{\mathrm{d} \psi}{\mathrm{~d} x}=e^{\mathrm{i} \tilde{\theta}} \mathrm{i} \frac{\mathrm{~d} \tilde{\theta}}{\mathrm{~d} x} \quad \frac{\mathrm{~d}^{2} \psi}{\mathrm{~d} x^{2}}=-e^{\mathrm{i} \tilde{\theta}}\left(\frac{\mathrm{~d} \tilde{\theta}}{\mathrm{~d} x}\right)^{2}+e^{\mathrm{i} \tilde{\theta}} \mathrm{i} \frac{\mathrm{~d}^{2} \tilde{\theta}}{\mathrm{~d} x^{2}}
$$

Then plugging $\psi$ and its second derivative above into the Hamiltonian eigenvalue problem and cleaning up gives:

$$
\begin{equation*}
\left(\frac{\mathrm{d} \tilde{\theta}}{\mathrm{~d} x}\right)^{2}=\frac{p_{\mathrm{c}}^{2}}{\hbar^{2}}+\mathrm{i} \frac{\mathrm{~d}^{2} \tilde{\theta}}{\mathrm{~d} x^{2}} \tag{D.30}
\end{equation*}
$$

For a given energy, $\tilde{\theta}$ will depend on both what $x$ is and what $\hbar$ is. Now, since $\hbar$ is small, mathematically it simplifies things if you expand $\tilde{\theta}$ in a power series with respect to $\hbar$ :

$$
\tilde{\theta}=\frac{1}{\hbar}\left(f_{0}+\hbar f_{1}+\frac{1}{2} \hbar^{2} f_{2}+\ldots\right)
$$

You can think of this as writing $\hbar \theta$ as a Taylor series in $\hbar$. The coefficients $f_{0}, f_{1}, f_{2}, \ldots$ will depend on $x$. Since $\hbar$ is small, the contribution of $f_{2}$ and further terms to $\psi$ is small and can be ignored; only $f_{0}$ and $f_{1}$ will need to be figured out.

Plugging the power series into the equation for $\tilde{\theta}$ produces

$$
\frac{1}{\hbar^{2}} f_{0}^{\prime 2}+\frac{1}{\hbar} 2 f_{0}^{\prime} f_{1}^{\prime}+\ldots=\frac{1}{\hbar^{2}} p_{\mathrm{c}}^{2}+\frac{1}{\hbar} \mathrm{i} f_{0}^{\prime \prime}+\ldots
$$

where primes denote $x$-derivatives and the dots stand for powers of $\hbar$ greater than $\hbar^{-1}$ that will not be needed. Now for two power series to be equal, the
coefficients of each individual power must be equal. In particular, the coefficients of $1 / \hbar^{2}$ must be equal, $f_{0}^{\prime 2}=p_{\mathrm{c}}^{2}$, so there are two possible solutions

$$
f_{0}^{\prime}= \pm p_{\mathrm{c}}
$$

For the coefficients of $1 / \hbar$ to be equal, $2 f_{0}^{\prime} f_{1}^{\prime}=\mathrm{i} f_{0}^{\prime \prime}$, or plugging in the solution for $f_{0}^{\prime}$,

$$
f_{1}^{\prime}=\mathrm{i} \frac{p_{\mathrm{c}}^{\prime}}{2 p_{\mathrm{c}}}
$$

It follows that the $x$-derivative of $\tilde{\theta}$ is given by

$$
\tilde{\theta}^{\prime}=\frac{1}{\hbar}\left( \pm p_{\mathrm{c}}+\hbar \mathrm{i} \frac{p_{\mathrm{c}}^{\prime}}{2 p_{\mathrm{c}}}+\ldots\right)
$$

and integrating gives $\tilde{\theta}$ as

$$
\tilde{\theta}= \pm \frac{1}{\hbar} \int p_{\mathrm{c}} \mathrm{~d} x+\mathrm{i} \frac{1}{2} \ln p_{\mathrm{c}}+\tilde{C} \ldots
$$

where $\tilde{C}$ is an integration constant. Finally, $e^{i \tilde{\theta}}$ now gives the two terms in the WKB solution, one for each possible sign, with $e^{\mathrm{i} \tilde{C}}$ equal to the constant $C_{\mathrm{f}}$ or $C_{\mathrm{b}}$.

## D. 47 Born differential cross section

This note derives the Born differential cross section of addendum \{A.30\}.
The general idea is to approximate (A.228) for large distances $r$. Then the asymptotic constant $C_{\mathrm{f}}$ in (A.216) can be identified, which gives the differential cross section according to (A.218). Note that the Born approximation took the asymptotic constant $C_{\mathrm{f}}^{\mathrm{f}}$ equal to one for simplicity.

The main difficulty in approximating (A.228) for large distances $r$ is the argument of the exponential in the fraction. It is not accurate enough to just say that $\left|\vec{r}-\vec{r}^{\prime}\right|$ is approximately equal to $r$. You need the more accurate approximation

$$
\left|\vec{r}-\vec{r}^{\prime}\right|=\sqrt{\left(\vec{r}-\vec{r}^{\prime}\right) \cdot\left(\vec{r}-\vec{r}^{\prime}\right)}=\sqrt{r^{2}-2 \vec{r} \cdot \vec{r}^{\prime}+\vec{r}^{\prime} \cdot \vec{r}^{\prime}} \sim r-\frac{\vec{r}}{r} \cdot \vec{r}^{\prime}
$$

The final approximation is from taking a factor $r^{2}$ out of the square root and then approximating the rest by a Taylor series. Note that the fraction in the final term is the unit vector $\hat{\imath}_{r}$ in the $r$-direction.

It follows that

$$
\frac{e^{\mathrm{i} p_{\infty}\left|\vec{r}-\vec{r}^{\prime}\right| / \hbar}}{\left|\vec{r}-\vec{r}^{\prime}\right|} \sim \frac{e^{\mathrm{i} p_{\infty} r / \hbar}}{r} e^{-\mathrm{i} \vec{p}_{\infty} \cdot \vec{r}^{\prime} / \hbar} \quad \vec{p}_{\infty}=p_{\infty} \hat{c}_{r}
$$

Also, in the second exponential, since $z^{\prime} \equiv \hat{k} \cdot \vec{r}^{\prime}$,

$$
e^{\mathrm{i} p_{\infty} z^{\prime} / \hbar}=e^{\mathrm{i} \vec{p}_{\infty} \cdot \vec{r}^{\prime} / \hbar} \quad \vec{p}_{\infty}^{1}=p_{\infty} \hat{k}
$$

Writing out the complete expression (A.228) and comparing with (A.216) gives the constant $C_{\mathrm{f}}$ and hence the differential cross section.

## D. 48 About Lagrangian multipliers

This note will derive the Lagrangian multipliers for an example problem. Only calculus will be used. The example problem will be to find a stationary point of a function $f$ of four variables if there are two constraints. Different numbers of variables and constraints would work out in similar ways as this example.

The four variables that example function $f$ depends on will be denoted by $x_{1}, x_{2}, x_{3}$, and $x_{4}$. The two constraints will be taken to be equations of the form $g\left(x_{1}, x_{2}, x_{3}, x_{4}\right)=0$ and $h\left(x_{1}, x_{2}, x_{3}, x_{4}\right)=0$, for suitable functions $g$ and $h$. Constraints can always be brought in such a form by taking everything in the constraint's equation to the left-hand side of the equals sign.

So the example problem is:

$$
\begin{aligned}
\text { stationarize: } & f\left(x_{1}, x_{2}, x_{3}, x_{4}\right) \\
\text { subject to: } & g\left(x_{1}, x_{2}, x_{3}, x_{4}\right)=0, h\left(x_{1}, x_{2}, x_{3}, x_{4}\right)=0
\end{aligned}
$$

Stationarize means to find locations where the function has a minimum or a maximum, or any other point where it does not change under small changes of the variables $x_{1}, x_{2}, x_{3}, x_{4}$ as long as these satisfy the constraints.

The first thing to note is that rather than considering $f$ to be a function of $x_{1}, x_{2}, x_{3}, x_{4}$, you can consider it instead to be to be a function of $g$ and $h$ and only two additional variables from $x_{1}, x_{2}, x_{3}, x_{4}$, say $x_{3}$ and $x_{4}$ :

$$
f\left(x_{1}, x_{2}, x_{3}, x_{4}\right)=\tilde{f}\left(g, h, x_{3}, x_{4}\right)
$$

The reason you can do that is that you should in principle be able to reconstruct the two missing variables $x_{1}$ and $x_{2}$ given $g, h, x_{3}$, and $x_{4}$.

As a result, any small change in the function $f$, regardless of constraints, can be written using the expression for a total differential as:

$$
\mathrm{d} f=\frac{\partial \tilde{f}}{\partial g} \mathrm{~d} g+\frac{\partial \tilde{f}}{\partial h} \mathrm{~d} h+\frac{\partial \tilde{f}}{\partial x_{3}} \mathrm{~d} x_{3}+\frac{\partial \tilde{f}}{\partial x_{4}} \mathrm{~d} x_{4} .
$$

At the desired stationary point, acceptable changes in variables are those that keep $g$ and $h$ constant at zero; they have $\mathrm{d} g=0$ and $\mathrm{d} h=0$. So for $f$ to be stationary under all acceptable changes of variables, you must have that the final two terms are zero for any changes in variables. This means that the
partial derivatives in the final two terms must be zero since the changes $\mathrm{d} x_{3}$ and $\mathrm{d} x_{4}$ can be arbitrary.

For changes in variables that do go out of bounds, the change in $f$ will not be zero; that change will be given by the first two terms in the right-hand side. So, the erroneous changes in $f$ due to going out of bounds are these first two terms, and if we subtract them, we get zero net change for any arbitrary change in variables:

$$
\mathrm{d} f-\frac{\partial \tilde{f}}{\partial g} \mathrm{~d} g-\frac{\partial \tilde{f}}{\partial h} \mathrm{~d} h=0 \text { always. }
$$

In other words, if we "penalize" the change in $f$ for going out of bounds by amounts $\mathrm{d} g$ and $\mathrm{d} h$ at the rate above, any change in variables will produce a penalized change of zero, whether it stays within bounds or not.

The two derivatives at the stationary point in the expression above are the Lagrangian multipliers or penalty factors, call them $\epsilon_{1}=\partial \tilde{f} / \partial g$ and $\epsilon_{2}=\partial \tilde{f} / \partial h$. In those terms

$$
\mathrm{d} f-\epsilon_{1} \mathrm{~d} g-\epsilon_{2} \mathrm{~d} h=0
$$

for whatever is the change in the variables $g, h, x_{3}, x_{4}$, and that means for whatever is the change in the original variables $x_{1}, x_{2}, x_{3}, x_{4}$. Therefore, the change in the penalized function

$$
f-\epsilon_{1} g-\epsilon_{2} h
$$

is zero whatever is the change in the variables $x_{1}, x_{2}, x_{3}, x_{4}$.
In practical application, explicitly computing the Lagrangian multipliers $\epsilon_{1}$ and $\epsilon_{2}$ as the derivatives of function $\tilde{f}$ is not needed. You get four equations by putting the derivatives of the penalized $f$ with respect to $x_{1}$ through $x_{4}$ equal to zero, and the two constraints provide two more equations. Six equations is enough to find the six unknowns $x_{1}$ through $x_{4}, \epsilon_{1}$ and $\epsilon_{2}$.

## D. 49 The generalized variational principle

The purpose of this note is to verify directly that the variation of the expectation energy is zero at any energy eigenstate, not just the ground state.

Suppose that you are trying to find some energy eigenstate $\psi_{n}$ with eigenvalue $E_{n}$, and that you are close to it, but no cigar. Then the wave function can be written as

$$
\psi=\varepsilon_{1} \psi_{1}+\varepsilon_{2} \psi_{2}+\ldots+\varepsilon_{n-1} \psi_{n-1}+\left(1+\varepsilon_{n}\right) \psi_{n}+\varepsilon_{n+1} \psi_{n+1}+\ldots
$$

where $\psi_{n}$ is the one you want and the remaining terms together are the small error in wave function, written in terms of the eigenfunctions. Their coefficients $\varepsilon_{1}, \varepsilon_{2}, \ldots$ are small.

The normalization condition $\langle\psi \mid \psi\rangle=1$ is, using orthonormality:

$$
1=\varepsilon_{1}^{2}+\varepsilon_{2}^{2}+\ldots+\varepsilon_{n-1}^{2}+\left(1+\varepsilon_{n}\right)^{2}+\varepsilon_{n+1}^{2}+\ldots
$$

The expectation energy is

$$
\langle E\rangle=\varepsilon_{1}^{2} E_{1}+\varepsilon_{2}^{2} E_{2}+\ldots+\varepsilon_{n-1}^{2} E_{n-1}+\left(1+\varepsilon_{n}\right)^{2} E_{n}+\varepsilon_{n+1}^{2} E_{n+1}+\ldots
$$

or plugging in the normalization condition to eliminate $\left(1+\varepsilon_{n}\right)^{2}$

$$
\begin{aligned}
\langle E\rangle= & \varepsilon_{1}^{2}\left(E_{1}-E_{n}\right)+\varepsilon_{2}^{2}\left(E_{2}-E_{n}\right)+\ldots+ \\
& \varepsilon_{n-1}^{2}\left(E_{n-1}-E_{n}\right)+E_{n}+\varepsilon_{n+1}^{2}\left(E_{n+1}-E_{n}\right)+\ldots
\end{aligned}
$$

Assuming that the energy eigenvalues are arranged in increasing order, the terms before $E_{n}$ in this sum are negative and the ones behind $E_{n}$ positive. So $E_{n}$ is neither a maximum nor a minimum; depending on conditions $\langle E\rangle$ can be greater or smaller than $E_{n}$.

Now, if you make small changes in the wave function, the values of $\varepsilon_{1}, \varepsilon_{2}, \ldots$ will slightly change, by small amounts that will be indicated by $\delta \varepsilon_{1}, \delta \varepsilon_{2}, \ldots$, and you get

$$
\begin{aligned}
\delta\langle E\rangle= & 2 \varepsilon_{1}\left(E_{1}-E_{n}\right) \delta \varepsilon_{1}+2 \varepsilon_{2}\left(E_{2}-E_{n}\right) \delta \varepsilon_{2}+\ldots \\
& +2 \varepsilon_{n-1}\left(E_{n-1}-E_{n}\right) \delta \varepsilon_{n-1}+2 \varepsilon_{n+1}\left(E_{n+1}-E_{n}\right) \delta \varepsilon_{n+1}+\ldots
\end{aligned}
$$

This is zero when $\varepsilon_{1}=\varepsilon_{2}=\ldots=0$, so when $\psi$ is the exact eigenfunction $\psi_{n}$. And it is nonzero as soon as any of $\varepsilon_{1}, \varepsilon_{2}, \ldots$ is nonzero; a change in that coefficient will produce a nonzero change in expectation energy. So the variational condition $\delta\langle E\rangle=0$ is satisfied at the exact eigenfunction $\psi_{n}$, but not at any nearby different wave functions.

The bottom line is that if you locate the nearest wave function for which $\delta\langle E\rangle$ $=0$ for all acceptable small changes in that wave function, well, if you are in the vicinity of an energy eigenfunction, you are going to find that eigenfunction.

One final note. If you look at the expression above, it seems like none of the other eigenfunctions are eigenfunctions. For example, the ground state would be the case that $\varepsilon_{1}$ is one, and all the other coefficients zero. So a small change in $\varepsilon_{1}$ would seem to produce a change $\delta\langle E\rangle$ in expectation energy, and the expectation energy is supposed to be constant at eigenstates.

The problem is the normalization condition, whose differential form says that

$$
0=2 \varepsilon_{1} \delta \varepsilon_{1}+2 \varepsilon_{2} \delta \varepsilon_{2}+\ldots+2 \varepsilon_{n-1} \delta \varepsilon_{n-1}+2\left(1+\varepsilon_{n}\right) \delta \varepsilon_{n}+2 \varepsilon_{n+1} \delta \varepsilon_{n+1}+\ldots
$$

At $\varepsilon_{1}=1$ and $\varepsilon_{2}=\ldots=\varepsilon_{n-1}=1+\varepsilon_{n}=\varepsilon_{n+1}=\ldots=0$, this implies that the change $\delta \varepsilon_{1}$ must be zero. And that means that the change in expectation energy is in fact zero. You see that you really need to eliminate $\varepsilon_{1}$ from the list of coefficients near $\psi_{1}$, rather than $\varepsilon_{n}$ as the analysis for $\psi_{n}$ did, for the mathematics not to blow up. A coefficient that is not allowed to change at a point in the vicinity of interest is a confusing coefficient to work with.

## D. 50 Spin degeneracy

To see that generally speaking the basic form of the Hamiltonian produces energy degeneracy with respect to spin, but that it is not important for using the Born-Oppenheimer approximation, consider the example of three electrons.

Any three-electron energy eigenfunction $\psi^{\mathrm{E}}$ with $H \psi^{\mathrm{E}}=E^{\mathrm{E}} \psi^{\mathrm{E}}$ can be split into separate spatial functions for the distinct combinations of electron spin values as

$$
\begin{aligned}
\psi^{\mathrm{E}}= & \psi_{+++}^{\mathrm{E}} \uparrow \uparrow \uparrow+\psi_{+--}^{\mathrm{E}} \uparrow \downarrow \downarrow+\psi_{-+-}^{\mathrm{E}} \downarrow \uparrow \downarrow+\psi_{--+}^{\mathrm{E}} \downarrow \downarrow \uparrow+ \\
& \psi_{---\downarrow \downarrow \downarrow+\psi_{-++}^{\mathrm{E}} \downarrow \uparrow \uparrow \uparrow+\psi_{+-+}^{\mathrm{E}} \uparrow \downarrow \uparrow+\psi_{++-}^{\mathrm{E}} \uparrow \uparrow \downarrow .} .
\end{aligned}
$$

Since the assumed Hamiltonian $H$ does not involve spin, each of the eight spatial functions $\psi_{ \pm \pm \pm}$above will separately have to be an eigenfunction of the Hamiltonian with eigenvalue $E^{\mathrm{E}}$ if nonzero. In addition, since the first four functions have an odd number of spin up states and the second four an even number, the antisymmetry requirements apply only within the two sets, not between them. The exchanges only affect the order of the spin states, not their number. So the two sets satisfy the antisymmetry requirements individually.

It is now seen that given a solution for the first four wave functions, there is an equally good solution for the second four wave functions that is obtained by inverting all the spins. Since the spins are not in the Hamiltonian, inverting the spins does not change the energy. They have the same energy, but are different because they have different spins.

However, they are orthogonal because their spins are, and the spatial operations in the derivation of the Born-Oppenheimer approximation in the next note do not change that fact. So they turn out to lead to nuclear wave functions that do not affect each other. More precisely, the inner products appearing in the coefficients $a_{n \underline{n}}$ are zero because the spins are orthogonal.

## D. 51 Born-Oppenheimer nuclear motion

This note gives a derivation of the Born-Oppenheimer Hamiltonian eigenvalue problems (9.14) for the wave functions of the nuclei.

First consider an exact eigenfunction $\psi$ of the complete system, including both the electrons and the nuclei fully. Can it be related somehow to the simpler electron eigenfunctions $\psi_{1}^{\mathrm{E}}, \psi_{2}^{\mathrm{E}}, \ldots$ that ignored nuclear kinetic energy? Yes it can. For any given set of nuclear coordinates, the electron eigenfunctions are complete; they are the eigenfunctions of an Hermitian electron Hamiltonian. And that means that you can for any given set of nuclear coordinates write the exact wave function as

$$
\psi=\sum_{\underline{n}} c_{\underline{n}} \psi_{\underline{n}}^{\mathrm{E}}
$$

You can do this for any set of nuclear coordinates that you like, but the coefficients $c_{\underline{n}}$ will be different for different sets of nuclear coordinates. That is just another way of saying that the $c_{\underline{n}}$ are functions of the nuclear coordinates.

So, to be really precise, the wave function of $I$ electrons and $J$ nuclei can be written as:

$$
\begin{aligned}
& \psi\left(\vec{r}_{1}, S_{z 1}, \ldots, \vec{r}_{I}, S_{z I}, \vec{r}_{1}^{\mathrm{n}}, S_{z 1}^{\mathrm{n}}, \ldots, \vec{r}_{J}^{\mathrm{n}}, S_{z J}^{\mathrm{n}}\right)= \\
& \quad \sum_{\underline{n}} c_{\underline{n}}\left(\vec{r}_{1}^{\mathrm{n}}, S_{z 1}^{\mathrm{n}}, \ldots, \vec{r}_{J}^{\mathrm{n}}, S_{z J}^{\mathrm{n}}\right) \psi_{\underline{n}}^{\mathrm{E}}\left(\vec{r}_{1}, S_{z 1}, \ldots, \vec{r}_{I}, S_{z I} ; \vec{r}_{1}^{\mathrm{n}}, S_{z 1}^{\mathrm{n}}, \ldots, \vec{r}_{J}^{\mathrm{n}}, S_{z J}^{\mathrm{n}}\right)
\end{aligned}
$$

where superscripts n indicate nuclear coordinates. (The nuclear spins are really irrelevant, but it cannot hurt to keep them in.)

Consider what this means physically. By construction, the square electron eigenfunctions $\left|\psi_{\underline{n}}^{\mathrm{E}}\right|^{2}$ give the probability of finding the electrons assuming that they are in eigenstate $\underline{n}$ and that the nuclei are at the positions listed in the final arguments of the electron eigenfunction. But then the probability that the nuclei are actually at those positions, and that the electrons are actually in eigenstate $\psi_{\underline{n}}^{\mathrm{E}}$, will have to be $\left|c_{\underline{n}}\right|^{2}$. After all, the full wave function $\psi$ must describe the probability for the entire system to actually be in a specific state. That means that $c_{\underline{n}}$ must be the nuclear wave function $\psi_{\underline{n}}^{\mathbf{N}}$ for when the electrons are in energy eigenstate $\psi_{\underline{\underline{n}}}^{\mathrm{E}}$. So from now on, just call it $\psi_{\underline{n}}^{\mathrm{N}}$ instead of $c_{\underline{n}}$. The full wave function is then

$$
\begin{equation*}
\psi=\sum \psi_{\underline{n}}^{\mathrm{N}} \psi_{\underline{n}}^{\mathrm{E}} \tag{D.31}
\end{equation*}
$$

In the unsteady case, the $c_{\underline{n}}$, hence the $\psi_{\underline{n}}^{N}$, will also be functions of time. The $\psi_{\underline{n}}^{\mathrm{E}}$ will remain time independent as long as no explicitly time-dependent terms are added. The derivation then goes exactly the same way as the timeindependent Schrödinger equation (Hamiltonian eigenvalue problem) derived below, with i $\hbar \partial / \partial t$ replacing $E$.

So far, no approximations have been made; the only thing that has been done is to define the nuclear wave functions $\psi_{\underline{n}}^{N}$. But the objective is still to derive the claimed equation (9.14) for them. To do so plug the expression $\psi=$ $\sum \psi_{\underline{n}}^{\mathrm{N}} \psi_{\underline{n}}^{\mathrm{E}}$ into the exact Hamiltonian eigenvalue problem:

$$
\left[\widehat{T}^{\mathrm{N}}+\widehat{T}^{\mathrm{E}}+V^{\mathrm{NE}}+V^{\mathrm{EE}}+V^{\mathrm{NN}}\right] \sum_{\underline{n}} \psi_{\underline{\underline{N}}}^{\mathrm{N}} \psi_{\underline{n}}^{\mathrm{E}}=E \sum_{\underline{n}} \psi_{\underline{n}}^{\mathrm{N}} \psi_{\underline{\underline{E}}}^{\mathrm{E}}
$$

Note first that the eigenfunctions can be taken to be real since the Hamiltonian is real. If the eigenfunctions were complex, then their real and imaginary parts separately would be eigenfunctions, and both of these are real. This argument applies to both the electron eigenfunctions separately as well as to the full eigenfunction. The trick is now to take an inner product of the equation
above with a chosen electron eigenfunction $\psi_{n}^{\mathrm{E}}$. More precisely, multiply the entire equation by $\psi_{n}^{E}$, and integrate/sum over the electron coordinates and spins only, keeping the nuclear positions and spins at fixed values.

What do you get? Consider the terms in reverse order, from right to left. In the right hand side, the electron-coordinate inner product $\left\langle\psi_{n}^{\mathrm{E}} \mid \psi_{n}^{\mathrm{E}}\right\rangle_{e}$ is zero unless $\underline{n}=n$, and then it is one, since the electron wave functions are orthonormal for given nuclear coordinates. So all we have left in the right-hand side is $E \psi_{n}^{\mathrm{N}}$, Check, $E \psi_{n}^{\mathrm{N}}$ is the correct right hand side in the nuclear-wave-function Hamiltonian eigenvalue problem (9.14).

Turning to the latter four terms in the left-hand side, remember that by definition the electron eigenfunctions satisfy

$$
\left[\widehat{T}^{\mathrm{E}}+V^{\mathrm{NE}}+V^{\mathrm{EE}}+V^{\mathrm{NN}}\right] \psi_{\underline{n}}^{\mathrm{E}}=\left(E_{\underline{n}}^{\mathrm{E}}+V^{\mathrm{NN}}\right) \psi_{\underline{n}}^{\mathrm{E}}
$$

and if you then take an inner product of $\sum \psi_{n}^{\mathrm{N}}\left(E_{n}^{\mathrm{E}}+V^{\mathrm{NN}}\right) \psi_{n}^{\mathrm{E}}$ with $\psi_{n}^{\mathrm{E}}$, it is just like the earlier term, and you get $\left(E_{n}^{\mathrm{E}}+V^{\mathrm{NN}}\right) \psi_{n}^{\mathrm{N}}$. Check, that are two of the terms in the left-hand side of (9.14) that you need.

That leaves only the nuclear kinetic term, and that one is a bit tricky. Recalling the definition (9.5) of the kinetic energy operator $\widehat{T}^{\mathrm{N}}$ in terms of the nuclear coordinate Laplacians, you have

$$
-\sum_{j=1}^{J} \sum_{\alpha=1}^{3} \sum_{\underline{n}} \frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}} \frac{\partial^{2}}{\partial r_{\alpha j}^{\mathrm{n}}} \psi_{\underline{n}}^{\mathrm{N}} \psi_{\underline{n}}^{\mathrm{E}}
$$

Remember that not just the nuclear wave functions, but also the electron wave functions depend on the nuclear coordinates. So, if you differentiate out the product, you get

$$
-\sum_{j=1}^{J} \sum_{\alpha=1}^{3} \sum_{\underline{n}}\left[\frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}} \frac{\partial^{2} \psi_{\underline{n}}^{\mathrm{N}}}{\partial r_{\alpha j}^{\mathrm{n}}} \psi_{\underline{n}}^{\mathrm{E}}+\frac{\hbar^{2}}{m_{j}^{\mathrm{n}}} \frac{\partial \psi_{\underline{n}}^{\mathrm{N}}}{\partial r_{\alpha j}^{\mathrm{n}}} \frac{\partial \psi_{\underline{n}}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}}+\frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}} \psi_{\underline{n}}^{\mathrm{N}} \frac{\partial^{2} \psi_{\underline{n}}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}}\right]
$$

Now if you take the inner product with electron eigenfunction $\psi_{n}^{\mathrm{E}}$, the first term in the brackets gives you what you need, the expression for the kinetic energy of the nuclei. But you do not want the other two terms; these terms have the nuclear kinetic energy differentiations at least in part on the electron wave function instead of on the nuclear wave function.

Well, whether you like it or not, the exact equation is, collecting all terms and rearranging,

$$
\begin{equation*}
\left[\widehat{T}^{\mathrm{N}}+V^{\mathrm{NN}}+E_{n}^{\mathrm{E}}\right] \psi_{n}^{\mathrm{N}}=E \psi_{n}^{\mathrm{N}}+\sum_{\underline{n}} a_{n \underline{n}} \psi_{\underline{n}}^{\mathrm{N}} \tag{D.32}
\end{equation*}
$$

where

$$
\begin{gather*}
\widehat{T}^{\mathrm{N}}=-\sum_{j=1}^{J} \sum_{\alpha=1}^{3} \frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}} \frac{\partial^{2}}{\partial r_{\alpha j}^{\mathrm{n}}{ }^{2}}  \tag{D.33}\\
a_{n \underline{n}}=\sum_{j=1}^{J} \sum_{\alpha=1}^{3} \frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}}\left(2\left\langle\psi_{n}^{\mathrm{E}} \left\lvert\, \frac{\partial \psi_{\underline{\mathrm{E}}}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}}\right.\right\rangle \frac{\partial}{\partial r_{\alpha j}^{\mathrm{n}}}+\left\langle\psi_{n}^{\mathrm{E}} \left\lvert\, \frac{\partial^{2} \psi_{\underline{n}}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}{ }^{2}}\right.\right\rangle\right) \tag{D.34}
\end{gather*}
$$

The first thing to note is the final sum in (D.32). Unless you can talk away this sum as negligible, (9.14) is not valid. The "off-diagonal" coefficients, the $a_{n \underline{n}}$ for $\underline{n} \neq n$, are particularly bad news, because they produce interactions between the different potential energy surfaces, shifting energy from one value of $n$ to another. These off-diagonal terms are called "vibronic coupling terms." (The word is a contraction of "vibration" and "electronic," if you are wondering.)

Let's have a closer look at (D.33) and (D.34) to see how big the various terms really are. At first appearance it might seem that both the nuclear kinetic energy $\widehat{T}^{\mathrm{N}}$ and the coefficients $a_{n \underline{n}}$ can be ignored, since both are inversely proportional to the nuclear masses, hence apparently thousands of times smaller than the electronic kinetic energy included in $E_{n}^{\mathrm{E}}$. But do not go too quick here. First ballpark the typical derivative, $\partial / \partial r_{\alpha j}^{\mathrm{n}}$ when applied to the nuclear wave function. You can estimate such a derivative as $1 / \ell^{\mathrm{N}}$, where $\ell^{\mathrm{N}}$ is the typical length over which there are significant changes in a nuclear wave function $\psi_{n}^{\mathrm{N}}$. Well, there are significant changes in nuclear wave functions if you go from the middle of a nucleus to its outside, and that is a very small distance compared to the typical size of the electron blob $\ell^{\mathrm{E}}$. It means that the distance $\ell^{\mathrm{N}}$ is small. So the relative importance of the nuclear kinetic energy increases by a factor $\left(\ell^{\mathrm{E}} / \ell^{\mathrm{N}}\right)^{2}$ relative to the electron kinetic energy, compensating quite a lot for the much higher nuclear mass. So keeping the nuclear kinetic energy is definitely a good idea.

How about the coefficients $a_{n \underline{n}}$ ? Well, normally the electron eigenfunctions only change appreciable when you vary the nuclear positions over a length comparable to the electron blob scale $\ell^{\mathrm{E}}$. Think back of the example of the hydrogen molecule. The ground state separation between the nuclei was found as $0.87 \AA$. But you would not see a dramatic change in electron wave functions if you made it a few percent more or less. To see a dramatic change, you would have to make the nuclear distance $1.5 \AA$, for example. So the derivatives $\partial / \partial r_{\alpha j}^{\mathrm{n}}$ applied to the electron wave functions are normally not by far as large as those applied to the nuclear wave functions, hence the $a_{n \underline{n}}$ terms are relatively small compared to the nuclear kinetic energy, and ignoring them is usually justified. So the final conclusion is that equation (9.14) is usually justified.

But there are exceptions. If different energy levels get close together, the electron wave functions become very sensitive to small effects, including small changes in the nuclear positions. When the wave functions have become sensitive
enough that they vary significantly under nuclear position changes comparable in size to the nuclear wave function blobs, you can no longer ignore the $a_{n \underline{n}}$ terms and (9.14) becomes invalid.

You can be a bit more precise about that claim with a few tricks. Consider the factors

$$
\left\langle\psi_{n}^{\mathrm{E}} \left\lvert\, \frac{\partial \psi_{n}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}}\right.\right\rangle
$$

appearing in the $a_{n \underline{n}}$, (D.34). First of all, these factors are zero when $\underline{n}=$ $n$. The reason is that because of orthonormality, $\left\langle\psi_{n}^{\mathrm{E}} \mid \psi_{n}^{\mathrm{E}}\right\rangle=1$, and taking the $\partial / \partial r_{\alpha j}^{\mathrm{n}}$ derivative of that, noting that the eigenfunctions are real, you see that the factor is zero.

For $\underline{n} \neq n$, the following trick works:

$$
\begin{aligned}
\left\langle\psi_{n}^{\mathrm{E}}\right| \frac{\partial}{\partial r_{\alpha j}^{\mathrm{n}}} H^{\mathrm{E}}-H^{\mathrm{E}} \frac{\partial}{\partial r_{\alpha j}^{\mathrm{n}}}\left|\psi_{\underline{n}}^{\mathrm{E}}\right\rangle & =\left(E_{\underline{n}}^{\mathrm{E}}-E_{n}^{\mathrm{E}}\right)\left\langle\psi_{n}^{\mathrm{E}} \left\lvert\, \frac{\partial \psi_{\underline{n}}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}}\right.\right\rangle \\
& =\frac{Z_{j} e^{2}}{4 \pi \epsilon_{0}} \sum_{i=1}^{I}\left\langle\psi_{n}^{\mathrm{E}}\right| \frac{r_{\alpha j}^{\mathrm{n}}-r_{\alpha i}}{r_{i j}^{3}}\left|\psi_{\underline{n}}^{\mathrm{E}}\right\rangle
\end{aligned}
$$

The first equality is just a matter of the definition of the electron eigenfunctions and taking the second $H^{\mathrm{E}}$ to the other side, which you can do since it is Hermitian. The second equality is a matter of looking up the Hamiltonian in chapter 9.2.1 and then working out the commutator in the leftmost inner product. ( $V^{\mathrm{NN}}$ does not commute with the derivative, but you can use orthogonality on the cleaned up expression.) The bottom line is that the final inner product is finite, with no reason for it to become zero when energy levels approach. So, looking at the second equality, the first term in $a_{n \underline{n}}$, (D.34), blows up like $1 /\left(E_{\underline{n}}^{\mathrm{E}}-E_{n}^{\mathrm{E}}\right)$ when those energy levels become equal.

As far as the final term in $a_{n \underline{n}}$ is concerned, like the second term, you would expect it to become important when the scale of nontrivial changes in electron wave functions with nuclear positions becomes comparable to the size of the nuclear wave functions. You can be a little bit more precise by taking one more derivative of the inner product expression derived above,

$$
\left\langle\frac{\partial \psi_{n}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}} \left\lvert\, \frac{\partial \psi_{\underline{n}}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}}\right.\right\rangle+\left\langle\psi_{n}^{\mathrm{E}} \left\lvert\, \frac{\partial^{2} \psi_{\underline{n}}^{\mathrm{E}}}{\partial r_{\alpha j}^{\mathrm{n}}}\right.\right\rangle=\frac{\partial}{\partial r_{\alpha j}^{\mathrm{n}}} \frac{1}{E_{\underline{\underline{E}}}^{\mathrm{E}}-E_{n}^{\mathrm{E}}} \frac{Z_{j} e^{2}}{4 \pi \epsilon_{0}} \sum_{i=1}^{I}\left\langle\psi_{n}^{\mathrm{E}}\right| \frac{r_{\alpha j}^{\mathrm{n}}-r_{\alpha i}}{r_{i j}}\left|\psi_{\underline{n}}^{\mathrm{E}}\right\rangle
$$

The first term should not be large: while the left hand side of the inner product has a large component along $\psi_{\underline{\underline{n}}}^{\mathrm{E}}$, the other side has zero component and viceversa. The final term should be of order $1 /\left(E_{n}^{\mathrm{E}}-E_{n}^{\mathrm{E}}\right)^{2}$, as you can see if you first change the origin of the integration variable in the inner product to be at the nuclear position, to avoid having to differentiate the potential derivative. So you conclude that the second term of coefficient $a_{n \underline{n}}$ is of order $1 /\left(E_{n}^{\mathrm{E}}-E_{n}^{\mathrm{E}}\right)^{2}$.

In view of the fact that this term has one less derivative on the nuclear wave function, that is just enough to allow it to become significant at about the same time that the first term does.

The diagonal part of matrix $a_{n \underline{n}}$, i.e. the $a_{n n}$ terms, is somewhat interesting since it produces a change in effective energy without involving interactions with the other potential energy surfaces, i.e. without interaction with the $\psi_{\underline{n}}^{\mathbb{N}}$ for $\underline{n}$ $\neq n$. The diagonal part is called the "Born-Oppenheimer diagonal correction." Since as noted above, the first term in the expression (D.34) for the $a_{n \underline{n}}$ does not have a diagonal part, the diagonal correction is given by the second term.

Note that in a transient case that starts out as a single nuclear wave function $\psi_{n}^{\mathrm{N}}$, the diagonal term $a_{n n}$ multiplies the predominant nuclear wave function $\psi_{n}^{\mathrm{N}}$, while the off-diagonal terms only multiply the small other nuclear wave functions. So despite not involving any derivative of the nuclear wave function, the diagonal term will initially be the main correction to the Born-Oppenheimer approximation. It will remain important at later times.

## D. 52 Simplification of the Hartree-Fock energy

This note derives the expectation energy for a wave function given by a single Slater determinant.

First note that if you multiply out a Slater determinant

$$
\Psi=\left|\operatorname{det} \psi_{1}^{\mathrm{s}} \uparrow_{1}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \psi_{3}^{\mathrm{s}} \downarrow_{3}, \ldots\right\rangle
$$

you are going to get terms, or Hartree products if you want, of the form

$$
\frac{ \pm}{\sqrt{I!}} \psi_{n_{1}}^{\mathrm{s}}\left(\vec{r}_{1}\right) \imath_{n_{1}}\left(S_{z 1}\right) \psi_{n_{2}}^{\mathrm{s}}\left(\vec{r}_{2}\right) \imath_{n_{2}}\left(S_{z 2}\right) \psi_{n_{3}}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{n_{3}}\left(S_{z 3}\right) \ldots
$$

where the numbers $n_{1}, n_{2}, n_{3}, \ldots$ of the single-electron states can have values from 1 to $I$, but they must be all different. So there are $I$ ! such terms: there are $I$ possibilities among $1,2,3, \ldots, I$ for the number $n_{1}$ of the single-electron state for electron 1 , which leaves $I-1$ remaining possibilities for the number $n_{2}$ of the single-electron state for electron $2, I-2$ remaining possibilities for $n_{3}$, etcetera. That means a total of $I(I-1)(I-2) \ldots 21=I!$ terms. As far as the sign of the term is concerned, just don't worry about it. The only thing to remember is that whenever you exchange two $n$ values, it changes the sign of the term. It has to be, because exchanging $n$ values is equivalent to exchanging electrons, and the complete wave function must change sign under that.

To make the above more concrete, consider the example of a Slater determinant of three single-electron functions. It writes out to, taking $\sqrt{I!}$ to the other side for convenience,

$$
\left|\operatorname{det} \psi_{1}^{\mathrm{s} \imath_{1}}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \psi_{3}^{\mathrm{s}} \uparrow_{3}\right\rangle \sqrt{I!}=
$$

$$
\begin{aligned}
& +\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{1}\left(S_{z 1}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{2}\left(S_{z 2}\right) \psi_{3}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{3}\left(S_{z 3}\right) \\
& -\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{1}\left(S_{z 1}\right) \psi_{3}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{3}\left(S_{z 2}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{2}\left(S_{z 3}\right) \\
& -\psi_{2}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{2}\left(S_{z 1}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{1}\left(S_{z 2}\right) \psi_{3}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{3}\left(S_{z 3}\right) \\
& +\psi_{2}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{2}\left(S_{z 1}\right) \psi_{3}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{3}\left(S_{z 2}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{1}\left(S_{z 3}\right) \\
& +\psi_{3}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{3}\left(S_{z 1}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \downarrow_{1}\left(S_{z 2}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{2}\left(S_{z 3}\right) \\
& -\psi_{3}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{3}\left(S_{z 1}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{2}\left(S_{z 2}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{1}\left(S_{z 3}\right)
\end{aligned}
$$

The first two rows in the expansion cover the possibility that $n_{1}=1$, with the first one the possibility that $n_{2}=2$ and the second one the possibility that $n_{2}$ $=3$; note that then there are no choices left for $n_{3}$. Similarly the second two rows cover the two possibilities that $n_{1}=2$, and the third that $n_{1}=3$. You see that there are $3!=6$ Hartree product terms total.

Next, recall that the Hamiltonian consists of single-electron Hamiltonians $h_{i}^{e}$ and electron-pair repulsion potentials $v_{i i}^{e e}$. The expectation value of a single electron Hamiltonian $h_{i}^{e}$ will be done first. In forming the inner product $\langle\Psi| h_{i}^{e}|\Psi\rangle$, and taking $\Psi$ apart into its Hartree product terms as above, you are going to end up with a large number of individual terms that all look like

$$
\begin{aligned}
& \left\langle\frac{ \pm}{\sqrt{I!}} \psi_{n_{1}}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{n_{1}}\left(S_{z 1}\right) \psi_{n_{2}}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{n_{2}}\left(S_{z 2}\right) \ldots \psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{n_{i}}\left(S_{z i}\right) \ldots \psi_{n_{I}}^{\mathrm{s}}\left(\vec{r}_{I}\right) \uparrow_{n_{I}}\left(S_{z I}\right)\right| \\
& \quad h_{i}^{\mathrm{e}}\left|\frac{ \pm}{\sqrt{I!}} \psi_{\bar{n}_{1}}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{\bar{n}_{1}}\left(S_{z 1}\right) \psi_{\bar{n}_{2}}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{\bar{n}_{2}}\left(S_{z 2}\right) \ldots \psi_{\bar{n}_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{\bar{n}_{i}}\left(S_{z i}\right) \ldots \psi_{\bar{n}_{I}}^{\mathrm{s}}\left(\vec{r}_{I}\right) \uparrow_{\bar{n}_{I}}\left(S_{z I}\right)\right\rangle
\end{aligned}
$$

Note that overlines will be used to distinguish the wave function in the right hand side of the inner product from the one in the left hand side. Also note that to take this inner product, you have to integrate over $3 I$ scalar position coordinates, and sum over $I$ spin values.

But multiple integrals, and sums, can be factored into single integrals, and sums, as long as the integrands and limits only involve single variables. So you can factor out the inner product as

$$
\begin{aligned}
& \frac{ \pm}{\sqrt{I!}} \frac{ \pm}{\sqrt{I!}}\left\langle\psi_{n_{1}}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{n_{1}}\left(S_{z 1}\right) \mid \psi_{\bar{n}_{1}}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{\bar{n}_{1}}\left(S_{z 1}\right)\right\rangle \\
& \times\left\langle\psi_{n_{2}}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{n_{2}}\left(S_{z 2}\right) \mid \psi_{\bar{n}_{2}}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{\bar{n}_{2}}\left(S_{z 2}\right)\right\rangle \\
& \times \ldots \\
& \times\left\langle\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{n_{i}}\left(S_{z i}\right)\right| h_{i}^{\mathrm{e}}\left|\psi_{\bar{n}_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{\bar{n}_{i}}\left(S_{z i}\right)\right\rangle \\
& \times \ldots \\
& \times\left\langle\psi_{n_{I}}^{\mathrm{s}}\left(\vec{r}_{I}\right) \uparrow_{n_{I}}\left(S_{z I}\right) \mid \psi_{\bar{n}_{I}}^{\mathrm{s}}\left(\vec{r}_{I}\right) \uparrow_{\bar{n}_{I}}\left(S_{z I}\right)\right\rangle
\end{aligned}
$$

Now you can start the weeding-out process, because the single-electron functions are orthonormal. So factors in this product are zero unless all of the
following requirements are met:

$$
n_{1}=\bar{n}_{1}, n_{2}=\bar{n}_{2}, \ldots, n_{i-1}=\bar{n}_{i-1}, n_{i+1}=\bar{n}_{i+1}, \ldots, n_{I}=\bar{n}_{I}
$$

Note that $\left\langle\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{n_{i}}\left(S_{z i}\right)\right| h_{i}^{\mathrm{e}}\left|\psi_{\bar{n}_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{\bar{n}_{i}}\left(S_{z i}\right)\right\rangle$ does not require $n_{i}=\bar{n}_{i}$ for a nonzero value, since the single-electron functions are most definitely not eigenfunctions of the single-electron Hamiltonians, (you would wish things were that easy!) But now remember that the numbers $n_{1}, n_{2}, n_{3}, \ldots$ in an individual term are all different. So the numbers $n_{1}, n_{2}, \ldots, n_{i-1}, n_{i+1}, \ldots$ include all the numbers that are not equal to $n_{i}$. Then so do $\bar{n}_{1}, \bar{n}_{2}, \ldots, \bar{n}_{i-1}, \bar{n}_{i+1}, \ldots$, because they are the same. And since $\bar{n}_{i}$ must be different from all of those, it can only be equal to $n_{i}$ anyway.

So what is left? Well, with all the $\bar{n}$ values equal to the corresponding $n$ values, all the plain inner products are one on account of orthonormality, and the only thing left is:

$$
\frac{ \pm}{\sqrt{I!}} \frac{ \pm}{\sqrt{I!}}\left\langle\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \downarrow_{n_{i}}\left(S_{z i}\right)\right| h_{i}^{\mathrm{e}}\left|\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \mathfrak{\imath}_{n_{i}}\left(S_{z i}\right)\right\rangle
$$

Also, the two signs are equal, because with all the $\bar{n}$ values equal to the corresponding $n$ values, the wave function term in the right side of the inner product is the exact same one as in the left side. So the signs multiply to 1 , and you can further factor out the spin inner product, which is one since the spin states are normalized:

$$
\frac{1}{I!}\left\langle\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right)\right| h_{i}^{\mathrm{e}}\left|\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right)\right\rangle\left\langle\imath_{n_{i}}\left(S_{z i}\right) \mid \uparrow_{n_{i}}\left(S_{z i}\right)\right\rangle=\frac{1}{I!}\left\langle\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right)\right| h_{i}^{\mathrm{e}}\left|\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right)\right\rangle \equiv \frac{1}{I!} E_{n}^{\mathrm{e}}
$$

where for brevity the remaining inner product was called $E_{n}^{e}$. Normally you would call it $E_{n_{i} i}^{e}$, but an inner product integral does not care what the integration variable is called, so the thing has the same value regardless what the electron $i$ is. Only the value of the single-electron function number $n_{i}=n$ makes a difference.

Next, how many such terms are there for a given electron $i$ and singleelectron function number $n$ ? Well, for a given $n$ value for electron $i$, there are $I-1$ possible values left among $1,2,3, \ldots$ for the $n$ value of the first of the other electrons, then $I-2$ left for the second of the other electrons, etcetera. So there are a total of $(I-1)(I-2) \ldots 1=(I-1)$ ! such terms. Since $(I-1)!/ I!=1 / I$, if you sum them all together you get a total contribution from terms in which electron $i$ is in state $n$ equal to $E_{n}^{e} / I$. Summing over the $I$ electrons kills off the factor $1 / I$ and so you finally get the total energy due to the single-electron Hamiltonians as

$$
\sum_{n=1}^{I} E_{n}^{\mathrm{e}} \quad E_{n}^{\mathrm{e}}=\left\langle\psi_{n}^{\mathrm{s}}(\vec{r})\right| h^{\mathrm{e}}\left|\psi_{n}^{\mathrm{s}}(\vec{r})\right\rangle
$$

You might have guessed that answer from the start. Since the inner product integral is the same for all electrons, the subscripts $i$ have been omitted.

The good news is that the reasoning to get the Coulomb and exchange contributions is pretty much the same. A single electron to electron repulsion term $v_{i i}^{\text {ee }}$ between an electron numbered $i$ and another numbered $\underline{i}$ makes a contribution to the expectation energy equal to $\langle\Psi| v_{i \underline{i}}^{\mathrm{ee}}|\Psi\rangle$, and if you multiply out $\Psi$, you get terms of the general form:

$$
\begin{aligned}
& \frac{1}{I!}\left\langle\psi_{n_{1}}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{n_{1}}\left(S_{z 1}\right) \psi_{n_{2}}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{n_{2}}\left(S_{z 2}\right) \ldots \psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{n_{i}}\left(S_{z i}\right) \ldots \psi_{n_{\underline{i}}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right) \uparrow_{n_{\underline{i}}}\left(S_{z \underline{i}}\right) \ldots\right| \\
& \quad v_{i \underline{i}}^{\mathrm{ee}}\left|\psi_{\bar{n}_{1}}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{\bar{n}_{1}}\left(S_{z 1}\right) \psi_{\bar{n}_{2}}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{\bar{n}_{2}}\left(S_{z 2}\right) \ldots \psi_{\bar{n}_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{\bar{n}_{i}}\left(S_{z i}\right) \ldots \psi_{\bar{n}_{\underline{i}}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right) \uparrow_{\bar{n}_{\underline{i}}}\left(S_{z \underline{\underline{i}}}\right) \ldots\right\rangle
\end{aligned}
$$

You can again split into a product of individual inner products, except that you cannot split between electrons $i$ and $\underline{i}$ since $v_{i i}^{\text {ee }}$ involves both electrons in a nontrivial way. Still, you get again that all the other $n$ values must be the same as the corresponding $\bar{n}$ values, eliminating those inner products from the expression:

$$
\frac{1}{I!}\left\langle\psi_{n_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \downarrow_{n_{i}}\left(S_{z i}\right) \psi_{n_{\underline{i}}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right) \rrbracket_{n_{\underline{i}}}\left(S_{z \underline{i}}\right)\right| v_{i \underline{i} \underline{e}}^{\mathrm{ee}}\left|\psi_{\bar{n}_{i}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{\bar{n}_{i}}\left(S_{z i}\right) \psi_{\bar{n}_{\underline{\underline{i}}}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right) \uparrow_{\bar{n}_{\underline{n_{\underline{E}}}}}\left(S_{z \underline{i}}\right)\right\rangle
$$

For given values of $n_{i}$ and $n_{\underline{i}}$, there are $(I-2)$ ! equivalent terms, since that is the number of possibilities left for the $n=\bar{n}$-values of the other $I-2$ electrons.

Next, $\bar{n}_{i}$ and $\bar{n}_{\underline{i}}$ must together be the same pair of numbers as $n_{i}$ and $n_{\underline{i}}$, since they must be the two numbers left by the set of numbers not equal to $\bar{n}_{i}$ and $n_{\underline{i}}$. But that still leaves two possibilities, they can be in the same order or in reversed order:

$$
\bar{n}_{i}=n_{i}, \bar{n}_{\underline{i}}=n_{\underline{i}} \quad \text { or } \quad \bar{n}_{i}=n_{\underline{i}}, \bar{n}_{\underline{i}}=n_{i}
$$

The first possibility gives rise to the Coulomb terms, the second to the exchange ones. Note that the former case represents an inner product involving a Hartree product with itself, and the latter case an inner product of a Hartree product with the Hartree product that is the same save for the fact that it has $n_{i}$ and $n_{\underline{i}}$ reversed, or equivalently, electrons $i$ and $\underline{i}$ exchanged.

Consider the Coulomb terms first. For those the two Hartree products in the inner product are the same, so their signs multiply to one. Also, their spin states will be the same, so that inner product will be one too. And as noted there are $(I-2)$ ! equivalent terms for given $n_{i}$ and $n_{\underline{i}}$, so for each pair of electrons $i$ and $\underline{i} \neq i$, and each pair of states $n=n_{i}$ and $\underline{n}=n_{\underline{i}}$, you get one term

$$
\frac{1}{I(I-1)} J_{n \underline{n}}
$$

with

$$
J_{n \underline{n}} \equiv\left\langle\psi_{n}^{\mathrm{s}}(\vec{r}) \psi_{\underline{n}}^{\mathrm{s}}(\underline{\vec{r}})\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}(\vec{r}) \psi_{\underline{n}}^{\mathrm{s}}(\underline{\vec{r}})\right\rangle
$$

Again, the $J_{n \underline{n}}$ are the same regardless of what $i$ and $\underline{i}$ are; they depend only on what $n=n_{i}$ and $\underline{n}=n_{\underline{i}}$ are. So the subscripts $i$ and $\underline{i}$ were left out, after setting $\vec{r}=\vec{r}_{i}$ and $\underline{\vec{r}}=\vec{r}_{\underline{i}}$.

You now need to sum over all pairs of electrons with $i \neq \underline{i}$ and pairs of single-electron function numbers $n \neq \underline{n}$. Since there are a total of $I(I-1)$ electron pairs, it takes out the factor $1 / I(I-1)$, and you get a contribution to the energy

$$
\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{n=1 \\ \underline{n} \neq n}}^{I} J_{n \underline{n}}
$$

The factor $\frac{1}{2}$ was added since for every electron pair, you are summing both $v_{i \underline{i}}^{\text {ee }}$ and $v_{i i}^{\mathrm{ee}}$, and that counts the same energy twice.

The exchange integrals go exactly the same way; the only differences are that the Hartree product in the right hand side of the inner product has the values of $\bar{n}_{i}$ and $\bar{n}_{\underline{i}}$ reversed, producing a change of sign, and that the inner product of the spins is not trivial. Define

$$
K_{n \underline{n}} \equiv\left\langle\psi_{n}^{\mathrm{s}}(\vec{r}) \psi_{\underline{n}}^{\mathrm{s}}(\underline{\vec{r}})\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}}(\vec{r}) \psi_{n}^{\mathrm{s}}(\underline{\vec{r}})\right\rangle
$$

and then the total contribution is

$$
-\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{n=1 \\ \underline{n} \neq n}}^{I} K_{n \underline{n}}\left\langle\hat{\imath}_{n} \mid \hat{\imath}_{\underline{n}}\right\rangle^{2}
$$

Finally, you can leave the constraint $\underline{n} \neq n$ on the sums away since $K_{n n}=$ $J_{n n}$, so they cancel each other.

## D. 53 Integral constraints

This note verifies the mentioned constraints on the Coulomb and exchange integrals.

To verify that $J_{n n}=K_{n n}$, just check their definitions.
The fact that

$$
\begin{aligned}
J_{n \underline{n}} & =\left\langle\psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)\right| v_{i \underline{i}}^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{\underline{\underline{i}}}\right)\right\rangle \\
& =\int_{\text {all } \vec{r}_{i}} \int_{\text {all } \vec{r}_{\underline{\underline{l}}}}\left|\psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)\right|^{2} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i \underline{i}}} \mathrm{~d}^{3} \vec{r}_{i} \mathrm{~d}^{3} \vec{r}_{\underline{\underline{i}}} .
\end{aligned}
$$

is real and positive is self-evident, since it is an integral of a real and positive function.

The fact that

$$
\begin{aligned}
K_{n \underline{n}} & =\left\langle\psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)\right| v_{\underline{i \underline{i}}}^{\mathrm{ee}}\left|\psi_{\underline{\underline{n}}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{n}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)\right\rangle \\
& =\int_{\text {all } \vec{r}_{i}} \int_{\operatorname{all}_{\underline{r_{\underline{\underline{r}}}}}} \psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right)^{*} \psi_{\underline{\underline{s}}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)^{*} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i \underline{i}}} \psi_{\underline{\underline{s}}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{n}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right) \mathrm{d}^{3} \vec{r}_{i} \mathrm{~d}^{3} \vec{r}_{\underline{i}}
\end{aligned}
$$

is real can be seen by taking complex conjugate, and then noting that the names of the integration variables do not make a difference, so you can swap them.

The same name swap shows that $J_{n \underline{n}}$ and $K_{n \underline{n}}$ are symmetric matrices; $J_{n \underline{n}}$ $=J_{\underline{n} n}$ and $K_{n \underline{n}}=K_{\underline{n} n}$.
$\bar{T}$ That $K_{n \underline{n}} \overline{\text { is }}$ positive is a bit trickier; write it as

$$
\int_{\text {all } \vec{r}_{i}}-e f^{*}\left(\vec{r}_{i}\right)\left(\int_{\text {all }} \frac{-e f\left(\vec{r}_{\underline{\underline{r}}}^{\underline{\underline{~}}}\right)}{4 \pi \epsilon_{0}} \frac{1}{r_{i \underline{i}}} \mathrm{~d}^{3} \vec{r}_{\underline{i}}\right) \mathrm{d}^{3} \vec{r}_{i}
$$

with $f=\psi_{\underline{n}}^{s^{*}} \psi_{n}^{\mathrm{s}}$. The part within parentheses is just the potential $V\left(\vec{r}_{i}\right)$ of a distribution of charges with density $-e f$. Sure, $f$ may be complex but that merely means that the potential is too. The electric field is minus the gradient of the potential, $\overrightarrow{\mathcal{E}}=-\nabla V$, and according to Maxwell's equation, the divergence of the electric field is the charge density divided by $\epsilon_{0}: \operatorname{div} \overrightarrow{\mathcal{E}}=-\nabla^{2} V=-e f / \epsilon_{0}$. So $-e f^{*}=-\epsilon_{0} \nabla^{2} V^{*}$ and the integral is

$$
-\epsilon_{0} \int_{\text {all } \vec{r}_{i}} V \nabla^{2} V^{*} \mathrm{~d}^{3} \vec{r}_{i}
$$

and integration by parts shows it is positive. Or zero, if $\psi_{\underline{n}}^{\mathbf{s}}$ is zero wherever $\psi_{n}^{\mathbf{s}}$ is not, and vice versa.

To show that $J_{n \underline{n}} \geqslant K_{n \underline{n}}$, note that

$$
\left\langle\psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)-\psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{n}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{\underline{\underline{r}}}\right)-\psi_{\underline{n}}^{\mathrm{s}}\left(\vec{r}_{i}\right) \psi_{n}^{\mathrm{s}}\left(\vec{r}_{\underline{i}}\right)\right\rangle
$$

is nonnegative, for the same reasons as $J_{n \underline{n}}$ but with $\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}-\psi_{\underline{n}}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}$ replacing $\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}$. If you multiply out the inner product, you get that $2 \bar{J}_{n \underline{n}}^{n}-2 K_{n \underline{n}}$ is nonnegative, so $J_{n \underline{n}} \geqslant K_{n \underline{n}}$.

## D. 54 Derivation of the Hartree-Fock equations

This note derives the canonical Hartree-Fock equations. It will use some linear algebra; see the Notations section under "matrix" for some basic concepts. The derivation will be performed under the normally stated rules of engagement that the orbitals are of the form $\psi_{n}^{\mathbf{s}} \uparrow$ or $\psi_{n}^{\mathbf{s}} \downarrow$. So the spins are chosen, and only the spatial orbitals $\psi_{n}^{\mathrm{s}}$ are to be found.

The derivations must allow for the fact that in restricted Hartree-Fock, it is required that pairs of spin-up and spin-down orbitals have the same spatial
orbital. So there are three possible kinds of spatial orbitals. A spatial orbital may produce a single unpaired spin orbital that is spin-up, or a single unpaired spin orbital that is spin-down, or a pair of spin-up and spin-down orbitals with the same spatial orbital. These three types of spatial orbitals will be referred to as unpaired spin-up, unpaired spin-down, and restricted. Note that these names do not refer to properties of the spatial orbits themselves, of course, but to the properties of the spin orbits that these spatial orbitals produce.

Assume that there are $N_{\mathrm{u}}$ spin-up spatial orbitals, $N_{\mathrm{d}}$ spin-down ones, and $N_{\mathrm{r}}$ restricted ones. The total number of spatial orbitals, call it N , is then

$$
N=N_{\mathrm{u}}+N_{\mathrm{d}}+N_{\mathrm{r}}
$$

and that is the total number of unknown spatial orbitals to find. A corresponding number of $N$ equations will be needed for them.

However, the total number of spin orbitals, $I$, is larger than $N$ by an additional amount $N_{\mathrm{r}}$, because the restricted spatial orbitals appear in both spin-up and spin-down versions. That makes the mathematics messy.

Things become a bit easier if the ordering of the orbitals is specified a priori. The ordering makes no difference physically. So it will be assumed that the spatial orbitals are ordered with the unpaired spin-up ones first, the unpaired spin-down ones second, and the restricted ones last. The ordering of the spin orbitals will be the same as that of the spatial orbitals, but with the restricted orbitals at the end appearing twice; first in the spin-up versions and then in the spin-down versions.

To find the spatial orbitals, the variational method as discussed in chapter 9.1.3 says that the expectation energy $\langle E\rangle$ must be unchanged under small changes in the orbitals, provided that the orbitals remain orthonormal. To easily enforce that orthonormality constraint requires that terms are added to the change in orbitals that penalize for any going out of bounds.

To do so, first note that $\langle E\rangle$ can be considered to be a real function from the real and imaginary parts of the spatial orbitals, and both these parts are real functions. The condition that any spatial orbital $\psi_{n}^{\mathrm{s}}$ must be normalized means that the inner product of the orbital with itself must be 1 ,

$$
\left\langle\psi_{n}^{\mathrm{s}} \mid \psi_{n}^{\mathrm{s}}\right\rangle=1
$$

This condition is real too. However, the condition that any spatial mode $\psi_{n}^{\mathrm{s}}$ must be orthogonal to any other spatial mode $\psi_{\underline{n}}^{s}$ means that the inner product of the two modes must be zero,

$$
\left\langle\psi_{n}^{\mathrm{s}} \mid \psi_{\underline{n}}^{\mathrm{s}}\right\rangle=0
$$

In general this condition has both a real and an imaginary component. But it can be written as two real conditions;

$$
\frac{1}{2}\left(\left\langle\psi_{n}^{\mathrm{s}} \mid \psi_{\underline{n}}^{\mathrm{s}}\right\rangle+\left\langle\psi_{\underline{n}}^{\mathrm{s}} \mid \psi_{n}^{\mathrm{s}}\right\rangle\right)=0, \quad \frac{1}{2} \mathrm{i}\left(\left\langle\psi_{n}^{\mathrm{s}} \mid \psi_{\underline{n}}^{\mathrm{s}}\right\rangle-\left\langle\psi_{\underline{n}}^{\mathrm{s}} \mid \psi_{n}^{\mathrm{s}}\right\rangle\right)=0
$$

The reason is that if you swap the sides in an inner product, you get the complex conjugate; therefore the first equation above is the real part of the inner product and the second the imaginary part.

Since we now have a completely real problem in real independent variables, the penalty factors (the Lagrangian multipliers) in the problem will be real too. For reasons evident in a second, the penalty factor for the normalization condition above will be called $\epsilon_{n n}$, while the ones for the two real orthogonality conditions will be called $2 \epsilon_{n n, r}$ and $2 \epsilon_{n n, i}$, respectively. To avoid enforcing the same orthogonality condition twice, it is here assumed that $\underline{n}>n$.

The reason for these notations is that in terms of them, the penalized variational condition that the spatial orbitals must satisfy, chapter 9.1.3, takes the simple form

$$
\delta\langle E\rangle-\sum_{n=1}^{N} \sum_{\underline{n}=1}^{N} \epsilon_{n \underline{n}} \delta\left\langle\psi_{n}^{\mathrm{s}} \mid \psi_{\underline{n}}^{\mathrm{s}}\right\rangle=0
$$

where $\delta$ denotes a small change in the following quantity, $\underline{n}$ is now allowed to be both smaller or larger than $n$, and $\epsilon_{n \underline{n}}$ is a Hermitian matrix, meaning that $\epsilon_{\underline{n} n}=\epsilon_{n \underline{n}}^{*}$

Note however that two spatial orbitals do not have to be orthogonal if one is a unpaired spin-up one and the other an unpaired spin-down one. In that case the spins take care of orthogonality. This can be accomodated by stipulating that the penalty factors of the corresponding constraints are zero,

$$
\epsilon_{n \underline{n}}=0 \text { if } \psi_{n}^{\mathrm{s}} \text { is spin-up and } \psi_{n}^{\mathrm{s}} \text { is spin-down, or vice versa }
$$

Next the variational condition is to be evaluated for a small change $\delta \psi_{m}^{\mathrm{s}}$ in a sample spatial wave function $\psi_{m}^{\mathrm{s}}$ where $m$ is no larger than $N$. This is straightforward for the inner products in the penalty terms. However, the expectation value of energy $\langle E\rangle$ was obtained in chapter 9.3.3 in terms of the spin, rather than spatial orbitals:
$\langle E\rangle=\sum_{n=1}^{I}\left\langle\psi_{n}^{\mathrm{s}}\right| h^{\mathrm{e}}\left|\psi_{n}^{\mathrm{s}}\right\rangle$

$$
+\frac{1}{2} \sum_{n=1}^{I} \sum_{\underline{n}=1}^{I}\left\langle\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right\rangle-\frac{1}{2} \sum_{n=1}^{I} \sum_{\underline{n}=1}^{I}\left\langle\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}\right\rangle\left\langle\mathfrak{\imath}_{n} \mid \uparrow_{\underline{n}}\right\rangle^{2}
$$

(From here on, the argument of the first orbital of a pair in either side of an inner product is taken to be the first inner product integration variable $\vec{r}$ and the argument of the second orbital is the second integration variable $\underline{\vec{r}}$ )

Taking that into account, the variational condition for the $\delta \psi_{m}^{\mathrm{s}}$ takes the messy form

$$
[2 ?]\left(\left\langle\delta \psi_{m}^{\mathrm{s}}\right| h^{\mathrm{e}}\left|\psi_{m}^{\mathrm{s}}\right\rangle+\left\langle\psi_{m}^{\mathrm{s}}\right| h^{\mathrm{e}}\left|\delta \psi_{m}^{\mathrm{s}}\right\rangle\right)
$$

$$
\begin{aligned}
& +[2 ?] \frac{1}{2} \sum_{\underline{n}=1}^{I}\left(\left\langle\delta \psi_{m}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right\rangle+\left\langle\psi_{m}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\delta \psi_{m}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right\rangle\right) \\
& +[2 ?] \frac{1}{2} \sum_{n=1}^{I}\left(\left\langle\psi_{n}^{\mathrm{s}} \delta \psi_{m}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}} \psi_{m}^{\mathrm{s}}\right\rangle+\left\langle\psi_{n}^{\mathrm{s}} \psi_{m}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}} \delta \psi_{m}^{\mathrm{s}}\right\rangle\right) \\
& -\frac{1}{2} \sum_{\underline{n}=1}^{I}\left(\left\langle\delta \psi_{m}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}} \psi_{m}^{\mathrm{s}}\right\rangle+\left\langle\psi_{m}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}} \delta \psi_{m}^{\mathrm{s}}\right\rangle\right)\left[\left.\left\langle{\underset{\imath}{m}}_{m}\right| \hat{\imath}_{\underline{n}}\right|^{2} ?\right] \\
& -\frac{1}{2} \sum_{n=1}^{I}\left(\left\langle\psi_{n}^{\mathrm{s}} \delta \psi_{m}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}\right\rangle+\left\langle\psi_{n}^{\mathrm{s}} \psi_{m}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\delta \psi_{m}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}\right\rangle\right)\left[\left\langle\left\{_{n}\left|\uparrow_{m}\right\rangle^{2} ?\right]\right.\right. \\
& -\sum_{\underline{n}=1}^{N} \epsilon_{m \underline{n}}\left\langle\delta \psi_{m}^{\mathrm{s}} \mid \psi_{\underline{n}}^{\mathrm{s}}\right\rangle-\sum_{n=1}^{N} \epsilon_{n m}\left\langle\psi_{n}^{\mathrm{s}} \mid \delta \psi_{m}^{\mathrm{s}}\right\rangle=0
\end{aligned}
$$

Here [2?] means to insert a factor 2 there if $m$ is one of the restricted spatial orbitals, because each of the two corresponding spin orbitals produces a term like that. And $\left[\langle\mathcal{N}, \mid \mathfrak{i} .\rangle^{2}\right.$ ?] means leave away this inner product if $m$ is one of the restricted spatial orbitals, because exactly one of the two corresponding spin orbitals has that inner product equal to one, and the other has it zero.

Note that the difference between $\underline{n}$ and $n$ can from now on be ignored; the name of a summation variable makes no difference for the result, and there are no longer name conflicts in the individual terms. Note also that the sums over $n$ (or $\underline{n}$ ) with upper limit $I$ include the restricted spatial orbitals twice, once for each spin direction.

The second term in each row in the expression above is just the complex conjugate of the first. These second terms can be thrown out using the same trick as in chapter 9.1.3. (In other words, average with the same equation with $\delta \psi_{m}^{\mathrm{s}}$ replaced by $-\mathrm{i} \delta \psi_{m}^{\mathrm{s}}$ and divided by i.) And the integrals with the factors $\frac{1}{2}$ are pairwise the same; the difference is just a name swap of the inner product integration variables. So all there is really left is

$$
\begin{aligned}
& {[2 ?]\left\langle\delta \psi_{m}^{\mathrm{s}}\right| h^{\mathrm{e}}\left|\psi_{m}^{\mathrm{s}}\right\rangle+} \\
& +[2 ?] \sum_{n=1}^{I}\left\langle\delta \psi_{m}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}\right\rangle \\
& -\sum_{n=1}^{I}\left\langle\delta \psi_{m}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}} \psi_{m}^{\mathrm{s}}\right\rangle\left[\left\langle\uparrow_{n} \mid \downarrow_{m}\right\rangle^{2} ?\right] \\
& -\sum_{n=1}^{N} \epsilon_{m n}\left\langle\delta \psi_{m}^{\mathrm{s}} \mid \psi_{n}^{\mathrm{s}}\right\rangle
\end{aligned}
$$

Now write out the inner product over the first position coordinate $\vec{r}$, being the argument of $\delta \psi_{m}^{\mathrm{s}}$, for all terms:

$$
\begin{aligned}
& \int_{\text {all } \vec{r}} \delta \psi_{m}^{\mathrm{s}}{ }^{*}( \\
& \quad[2 ?] h^{\mathrm{e}} \psi_{m}^{\mathrm{s}} \\
& \quad+[2 ?] \sum_{n=1}^{I}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}} \\
& \quad-\sum_{n=1}^{I}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}\left[\left\langle\uparrow_{n} \mid \imath_{m}\right\rangle^{2} ?\right] \\
& \quad-\sum_{n=1}^{N} \epsilon_{m n} \psi_{n}^{\mathrm{s}} \\
& \quad) \mathrm{d}^{3} \vec{r}=0
\end{aligned}
$$

If this integral is to be zero for whatever is $\delta \psi_{m}^{s}$, then the terms within the parentheses must be zero. (Otherwise just take $\delta \psi_{m}^{s}$ proportional to the parenthetical expression; you would get the norm of the expression, and that is only zero if the expression is.)

Unavoidably then, the following equations, one for each value of $m$, must be satisfied:

$$
[2 ?] h^{\mathrm{e}} \psi_{m}^{\mathrm{s}}+[2 ?] \sum_{n=1}^{I}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}-\sum_{n=1}^{I}\left[\left\langle\hat{\imath}_{n} \mid \uparrow_{m}\right\rangle^{2} ?\right]\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}=\sum_{n=1}^{N} \epsilon_{m n} \psi_{n}^{\mathrm{s}}
$$

This can be cleaned up a bit by dividing by [2?]:

$$
h^{\mathrm{e}} \psi_{m}^{\mathrm{s}}+\sum_{n=1}^{I}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}-\sum_{n=1}^{I}\left\{\left\langle\begin{array}{c}
\hat{\imath}_{n}\left|\uparrow_{m}\right\rangle^{2} \\
\frac{1}{2}
\end{array}\right\}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}=\left\{\begin{array}{l}
1 \\
\frac{1}{2}
\end{array}\right\} \sum_{n=1}^{N} \epsilon_{m n} \psi_{n}^{\mathrm{s}}\right.
$$

These are the general Hartree-Fock equations, one for each $m \leqslant N$ The upper value between braces applies if the spatial orbital $\psi_{m}^{\mathrm{s}}$ is not a restricted one; otherwise the lower value applies. Recall that the sums with upper limit $I$ include the restricted spatial orbitals twice. And that $\epsilon_{m n}$ is zero if spatial orbital $\psi_{m}^{\mathrm{s}}$ is unpaired spin-up and $\psi_{n}^{\mathrm{s}}$ unpaired spin-down or vice-versa. For such index values, $\left\langle\imath_{m} \mid \uparrow_{n}\right\rangle$ is zero too.

Note that the general Hartree-Fock equation above includes $N$ "eigenvalues" $\epsilon_{m n}$. The canonical equations include just a single eigenvalue $\epsilon_{m}$. So to get the
canonical Hartree-Fock equations, the sum in the right hand side must be further simplified to the form $\epsilon_{m} \psi_{m}^{\mathrm{s}}$.

The restricted closed-shell Hartree-Fock case will be done first, since it is the easiest one. Every spatial orbital is restricted, so the lower choice in the curly brackets always applies. The summation upper limits $I$, being the number of spin orbitals, can be reduced to the number of spatial orbitals $N$ by adding a factor 2 . We can also get rid of the factor $\frac{1}{2}$ in front of the $\epsilon_{m n}$ by simply redefining them by that factor. So for restricted closed-shell Hartree-Fock

$$
h^{\mathrm{e}} \psi_{m}^{\mathrm{s}}+2 \sum_{n=1}^{N}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}-\sum_{n=1}^{N}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}=\sum_{n=1}^{N} \epsilon_{m n} \psi_{n}^{\mathrm{s}}
$$

Now the reason why all these $\epsilon_{m n}$ are there is because the set of $N$ spatial orbitals that gives the lowest energy state are not unique. The equation above applies to a typical set. Only a special set will get rid of the $\epsilon_{m n}$ for $n$ not equal to $m$, leaving only $\epsilon_{m m}$, which can then be defined to be $\epsilon_{m}$.

Each orbital in the special set will be some combination of the orbitals in the typical set above. In particular, any orbital in the special set, call it $\bar{\psi}_{\nu}^{s}$, will be a linear combination of the orbitals $\psi_{n}^{\mathrm{s}}$ in the typical set as follows:

$$
\bar{\psi}_{\nu}^{\mathrm{s}} \equiv \sum_{n=1}^{N} c_{n, \nu} \psi_{n}^{\mathrm{s}} \quad \text { for any } \nu=1,2, \ldots, N
$$

where the numbers $c_{1, \nu}, c_{2, \nu}, \ldots$ are the multiples of the typical orbitals $\psi_{1}^{\mathrm{s}}, \psi_{2}^{\mathrm{s}}$,
.. The complete set of numbers $c_{n . \nu}$ for all possible values of both $n$ and $\nu$ can be written as a "matrix," a table of numbers. This matrix will be indicated by $C$. The first index in $c_{n, \nu}, n$, says what row in $C$ that coefficient is in, and the second index, $\nu$, what column.

The multiples $c_{n, \nu}$ cannot be arbitrary, because the special orbitals must still be orthonormal. As noted earlier, they will be if they are normalized (so the inner product of any orbital with itself is 1 ), and mutually orthogonal (so the inner product of any orbital with any other one is zero). In short, the requirement is that

$$
\left\langle\bar{\psi}_{\mu}^{\mathrm{s}} \mid \bar{\psi}_{\nu}^{\mathrm{s}}\right\rangle=\delta_{\mu \nu}
$$

where $\delta_{\mu \nu}$ is one if $\mu=\nu$, and zero otherwise. The set of numbers $\delta_{\mu \nu}$ is called the "Kronecker delta" or "unit matrix" or "identity matrix." (The identity matrix is for matrices what the number 1 is for normal numbers; multiplying an arbitrary matrix or vector by the identity matrix does not change that matrix or vector.)

Substituting in the expression for the special orbitals above, making sure not to use the same name $\nu$ for two different indices, the requirement becomes

$$
\sum_{m=1}^{N} \sum_{n=1}^{N}\left\langle c_{m, \mu} \psi_{m}^{\mathrm{s}} \mid c_{n, \nu} \psi_{n}^{\mathrm{s}}\right\rangle=\delta_{\mu \nu}
$$

or noting that numbers come out of the left side of an inner product as complex conjugates,

$$
\sum_{m=1}^{N} \sum_{n=1}^{N} c_{m, \mu}^{*} c_{n, \nu}\left\langle\psi_{m}^{\mathrm{s}} \mid \psi_{n}^{\mathrm{s}}\right\rangle=\delta_{\mu \nu}
$$

Now since the set of typical orbitals $\psi_{n}^{\mathrm{s}}$ are already orthonormal, the inner product in the requirement above is only nonzero when $m$ is $n$, and then it is one. So dropping the zero terms that have $m \neq n$, the requirement on the coefficients simplifies to

$$
\sum_{n=1}^{N} c_{n, \mu}^{*} c_{n, \nu}=\delta_{\mu \nu}
$$

What does that mean? Well, for given values of $\mu$ and $\nu$, consider the coefficients $c_{n, \mu}$ to form a vector $\vec{u}_{\mu}$, where $n$ indicates the component number of that vector. Similarly, consider the coefficients $c_{n, \nu}$ to form a vector $\vec{u}_{\nu}$. Then the left hand side in the requirement above is the inner (or dot, if real) product of these two vectors. So the set of vectors must be orthonormal, just like the special orbitals must be orthonormal. So the matrix of coefficients $C$ must consist of orthonormal vectors. Mathematicians call such matrices "unitary," rather than orthonormal, since it is easily confused with "unit," and that keeps mathematicians in business explaining all the confusion.

The Hermitian adjoint matrix $C^{\dagger}$ of $C$ is defined as the matrix you get by swapping the order of the indices of the elements of $C$ and adding a complex conjugate. So by definition the factor $c_{n, \mu}^{*}$ in the requirement above equals the coefficient $c_{\mu, n}^{\dagger}$ of $C^{\dagger}$. And matrix multiplication is defined such that then the sum over $n$ in the requirement gives exactly the coefficients of the product $C^{\dagger} C$. So the requirement above can be written as

$$
C^{\dagger} C=I
$$

where $I$ is the unit matrix. That means $C^{\dagger}$ is the inverse matrix to $C, C^{\dagger}=$ $C^{-1}$. Then you also have that $C$ is the inverse of $C^{\dagger}, C C^{\dagger}=I$, which writes out to

$$
\sum_{\nu=1}^{N} c_{n, \nu} c_{m, \nu}^{*}=\delta_{m n}
$$

This can be used to find the typical orbitals in terms of the special ones. To do so, premultiply the expression for the special orbitals as given earlier by $c_{m, \nu}^{*}$ and sum over $\nu$ :

$$
\sum_{\nu=1}^{N} c_{m, \nu}^{*} \bar{\psi}_{\nu}^{\mathrm{s}}=\sum_{\nu=1}^{N} c_{m, \nu}^{*} \sum_{n=1}^{N} c_{n \nu} \psi_{n}^{\mathrm{s}}
$$

As seen above, the sum over $\nu$ in the right hand side is just $\delta_{m n}$, so in the sum over $n$, only the term with $n$ equal to $m$ is nonzero:

$$
\sum_{\nu=1}^{N} c_{m, \nu}^{*} \bar{\psi}_{\nu}^{\mathrm{s}}=\psi_{m}^{\mathrm{s}}
$$

That then gives any typical orbital $\psi_{m}^{s}$ in terms of a sum of the special orbitals $\bar{\psi}_{\nu}^{s}$.

Now plug that into the non canonical restricted closed-shell Hartree-Fock equations given earlier. Be careful not to use the same summation index name twice in the same term; this derivation will use

$$
\psi_{m}^{\mathrm{s}}=\sum_{\nu=1}^{N} c_{m, \nu}^{*} \bar{\psi}_{\nu}^{\mathrm{s}} \quad \psi_{n}^{\mathrm{s}}=\sum_{\lambda=1}^{N} c_{n, \lambda}^{*} \bar{\psi}_{\lambda}^{\mathrm{s}} \quad \psi_{n}^{\mathrm{s}}=\sum_{\kappa=1}^{N} c_{n, \kappa}^{*} \bar{\psi}_{\kappa}^{\mathrm{s}}
$$

for $\psi_{m}^{\mathrm{s}}$, the first occurrence of $\psi_{n}^{\mathrm{s}}$ in the terms, and the second occurrence, respectively. Premultiply it all by $C$, i.e. put $\sum_{m=1}^{N} c_{m, \mu}$ in front of each term. That cleans up to

$$
h^{\mathrm{e}} \bar{\psi}_{\mu}^{\mathrm{s}}+2 \sum_{\lambda=1}^{N}\left\langle\bar{\psi}_{\lambda}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\bar{\psi}_{\lambda}^{\mathrm{s}}\right\rangle \bar{\psi}_{\mu}^{\mathrm{s}}-\sum_{\lambda=1}^{N}\left\langle\bar{\psi}_{\lambda}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\bar{\psi}_{\mu}^{\mathrm{s}}\right\rangle \bar{\psi}_{\lambda}^{\mathrm{s}}=\sum_{m=1}^{N} \sum_{n=1}^{N} \sum_{\lambda=1}^{N} c_{m, \mu} \epsilon_{m n} c_{n, \lambda}^{*} \bar{\psi}_{\lambda}^{\mathrm{s}}
$$

Note that the only thing that has changed more than just by symbol names is the matrix in the right hand side. Now for each separate value of $\lambda$, take $c_{n \lambda}^{*}$ as the $\lambda$-th orthonormal eigenvector of Hermitian matrix $\epsilon_{m n}$, calling the eigenvalue $\epsilon_{\lambda}$. Then by the definition of eigenvector,

$$
\sum_{n=1}^{N} \epsilon_{m n} c_{n, \lambda}^{*}=\epsilon_{\lambda} c_{m, \lambda}^{*}
$$

So the right hand side becomes

$$
\sum_{m=1}^{I} \sum_{\lambda=1}^{N} c_{m, \mu} \epsilon_{\lambda} c_{m, \lambda}^{*} \bar{\psi}_{\lambda}^{\mathrm{s}}=\sum_{\lambda=1}^{N} \delta_{\mu \lambda} \epsilon_{\lambda} \bar{\psi}_{\lambda}^{\mathrm{s}}=\epsilon_{\mu} \bar{\psi}_{\mu}^{\mathrm{s}}
$$

So, in terms of the special orbitals defined by the requirement that $c_{m, \mu}^{*}$ gives the $\mu$-th eigenvector of $\epsilon_{m n}$, the right hand side simplifies to the canonical one.

Since the old typical orbitals are no longer of interest, the overlines on the special orbitals can be dropped to save typing, and the Greek index names $\mu$ and $\lambda$ can be renamed $n$ and $\underline{n}$. That then finally produces the canonical closed-shell restricted Hartree-Fock equations:

$$
\begin{equation*}
h^{\mathrm{e}} \psi_{n}^{\mathrm{s}}+2 \sum_{\underline{n}=1}^{N}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}-\sum_{\underline{n}=1}^{N}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{\underline{n}}^{\mathrm{s}}=\epsilon_{n} \psi_{n}^{\mathrm{s}} \tag{D.36}
\end{equation*}
$$

Note that the left-hand side directly provides a Hermitian Fock operator if you identify it as $\mathcal{F} \psi_{n}^{\mathrm{s}}$; there is no need to involve spin in the closed-shell restricted case. This also provides a much simpler explanation than all the algebra above why all the earlier $\epsilon_{m n}$ with $m \neq n$ were not needed; existence of a set of orthonormal eigenfunctions of a Hermitian operator is automatic. So there is no fundamental need to enforce that separately through Lagrangian multipliers.

Turning now to the case of (fully) unrestricted Hartree-Fock (UHF), you might make the same simple argument as above and be done. But it is worthwhile to go through the full mathematics anyway, to better understand openshell restricted Hartree-Fock later. In the unrestricted case, the non canonical equations are

$$
h^{\mathrm{e}} \psi_{m}^{\mathrm{s}}+\sum_{n=1}^{N}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}-\sum_{n=1}^{N}\left\langle\mathfrak{\imath}_{n} \mid \mathfrak{\imath}_{m}\right\rangle^{2}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}=\sum_{n=1}^{N} \epsilon_{m n} \psi_{n}^{\mathrm{s}}
$$

In this case, there are two different types of spatial orbitals; those appearing in spin-up spin orbitals, and those appearing in spin-down spin orbitals. You cannot just make arbitrary combinations of all these orbitals. If you combine spin-up and spin-down orbitals, they correspond to spin orbitals of uncertain spin. That would make the assumptions used to derive the Hartree-Fock equations invalid.

However, combinations of purely spin-up orbitals can still be made without problems, and so can combinations of purely spin down orbitals. To do the mathematics, the spatial orbitals can be separated into two sets. The set of orbital numbers $n$ corresponding to spin-up spin orbitals will be indicated by U , and the set of numbers $n$ corresponding to spin-down spin orbitals by D. So you can partition (separate) the non canonical equations above into equations for $m \in \mathrm{U}$ (meaning $m$ is one of the values in set U ),
$h^{\mathrm{e}} \psi_{m}^{\mathrm{s}}+\sum_{n \in \mathrm{U}}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}+\sum_{n \in \mathrm{D}}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}-\sum_{n \in \mathrm{U}}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}=\sum_{n \in \mathrm{U}} \epsilon_{m n} \psi_{n}^{\mathrm{s}}$ and equations for $m \in \mathrm{D}$,
$h^{\mathrm{e}} \psi_{m}^{\mathrm{s}}+\sum_{n \in \mathrm{U}}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}+\sum_{n \in \mathrm{D}}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{m}^{\mathrm{s}}-\sum_{n \in \mathrm{D}}\left\langle\psi_{n}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{m}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}=\sum_{n \in \mathrm{D}} \epsilon_{m n} \psi_{n}^{\mathrm{s}}$
In these two types of equations, the fact that the up and down spin states are orthogonal was used to get rid of one pair of sums, and another pair was eliminated by the fact that there are no Lagrangian variables $\epsilon_{m n}$ linking the sets, since the spatial orbitals in the two sets are allowed to be mutually non orthogonal.

Now separately replace the orbitals of the up and down states by a modified set just like for the restricted closed-shell case above, for each using the unitary
matrix of eigenvectors of the $\epsilon_{m n}$ coefficients appearing in the right hand side of the equations for that set. It leaves the equations intact except for changes in names, but gets rid of the $\epsilon_{m n}$ for $m \neq n$, leaving only $\epsilon_{m m}$ values, call them $\epsilon_{m}$. Then combine the spin-up and spin-down equations again into a single expression. You get, in terms of revised symbol names,

$$
\begin{equation*}
h^{\mathrm{e}} \psi_{n}^{\mathrm{s}}+\sum_{\underline{n}=1}^{N}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}-\sum_{\underline{n}=1}^{N}\left\langle\mathfrak{\imath}_{\underline{n}} \mid \uparrow_{n}\right\rangle^{2}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{\underline{n}}^{\mathrm{s}}=\epsilon_{n} \psi_{n}^{\mathrm{s}} \tag{D.37}
\end{equation*}
$$

That leaves only the restricted open-shell Hartree-Fock method. Here, the partitioning also needs to include the set R of of restricted orbitals besides U and D. There is now a problem, because you cannot make combinations of restricted orbitals with spin-up or spin-down orbitals. That means that the $\epsilon_{m n}$ values where either $m$ or $n$ is restricted and the other is not, cannot be eliminated. Solutions range from just ignoring the whole thing to properly accounting for these $\epsilon_{m n}$ values by enforcing that restricted and non restricted orbitals must stay orthogonal as additional equations. This (even more) elaborate case will be left to the references that you can find in [46], in particular [28, pp. 242-253]. Woof.

## D. 55 Why the Fock operator is Hermitian

To verify that the Fock operator is Hermitian, first note that $h^{e}$ is Hermitian since it is an Hamiltonian. Next if you form the inner product $\left\langle\overline{\psi^{\mathrm{e}} \downarrow} \mid v^{\mathrm{HF}} \psi^{\mathrm{s}} \downarrow\right\rangle$, the first term in $v^{\mathrm{HF}}$, the Coulomb term, can be taken to the other side since it is just a real function. The second term, the exchange one, produces the inner product,
and if you take the operator to the other side, you get

$$
-\sum_{\underline{n}=1}^{I}\left\langle\left\langle\psi_{\underline{n}}^{\mathrm{s}}(\vec{r}) \uparrow_{\underline{n}}\left(S_{z}\right)\right| v^{\mathrm{ee}}\right| \overline{\left.\psi^{\mathrm{e}}(\vec{r}) \uparrow\left(S_{z}\right)\right\rangle} \psi_{\underline{n}}^{\mathrm{s}}(\vec{r}) \uparrow_{\underline{n}}\left(S_{z 1}\right)\left|\psi^{\mathrm{s}}(\underline{\vec{r}}) \uparrow\left(S_{z 1}\right)\right\rangle
$$

and writing out these inner products as six-dimensional spatial integrals and sums over spin, you see that they are the same.

## D. 56 Number of system eigenfunctions

This note derives the number of energy eigenfunctions $Q_{\vec{I}}$ for a given set $\vec{I}=$ $\left(I_{1}, I_{2}, I_{3}, \ldots\right)$ of shelf occupation numbers, $I_{s}$ being the number of particles on
shelf number $s$. The number of single-particle eigenfunctions on shelf number $s$ is indicated by $N_{s}$.

Consider first the case of distinguishable particles, referring to figure 11.1 for an example. The question is how many different eigenfunctions can be created with the given shelf numbers. What are the ways to create different ones? Well, the first choice that can be made is what are the $I_{1}$ particles that go on shelf 1. If you pick out $I_{1}$ particles from the $I$ total particles, you have $I$ choices for particle 1, next there are $I-1$ choices left for particle 2 , then $I-2$ for particle 3. The total number of possible ways of choosing the $I_{1}$ particles is then

$$
I \times(I-1) \times(I-2) \times \ldots \times\left(I-I_{1}+1\right)
$$

However, this overestimates the number of variations in eigenfunctions that you can create by selecting the $I_{1}$ particles: the only thing that makes a difference for the eigenfunctions is what particles you pick to go on shelf 1; the order in which you chose to pick them out of the total set of $I$ makes no difference. If you chose a set of $I_{1}$ particles in an arbitrary order, you get no difference in eigenfunction compared to the case that you pick out the same particles sorted by number. To correct for this, the number of eigenfunction variations above must be divided by the number of different orderings in which a set of $I_{1}$ particles can come out of the total collection. That will give the number of different sets of particles, sorted by number, that can be selected. The number of ways that a set of $I_{1}$ particles can be ordered is

$$
I_{1}!=I_{1} \times\left(I_{1}-1\right) \times\left(I_{1}-2\right) \times \ldots \times 3 \times 2 \times 1
$$

there are $I_{1}$ possibilities for the particle that comes first in the sorted set, then $I_{1}-1$ possibilities left for the particle that comes second, etcetera. Dividing the earlier expression by $I_{1}$ !, the number of different sets of $I_{1}$ particles that can be selected for shelf 1 becomes

$$
\frac{I \times(I-1) \times(I-2) \times \ldots \times\left(I-I_{1}+1\right)}{I_{1} \times\left(I_{1}-1\right) \times\left(I_{1}-2\right) \times \ldots \times 3 \times 2 \times 1}
$$

But further variations in eigenfunctions are still possible in the way these $I_{1}$ particles are distributed over the $N_{1}$ single-particle states on shelf 1. There are $N_{1}$ possible single-particle states for the first particle of the sorted set, times $N_{1}$ possible single-particle states for the second particle, etcetera, making a total of $N_{1}^{I_{1}}$ variations. That number of variations exists for each of the individual sorted sets of particles, so the total number of variations in eigenfunctions is the product:

$$
N_{1}^{I_{1}} \frac{I \times(I-1) \times(I-2) \times \ldots \times\left(I-I_{1}+1\right)}{I_{1} \times\left(I_{1}-1\right) \times\left(I_{1}-2\right) \times \ldots \times 3 \times 2 \times 1}
$$

This can be written more concisely by noting that the bottom of the fraction is per definition $I_{1}$ ! while the top equals $I!/\left(I-I_{1}\right)$ !: note that the terms missing
from $I$ ! in the top are exactly $\left(I-I_{1}\right)$ !. (In the special case that $I=I_{1}$, all particles on shelf 1 , this still works since mathematics defines $0!=1$.) So, the number of variations in eigenfunctions so far is:

$$
N_{1}^{I_{1}} \frac{I!}{I_{1}!\left(I-I_{1}\right)!} .
$$

The fraction is known in mathematics as "I choose $I_{1}$."
Further variations in eigenfunctions are possible in the way that the $I_{2}$ particles on shelf 2 are chosen and distributed over the single-particle states on that shelf. The analysis is just like the one for shelf 1 , except that shelf 1 has left only $I-I_{1}$ particles for shelf 2 to chose from. So the number of additional variations related to shelf 2 becomes

$$
N_{2}^{I_{2}} \frac{\left(I-I_{1}\right)!}{I_{2}!\left(I-I_{1}-I_{2}\right)!}
$$

The same way the number of eigenfunction variations for shelves $3,4, \ldots$ can be found, and the grand total of different eigenfunctions is

$$
N_{1}^{I_{1}} \frac{I!}{I_{1}!\left(I-I_{1}\right)!} \times N_{2}^{I_{2}} \frac{\left(I-I_{1}\right)!}{I_{2}!\left(I-I_{1}-I_{2}\right)!} \times N_{3}^{I_{3}} \frac{\left(I-I_{1}-I_{2}\right)!}{I_{3}!\left(I-I_{1}-I_{2}-I_{3}\right)!} \times \ldots
$$

This terminates at the shelf number $S$ beyond which there are no more particles left, when $I-I_{1}-I_{2}-I_{3}-\ldots-I_{B}=0$. All further shelves will be empty. Empty shelves might just as well not exist, they do not change the eigenfunction count. Fortunately, there is no need to exclude empty shelves from the mathematical expression above, it can be used either way. For example, if shelf 2 would be empty, e.g. $I_{2}=0$, then $N_{2}^{I_{2}}=1$ and $I_{2}$ ! $=1$, and the factors $\left(I-I_{1}\right)$ ! and ( $I-I_{1}-I_{2}$ )! cancel each other. So the factor due to empty shelf 2 becomes multiplying by one, it does not change the eigenfunction count.

Note that various factors cancel in the eigenfunction count above, it simplifies to the final expression

$$
Q_{\vec{I}}^{\mathrm{d}}=I!\frac{N_{1}^{I_{1}}}{I_{1}!} \times \frac{N_{2}^{I_{2}}}{I_{2}!} \times \frac{N_{3}^{I_{3}}}{I_{3}!} \times \ldots
$$

Mathematicians like to symbolically write a product of indexed factors like this using the product symbol $\Pi$ :

$$
Q_{\vec{I}}^{\mathrm{d}}=I!\prod_{\text {all } s} \frac{N_{s}^{I_{s}}}{I_{s}!}
$$

It means exactly the same as the written-out product.
Next the eigenfunction count for fermions. Refer now to figure 11.3. For any shelf $s$, it is given that there are $I_{s}$ particles on that shelf, and the only
variations in eigenfunctions that can be achieved are in the way that these particles are distributed over the $N_{s}$ single-particle eigenfunctions on that shelf. The fermions are identical, but to simplify the reasoning, for now assume that you stamp numbers on them from 1 to $I_{s}$. Then fermion 1 can go into $N_{s}$ singleparticle states, leaving $N_{s}-1$ states that fermion 2 can go into, then $N_{s}-2$ states that fermion 3 can go into, etcetera. That produces a total of

$$
N_{s} \times\left(N_{s}-1\right) \times\left(N_{s}-2\right) \times \ldots \times\left(N_{s}-I_{s}+1\right)=\frac{N_{s}!}{\left(N_{s}-I_{s}\right)!}
$$

variations. But most of these differ only in the order of the numbers stamped on the fermions; differences in the numbers stamped on the electrons do not constitute a difference in eigenfunction. The only difference is in whether a state is occupied by a fermion or not, not what number is stamped on it. Since, as explained under distinguishable particles, the number of ways $I_{s}$ particles can be ordered is $I_{s}!$, it follows that the formula above over-counts the number of variations in eigenfunctions by that factor. To correct, divide by $I_{s}!$, giving the number of variations as $N_{s}!/\left(N_{s}-I_{s}\right)!I_{s}$ !, or " $N_{s}$ choose $I_{s}$." The combined number of variations in eigenfunctions for all shelves then becomes

$$
Q_{\vec{I}}^{\mathrm{f}}=\frac{N_{1}!}{\left(N_{1}-I_{1}\right)!I_{1}!} \times \frac{N_{2}!}{\left(N_{2}-I_{2}\right)!I_{2}!} \times \frac{N_{3}!}{\left(N_{3}-I_{3}\right)!I_{3}!} \times \ldots=\prod_{\text {all } s} \frac{N_{s}!}{\left(N_{s}-I_{s}\right)!I_{s}!}
$$

If a shelf is empty, it makes again no difference; the corresponding factor is again one. But another restriction applies for fermions: there should not be any eigenfunctions if any shelf number $I_{s}$ is greater than the number of states $N_{s}$ on that shelf. There can be at most one particle in each state. Fortunately, mathematics defines factorials of negative integer numbers to be infinite, and the infinite factor $\left(N_{s}-I_{s}\right)$ ! in the bottom will turn the eigenfunction count into zero as it should. The formula can be used whatever the shelf numbers are.

Figure D.3: Schematic of an example boson distribution on a shelf.
Last but not least, the eigenfunction count for bosons. Refer now to figure 11.2. This one is tricky, but a trick solves it. To illustrate the idea, take shelf 2 in figure 11.2 as an example. It is reproduced in condensed form in figure D.3. The figure merely shows the particles and the lines separating the singleparticle states. Like for the fermions, the question is, how many ways can the $I_{s}$ bosons be arranged inside the $N_{s}$ single-particle states? In other words, how many variations are there on a schematic like the one shown in figure D.3? To figure it out, stamp identifying numbers on all the elements, particles and single-state separating lines alike, ranging from 1 to $I_{s}+N_{s}-1$. Following
the same reasoning as before, there are $\left(I_{s}+N_{s}-1\right)$ ! different ways to order these numbered objects. As before, now back off. All the different orderings of the numbers stamped on the bosons, $I_{s}$ ! of them, produce no difference in eigenfunction, so divide by $I_{s}$ ! to fix it up. Similarly, all the different orderings of the single-particle state boundaries produce no difference in eigenfunction, so divide by $\left(N_{s}-1\right)$ !. The number of variations in eigenfunctions possible by rearranging the particles on a single shelf $s$ is then $\left(I_{s}+N_{s}-1\right)!/ I_{s}!\left(N_{s}-1\right)!$. The total for all shelves is

$$
\begin{aligned}
Q_{\vec{I}}^{\mathrm{b}} & =\frac{\left(I_{1}+N_{1}-1\right)!}{I_{1}!\left(N_{1}-1\right)!} \times \frac{\left(I_{2}+N_{2}-1\right)!}{I_{2}!\left(N_{2}-1\right)!} \times \frac{\left(I_{3}+N_{3}-1\right)!}{I_{3}!\left(N_{3}-1\right)!} \times \ldots \\
& =\prod_{\text {all } s} \frac{\left(I_{s}+N_{s}-1\right)!}{I_{s}!\left(N_{s}-1\right)!}
\end{aligned}
$$

## D. 57 The particle energy distributions

This note derives the Maxwell-Boltzmann, Fermi-Dirac, and Bose-Einstein energy distributions of weakly interacting particles for a system for which the net energy is precisely known.

The objective is to find the shelf numbers $\vec{I}=\left(I_{1}, I_{2}, I_{3}, \ldots\right)$ for which the number of eigenfunctions $Q_{\vec{I}}$ is maximal. Actually, it is mathematically easier to find the maximum of $\ln \left(Q_{\vec{I}}\right)$, and that is the same thing: if $Q_{\vec{I}}$ is as big as it can be, then so is $\ln \left(Q_{\vec{I}}\right)$. The advantage of working with $\ln \left(Q_{\vec{I}}\right)$ is that it simplifies all the products in the expressions for the $Q_{\vec{I}}$ derived in derivation $\{$ D. 56$\}$ into sums: mathematics says that $\ln (a b)$ equals $\ln (a)$ plus $\ln (b)$ for any (positive) $a$ and $b$.

It will be assumed, following derivation $\{\mathrm{N} .24\}$, that if the maximum value is found among all shelf occupation numbers, whole numbers or not, it suffices. More daringly, errors less than a particle are not going to be taken seriously.

In finding the maximum of $\ln \left(Q_{\vec{I}}\right)$, the shelf numbers cannot be completely arbitrary; they are constrained by the conditions that the sum of the shelf numbers must equal the total number of particles $I$, and that the particle energies must sum together to the given total energy $E$ :

$$
\sum_{s} I_{s}=I \quad \sum_{s} I_{s} E_{s}^{\mathrm{p}}=E
$$

Mathematicians call this a constrained maximization problem.
According to calculus, without the constraints, you can just put the derivatives of $\ln \left(Q_{\vec{I}}\right)$ with respect to all the shelf numbers $I_{s}$ to zero to find the maximum. With the constraints, you have to add "penalty terms" that correct for any going out of bounds, $\{\mathrm{D} .48\}$, and the correct function whose derivatives
must be zero is

$$
F=\ln \left(Q_{\vec{I}}\right)-\epsilon_{1}\left(\sum_{s} I_{s}-I\right)-\epsilon_{2}\left(\sum_{s} I_{s} E_{s}^{\mathrm{p}}-E\right)
$$

where the constants $\epsilon_{1}$ and $\epsilon_{2}$ are unknown penalty factors called the Lagrangian multipliers.

At the shelf numbers for which the number of eigenfunctions is largest, the derivatives $\partial F / \partial I_{s}$ must be zero. However, that condition is difficult to apply exactly, because the expressions for $Q_{\vec{I}}$ as given in the text involve the factorial function, or rather, the gamma function. The gamma function does not have a simple derivative. Here typical textbooks will flip out the Stirling approximation of the factorial, but this approximation is simply incorrect in parts of the range of interest, and where it applies, the error is unknown.

It is a much better idea to approximate the differential quotient by a difference quotient, as in

$$
\begin{aligned}
0= & \frac{\partial F}{\partial I_{s}} \approx \frac{\Delta F}{\Delta I_{s}} \equiv \\
& \frac{F\left(I_{1}, I_{2}, \ldots, I_{s-1}, I_{s}+1, I_{s+1}, \ldots\right)-F\left(I_{1}, I_{2}, \ldots, I_{s-1}, I_{s}, I_{s+1}, \ldots\right)}{I_{s}+1-I_{s}} .
\end{aligned}
$$

This approximation is very minor, since according to the so-called mean value theorem of mathematics, the location where $\Delta F / \Delta I_{s}$ is zero is at most one particle away from the desired location where $\partial F / \partial I_{s}$ is zero. Better still, $I_{s}+\frac{1}{2}$ $\equiv I_{s, \text { best }}$ will be no more that half a particle off, and the analysis already had to commit itself to ignoring fractional parts of particles anyway. The difference quotient leads to simple formulae because the gamma function satisfies the condition $(n+1)!=(n+1) n$ ! for any value of $n$, compare the notations section under "!".

Now consider first distinguishable particles. The function $F$ to differentiate is defined above, and plugging in the expression for $Q_{\vec{I}}^{\mathrm{d}}$ as found in derivation \{D.56\} produces

$$
F=\ln (I!)+\sum_{s}\left[I_{s} \ln \left(N_{s}\right)-\ln \left(I_{s}!\right)\right]-\epsilon_{1}\left(\sum_{s} I_{s}-I\right)-\epsilon_{2}\left(\sum_{s} I_{s} E_{s}^{\mathrm{p}}-E\right)
$$

For any value of the shelf number $s$, in the limit $I_{s} \downarrow-1, F$ tends to negative infinity because $I_{s}$ ! tends to positive infinity in that limit and its logarithm appears with a minus sign. In the limit $I_{s} \uparrow+\infty, F$ tends once more to negative infinity, since $\ln \left(I_{s}!\right)$ for large values of $I_{s}$ is according to the so-called Stirling formula approximately equal to $I_{s} \ln \left(I_{s}\right)-I_{s}$, so the $-\ln \left(I_{s}!\right)$ term in $F$ goes to minus infinity more strongly than the terms proportional to $I_{s}$ might go to plus infinity. If $F$ tends to minus infinity at both ends of the range $-1<I_{s}<$ $\infty$, there must be a maximum value of $F$ somewhere within that range where
the derivative with respect to $I_{s}$ is zero. More specifically, working out the difference quotient:

$$
\frac{\Delta F}{\Delta I_{s}}=\ln \left(N_{s}\right)-\ln \left(I_{s}+1\right)-\epsilon_{1}-\epsilon_{2} E_{s}^{\mathrm{p}}=0
$$

and $-\ln \left(I_{s}+1\right)$ is infinity at $I_{s}=-1$ and minus infinity at $I_{s}=\infty$. Somewhere in between, $\Delta F / \Delta I_{s}$ will cross zero. In particular, combining the logarithms and then taking an exponential, the best estimate for the shelf occupation number is

$$
I_{s, \text { best }}=I_{s}+\frac{1}{2}=\frac{N_{s}}{e^{\epsilon_{2} E_{s}^{\mathrm{p}}+\epsilon_{1}}}-\frac{1}{2}
$$

The correctness of the final half particle is clearly doubtful within the made approximations. In fact, it is best ignored since it only makes a difference at high energies where the number of particles per shelf becomes small, and surely, the correct probability of finding a particle must go to zero at infinite energies, not to minus half a particle! Therefore, the best estimate $\iota^{\mathrm{d}} \equiv I_{s, \text { best }} / N_{s}$ for the number of particles per single-particle energy state becomes the MaxwellBoltzmann distribution. Note that the derivation might be off by a particle for the lower energy shelves. But there are a lot of particles in a macroscopic system, so it is no big deal.

The case of identical fermions is next. The function to differentiate is now

$$
\begin{aligned}
F= & \sum_{s}\left[\ln \left(N_{s}!\right)-\ln \left(I_{s}!\right)-\ln \left(\left(N_{s}-I_{s}\right)!\right)\right] \\
& -\epsilon_{1}\left(\sum_{s} I_{s}-I\right)-\epsilon_{2}\left(\sum_{s} I_{s} E_{s}^{\mathrm{p}}-E\right)
\end{aligned}
$$

This time $F$ is minus infinity when a shelf number reaches $I_{s}=-1$ or $I_{s}=$ $N_{s}+1$. So there must be a maximum to $F$ when $I_{s}$ varies between those limits. The difference quotient approximation produces

$$
\frac{\Delta F}{\Delta I_{s}}=-\ln \left(I_{s}+1\right)+\ln \left(N_{s}-I_{s}\right)-\epsilon_{1}-\epsilon_{2} E_{s}^{\mathrm{p}}=0
$$

which can be solved to give

$$
I_{s, \text { best }}=I_{s}+\frac{1}{2}=\frac{N_{s}}{e^{\epsilon_{2} E_{s}^{\mathrm{p}}+\epsilon_{1}}+1}+\frac{1}{2} \frac{1-e^{\epsilon_{2} E_{s}^{\mathrm{p}}+\epsilon_{1}}}{1+e^{\epsilon_{2} E_{s}^{\mathrm{p}}+\epsilon_{1}}}
$$

The final term, less than half a particle, is again best left away, to ensure that $0 \leqslant I_{s, \text { best }} \leqslant N_{s}$ as it should. That gives the Fermi-Dirac distribution.

Finally, the case of identical bosons, is, once more, the tricky one. The function to differentiate is now

$$
\begin{aligned}
F= & \sum_{s}\left[\ln \left(\left(I_{s}+N_{s}-1\right)!\right)-\ln \left(I_{s}!\right)-\ln \left(\left(N_{s}-1\right)!\right)\right] \\
& -\epsilon_{1}\left(\sum_{s} I_{s}-I\right)-\epsilon_{2}\left(\sum_{s} I_{s} E_{s}^{\mathrm{p}}-E\right)
\end{aligned}
$$

For now, assume that $N_{s}>1$ for all shelves. Then $F$ is again minus infinity for $I_{s}=-1$. For $I_{s} \uparrow \infty$, however, $F$ will behave like $-\left(\epsilon_{1}+\epsilon_{2} E_{s}^{\mathrm{p}}\right) I_{s}$. This tends to minus infinity if $\epsilon_{1}+\epsilon_{2} E_{s}^{\mathrm{p}}$ is positive, so for now assume it is. Then the difference quotient approximation produces

$$
\frac{\Delta F}{\Delta I_{s}}=\ln \left(I_{s}+N_{s}\right)-\ln \left(I_{s}+1\right)-\epsilon_{1}-\epsilon_{2} E_{s}^{\mathrm{p}}=0
$$

which can be solved to give

$$
I_{s, \text { best }}=I_{s}+\frac{1}{2}=\frac{N_{s}-1}{e^{\epsilon_{2} E_{s}^{\mathrm{p}}+\epsilon_{1}}-1}-\frac{1}{2}
$$

The final half particle is again best ignored to get the number of particles to become zero at large energies. Then, if it is assumed that the number $N_{s}$ of single-particle states on the shelves is large, the Bose-Einstein distribution is obtained. If $N_{s}$ is not large, the number of particles could be less than the predicted one by up to a factor 2 , and if $N_{s}$ is one, the entire story comes part. And so it does if $\epsilon_{1}+\epsilon_{2} E_{s}^{\mathrm{p}}$ is not positive.

Before addressing these nasty problems, first the physical meaning of the Lagrangian multiplier $\epsilon_{2}$ needs to be established. It can be inferred from examining the case that two different systems, call them $A$ and $B$, are in thermal contact. Since the interactions are assumed weak, the eigenfunctions of the combined system are the products of those of the separate systems. That means that the number of eigenfunctions of the combined system $Q_{\vec{I}_{A} \vec{I}_{B}}$ is the product of those of the individual systems. Therefore the function to differentiate becomes

$$
\begin{aligned}
F= & \ln \left(Q_{\vec{I}_{A}} Q_{\vec{I}_{B}}\right) \\
& -\epsilon_{1, A}\left(\sum_{s_{A}} I_{s_{A}}-I_{A}\right)-\epsilon_{1, B}\left(\sum_{s_{B}} I_{s_{B}}-I_{B}\right) \\
& -\epsilon_{2}\left(\sum_{s_{A}} I_{s_{A}} E_{s_{A}}^{\mathrm{p}}+\sum_{s_{B}} I_{s_{B}} E_{s_{B}}^{\mathrm{p}}-E\right)
\end{aligned}
$$

Note the constraints: the number of particles in system $A$ must be the correct number $I_{A}$ of particles in that system, and similar for system $B$. However, since the systems are in thermal contact, they can exchange energy through the weak interactions and there is no longer a constraint on the energy of the individual systems. Only the combined energy must equal the given total. That means the two systems share the same Lagrangian variable $\epsilon_{2}$. For the rest, the equations for the two systems are just like if they were not in thermal contact, because the logarithm in $F$ separates, and then the differentiations with respect to the shelf numbers $I_{s_{A}}$ and $I_{s_{B}}$ give the same results as before.

It follows that two systems that have the same value of $\epsilon_{2}$ can be brought into thermal contact and nothing happens, macroscopically. However, if two
systems with different values of $\epsilon_{2}$ are brought into contact, the systems will adjust, and energy will transfer between them, until the two $\epsilon_{2}$ values have become equal. That means that $\epsilon_{2}$ is a temperature variable. From here on, the temperature will be defined as $T=1 / \epsilon_{2} k_{\mathrm{B}}$, so that $\epsilon_{2}=1 / k_{\mathrm{B}} T$, with $k_{\mathrm{B}}$ the Boltzmann constant. The same way, for now the chemical potential $\mu$ will simply be defined to be the constant $-\epsilon_{1} / \epsilon_{2}$. Chapter 11.14 .4 will eventually establish that the temperature defined here is the ideal gas temperature, while derivation $\{$ D. 61$\}$ will establish that $\mu$ is the Gibbs free energy per atom that is normally defined as the chemical potential.

Returning now to the nasty problems of the distribution for bosons, first assume that every shelf has at least two states, and that $\left(E_{s}^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T$ is positive even for the ground state. In that case there is no problem with the derived solution. However, Bose-Einstein condensation will occur when either the number density is increased by putting more particles in the system, or the temperature is decreased. Increasing particle density is associated with increasing chemical potential $\mu$ because

$$
I_{s}=\frac{N_{s}-1}{e^{\left(E_{s}^{p}-\mu\right) / k_{\mathrm{B}} T}-1}
$$

implies that every shelf particle number increases when $\mu$ increases. Decreasing temperature by itself decreases the number of particles, and to compensate and keep the number of particles the same, $\mu$ must then once again increase. When $\mu$ gets very close to the ground state energy, the exponential in the expression for the number of particles on the ground state shelf $s=1$ becomes very close to one, making the total denominator very close to zero, so the number of particles $I_{1}$ in the ground state blows up. When it becomes a finite fraction of the total number of particles $I$ even when $I$ is macroscopically large, Bose-Einstein condensation is said to have occurred.

Note that under reasonable assumptions, it will only be the ground state shelf that ever acquires a finite fraction of the particles. For, assume the contrary, that shelf 2 also holds a finite fraction of the particles. Using Taylor series expansion of the exponential for small values of its argument, the shelf occupation numbers are

$$
\begin{aligned}
& I_{1}=\frac{\left(N_{1}-1\right) k_{\mathrm{B}} T}{E_{1}^{\mathrm{p}}-\mu} \\
& I_{2}=\frac{\left(N_{2}-1\right) k_{\mathrm{B}} T}{E_{1}^{\mathrm{p}}-\mu+\left(E_{2}^{\mathrm{p}}-E_{1}^{\mathrm{p}}\right)} \\
& I_{3}=\frac{\left(N_{3}-1\right) k_{\mathrm{B}} T}{E_{1}^{\mathrm{p}}-\mu+\left(E_{2}^{\mathrm{p}}-E_{1}^{\mathrm{p}}\right)+\left(E_{3}^{\mathrm{p}}-E_{2}^{\mathrm{p}}\right)}
\end{aligned}
$$

For $I_{2}$ to also be a finite fraction of the total number of particles, $E_{2}^{\mathrm{p}}-E_{1}^{\mathrm{p}}$ must be similarly small as $E_{1}^{\mathrm{p}}-\mu$. But then, reasonably assuming that the energy levels are at least roughly equally spaced, and that the number of states will not decrease with energy, so must $I_{3}$ be a finite fraction of the total, and so on. You cannot have a large number of shelves each having a finite fraction of the particles, because there are not so many particles. More precisely, a sum roughly like $\sum_{s=2}^{\infty}$ const $/ s \Delta E$, (or worse), sums to an amount that is much larger than the term for $s=2$ alone. So if $I_{2}$ would be a finite fraction of $I$, then the sum would be much larger than $I$.

What happens during condensation is that $\mu$ becomes much closer to $E_{1}^{\mathrm{p}}$ than $E_{1}^{\mathrm{p}}$ is to the next energy level $E_{2}^{\mathrm{p}}$, and only the ground state shelf ends up with a finite fraction of the particles. The remainder is spread out so much that the shelf numbers immediately above the ground state only contain a negligible fraction of the particles. It also follows that for all shelves except the ground state one, $\mu$ may be approximated as being $E_{1}^{\mathrm{p}}$. (Specific data for particles in a box is given in chapter 11.14.1. The entire story may of course need to be modified in the presence of confinement, compare chapter 6.12.)

The other problem with the analysis of the occupation numbers for bosons is that the number of single-particle states on the shelves had to be at least two. There is no reason why a system of weakly-interacting spinless bosons could not have a unique single-particle ground state. And combining the ground state with the next one on a single shelf is surely not an acceptable approximation in the presence of potential Bose-Einstein condensation. Fortunately, the mathematics still partly works:

$$
\frac{\Delta F}{\Delta I_{1}}=\ln \left(I_{1}+1\right)-\ln \left(I_{1}+1\right)-\epsilon_{1}-\epsilon_{2} E_{1}^{\mathrm{p}}=0
$$

implies that $\epsilon_{1}-\epsilon_{2} E_{1}^{\mathrm{p}}=0$. In other words, $\mu$ is equal to the ground state energy $E_{1}^{\mathrm{p}}$ exactly, rather than just extremely closely as above.

That then is the condensed state. Without a chemical potential that can be adjusted, for any given temperature the states above the ground state contain a number of particles that is completely unrelated to the actual number of particles that is present. Whatever is left can be dumped into the ground state, since there is no constraint on $I_{1}$.

Condensation stops when the number of particles in the states above the ground state wants to become larger than the actual number of particles present. Now the mathematics changes, because nature says "Wait a minute, there is no such thing as a negative number of particles in the ground state!" Nature now adds the constraint that $I_{1}=0$ rather than negative. That adds another penalty term, $\epsilon_{3} I_{1}$ to $F$ and $\epsilon_{3}$ takes care of satisfying the equation for the ground state shelf number. It is a sad story, really: below the condensation temperature, the ground state was awash in particles, above it, it has zero. None.

A system of weakly interacting helium atoms, spinless bosons, would have a unique single-particle ground state like this. Since below the condensation temperature, the elevated energy states have no clue about an impending lack of particles actually present, physical properties such as the specific heat stay analytical until condensation ends.

It may be noted that above the condensation temperature it is only the most probable set of the occupation numbers that have exactly zero particles in the unique ground state. The expectation value of the number in the ground state will include neighboring sets of occupation numbers to the most probable one, and the number has nowhere to go but up, compare $\{D .61\}$.

## D. 58 The canonical probability distribution

This note deduces the canonical probability distribution. Since the derivations in typical textbooks seem crazily convoluted and the made assumptions not at all as self-evident as the authors suggest, a more mathematical approach will be followed here.

Consider a big system consisting of many smaller subsystems $A, B, \ldots$ with a given total energy $E$. Call the combined system the collective. Following the same reasoning as in derivation $\{\mathrm{D} .57\}$ for two systems, the thermodynamically stable equilibrium state has shelf occupation numbers of the subsystems satisfying

$$
\begin{aligned}
& \frac{\partial \ln Q_{\vec{I}_{A}}}{\partial I_{s_{A}}}-\epsilon_{1, A}-\epsilon_{2} E_{s_{A}}^{\mathrm{p}}=0 \\
& \frac{\partial \ln Q_{\vec{I}_{B}}}{\partial I_{s_{B}}}-\epsilon_{1, B}-\epsilon_{2} E_{s_{B}}^{\mathrm{p}}=0
\end{aligned}
$$

where $\epsilon_{2}$ is a shorthand for $1 / k_{\mathrm{B}} T$.
An individual system, take $A$ as the example, no longer has an individual energy that is for certain. Only the collective has that. That means that when $A$ is taken out of the collective, its shelf occupation numbers will have to be described in terms of probabilities. There will still be an expectation value for the energy of the system, but system energy eigenfunctions $\psi_{q_{A}}^{\mathrm{S}}$ with somewhat different energy $E_{q_{A}}^{S}$ can no longer be excluded with certainty. However, still assume, following the fundamental assumption of quantum statistics, $\{\mathrm{N} .23\}$, that the physical differences between the system energy eigenfunctions do not make (enough of) a difference to affect which ones are likely or not. So, the probability $P_{q_{A}}$ of a system eigenfunction $\psi_{q_{A}}^{\mathrm{S}}$ will be assumed to depend only on its energy $E_{q_{A}}^{\mathrm{S}}$ :

$$
P_{q_{A}}=P\left(E_{q_{A}}^{\mathrm{S}}\right)
$$

where $P$ is some as yet unknown function.
For the isolated example system $A$, the question is now no longer "What shelf numbers have the most eigenfunctions?" but "What shelf numbers have the highest probability?" Note that all system eigenfunctions $\psi_{q_{A}}^{\mathrm{S}}$ for a given set of shelf numbers $\overrightarrow{I_{A}}$ have the same system energy $E_{\vec{I}_{A}}^{\mathrm{S}}=\sum_{s_{A}} I_{s_{A}} E_{s_{A}}^{\mathrm{p}}$. Therefore, the probability of a given set of shelf numbers $\stackrel{I}{A}_{P_{A}}$ will be the number of eigenfunctions with those shelf numbers times the probability of each individual eigenfunction:

$$
P_{\vec{I}_{A}}=Q_{\vec{I}_{A}} P\left(E_{\vec{I}_{A}}^{S}\right)
$$

Mathematically, the function whose partial derivatives must be zero to find the most probable shelf numbers is

$$
F=\ln \left(P_{\vec{I}_{A}}\right)-\epsilon_{1, A}\left(\sum_{s_{A}} I_{s_{A}}-I_{A}\right) .
$$

The maximum is now to be found for the shelf number probabilities, not their eigenfunction counts, and there is no longer a constraint on energy.

Substituting $P_{\vec{I}_{A}}=Q_{\vec{I}_{A}} P\left(E_{\vec{I}_{A}}^{S}\right)$, taking apart the logarithm, and differentiating, produces

$$
\frac{\partial \ln Q_{\vec{I}_{A}}}{\partial I_{s_{A}}}+\frac{\mathrm{d} \ln (P)}{\mathrm{d} E_{\vec{I}_{A}}^{\mathrm{S}}} E_{s_{A}}^{\mathrm{p}}-\epsilon_{1, A}=0
$$

That is exactly like the equation for the shelf numbers of system $A$ when it was part of the collective, except that the derivative of the as yet unknown function $\ln \left(P_{A}\right)$ takes the place of $-\epsilon_{2}$, i.e. $-1 / k_{\mathrm{B}} T$. It follows that the two must be the same, because the shelf numbers cannot change when the system $A$ is taken out of the collective it is in thermal equilibrium with. For one, the net energy would change if that happened, and energy is conserved.

It follows that $\mathrm{d} \ln P / \mathrm{d} E_{\tilde{I}_{A}}^{\mathrm{S}}=-1 / k_{\mathrm{B}} T$ at least in the vicinity of the most probable energy $E_{\tilde{I}_{A}}^{\mathrm{S}}$. Hence in the vicinity of that energy

$$
P\left(E_{A}^{\mathrm{S}}\right)=\frac{1}{Z_{A}} e^{-E_{A}^{\mathrm{S}} / k_{\mathrm{B}} T}
$$

which is the canonical probability. Note that the given derivation only ensures it to be true in the vicinity of the most probable energy. Nothing says it gives the correct probability for, say, the ground state energy. But then the question becomes "What difference does it make?" Suppose the ground state has a probability of 0 . followed by only 100 zeros instead of the predicted 200 zeros? What would change in the price of eggs?

Note that the canonical probability is self-consistent: if two systems at the same temperature are combined, the probabilities of the combined eigenfunctions multiply, as in

$$
P_{A B}=\frac{1}{Z_{A} Z_{B}} e^{-\left(E_{A}^{\mathrm{S}}+E_{B}^{\mathrm{S}}\right) / k_{\mathrm{B}} T}
$$

That is still the correct expression for the combined system, since its energy is the sum of those of the two separate systems. Also for the partition functions

$$
Z_{A} Z_{B}=\sum_{q_{A}} \sum_{q_{B}} e^{-\left(E_{q_{A}}^{S}+E_{q_{B}}^{S}\right) / k_{\mathrm{B}} T}=Z_{A B}
$$

## D. 59 Analysis of the ideal gas Carnot cycle

Refer to figure D. 4 for the physical device to be analyzed. The refrigerant circulating through the device is an ideal gas with constant specific heats, like a thin gas of helium atoms. Chapter 11.14 will examine ideal gases in detail, but for now some reminders from introductory classical physics classes about ideal gasses must do. The internal energy of the gas is $E=m I C_{V} T$ where $m I$ is its mass and $C_{v}$ is a constant for a gas like helium whose atoms only have translational kinetic energy. Also, the ideal gas law says that $P V=m I R T$, where $P$ is the pressure, $V$ the volume, and the constant $R$ is the gas constant, equal to the universal gas constant divided by the molar mass.

The differential version of the first law, energy conservation, (11.11), says that

$$
\mathrm{d} E=\delta Q-P \mathrm{~d} V
$$

or getting rid of internal energy and pressure using the given expressions,

$$
m I C_{v} \mathrm{~d} T=\delta Q-m I R T \frac{\mathrm{~d} V}{V}
$$

High temperature side $T_{\mathrm{H}}$. (Kitchen.)

Low temperature side $T_{\mathrm{L}}$. (Fridge.)
Figure D.4: Schematic of the Carnot refrigeration cycle.
Now for the transitions through the heat exchangers, from 1 to 2 or from 3 to 4 in figure D.4, the temperature is approximated to be constant. The first law above can then be integrated to give the heat added to the substance as:

$$
Q_{\mathrm{L}}=m I R T_{\mathrm{L}}\left(\ln V_{2}-\ln V_{1}\right) \quad Q_{\mathrm{H}}=-m I R T_{\mathrm{H}}\left(\ln V_{4}-\ln V_{3}\right)
$$

Remember that unlike $Q_{\mathrm{L}}, Q_{\mathrm{H}}$ is taken positive if it comes out of the substance.
On the other hand, for the transitions through the adiabatic turbine and compressor, the heat $\delta Q$ added is zero. Then the first law can be divided through by $T$ and integrated to give

$$
\begin{aligned}
& m I C_{v}\left(\ln T_{\mathrm{H}}-\ln T_{\mathrm{L}}\right)=-m I R\left(\ln V_{3}-\ln V_{2}\right) \\
& m I C_{v}\left(\ln T_{\mathrm{L}}-\ln T_{\mathrm{H}}\right)=-m I R\left(\ln V_{1}-\ln V_{4}\right)
\end{aligned}
$$

Adding these two expressions shows that

$$
\ln V_{3}-\ln V_{2}+\ln V_{1}-\ln V_{4}=0 \quad \Longrightarrow \quad \ln V_{3}-\ln V_{4}=\ln V_{2}-\ln V_{1}
$$

and plugging that into the expressions for the exchanged heats shows that $Q_{\mathrm{H}} / T_{\mathrm{H}}=Q_{\mathrm{L}} / T_{\mathrm{L}}$.

## D. 60 Checks on the expression for entropy

According to the microscopic definition, the differential of the entropy $S$ should be

$$
\mathrm{d} S=-k_{\mathrm{B}} \mathrm{~d}\left[\sum_{q} P_{q} \ln P_{q}\right]
$$

where the sum is over all system energy eigenfunctions $\psi_{q}^{\mathrm{S}}$ and $P_{q}$ is their probability. The differential can be simplified to

$$
\mathrm{d} S=-k_{\mathrm{B}} \sum_{q}\left[\ln P_{q}+1\right] \mathrm{d} P_{q}=-k_{\mathrm{B}} \sum_{q} \ln P_{q} \mathrm{~d} P_{q}
$$

the latter equality since the sum of the probabilities is always one, so $\sum_{q} \mathrm{~d} P_{q}$ $=0$.

This is to be compared with the macroscopic differential for the entropy. Since the macroscopic expression requires thermal equilibrium, $P_{q}$ in the microscopic expression above can be equated to the canonical value $e^{-E_{q}^{\mathrm{S}} / k_{\mathrm{B}} T} / Z$ where $E_{q}^{\mathrm{S}}$ is the energy of system eigenfunction $\psi_{q}^{\mathrm{S}}$. It simplifies the microscopic differential of the entropy to

$$
\begin{equation*}
\mathrm{d} S=-k_{\mathrm{B}} \sum_{q}\left[-\frac{E_{q}^{\mathrm{S}}}{k_{\mathrm{B}} T}-\ln Z\right] \mathrm{d} P_{q}=-k_{\mathrm{B}} \sum_{q}\left[-\frac{E_{q}^{\mathrm{S}}}{k_{\mathrm{B}} T}\right] \mathrm{d} P_{q}=\frac{1}{T} \sum_{q} E_{q}^{\mathrm{S}} \mathrm{~d} P_{q} \tag{D.38}
\end{equation*}
$$

the second inequality since $Z$ is a constant in the summation and $\sum_{q} \mathrm{~d} P_{q}=0$.
The macroscopic expression for the differential of entropy is given by (11.18),

$$
\mathrm{d} S=\frac{\delta Q}{T}
$$

Substituting in the differential first law (11.11),

$$
\mathrm{d} S=\frac{1}{T} \mathrm{~d} E+\frac{1}{T} P \mathrm{~d} V
$$

and plugging into that the definitions of $E$ and $P$,

$$
\mathrm{d} S=\frac{1}{T} \mathrm{~d}\left[\sum_{q} P_{q} E_{q}^{\mathrm{S}}\right]-\frac{1}{T}\left[\sum_{q} P_{q} \frac{\mathrm{~d} E_{q}^{\mathrm{S}}}{\mathrm{~d} V}\right] \mathrm{d} V
$$

and differentiating out the product in the first term, one part drops out versus the second term and what is left is the differential for $S$ according to the microscopic definition (D.38). So, the macroscopic and microscopic definitions agree to within a constant on the entropy. That means that they agree completely, because the macroscopic definition has no clue about the constant.

Now consider the case of a system with zero indeterminacy in energy. According to the fundamental assumption, all the eigenfunctions with the correct energy should have the same probability in thermal equilibrium. From the entropy's point of view, thermal equilibrium should be the stable most messy state, having the maximum entropy. For the two views to agree, the maximum of the microscopic expression for the entropy should occur when all eigenfunctions of the given energy have the same probability. Restricting attention to only the energy eigenfunctions $\psi_{q}^{S}$ with the correct energy, the maximum entropy occurs when the derivatives of

$$
F=-k_{\mathrm{B}} \sum_{q} P_{q} \ln P_{q}-\epsilon\left(\sum_{q} P_{q}-1\right)
$$

with respect to the $P_{q}$ are zero. Note that the constraint that the sum of the probabilities must be one has been added as a penalty term with a Lagrangian multiplier, $\{\mathrm{D} .48\}$. Taking derivatives produces

$$
-k_{\mathrm{B}} \ln \left(P_{q}\right)-k_{\mathrm{B}}-\epsilon=0
$$

showing that, yes, all the $P_{q}$ have the same value at the maximum entropy. (Note that the minima in entropy, all $P_{q}$ zero except one, do not show up in the derivation; $P_{q} \ln P_{q}$ is zero when $P_{q}=0$, but its derivative does not exist there. In fact, the infinite derivative can be used to verify that no maxima exist with any of the $P_{q}$ equal to zero if you are worried about that.)

If the energy is uncertain, and only the expectation energy is known, the penalized function becomes

$$
F=-k_{\mathrm{B}} \sum_{q} P_{q} \ln P_{q}-\epsilon_{1}\left(\sum P_{q}-1\right)-\epsilon_{2}\left(\sum E_{q}^{\mathrm{S}} P_{q}-E\right)
$$

and the derivatives become

$$
-k_{\mathrm{B}} \ln \left(P_{q}\right)-k_{\mathrm{B}}-\epsilon_{1}-\epsilon_{2} E_{q}^{\mathrm{S}}=0
$$

which can be solved to show that

$$
P_{q}=C_{1} e^{-E_{q}^{\mathrm{S}} / C_{2}}
$$

with $C_{1}$ and $C_{2}$ constants. The requirement to conform with the given definition of temperature identifies $C_{2}$ as $k_{\mathrm{B}} T$ and the fact that the probabilities must sum to one identifies $C_{1}$ as $1 / Z$.

For two systems $A$ and $B$ in thermal contact, the probabilities of the combined system energy eigenfunctions are found as the products of the probabilities of those of the individual systems. The maximum of the combined entropy, constrained by the given total energy $E$, is then found by differentiating

$$
\begin{aligned}
F= & -k_{\mathrm{B}} \sum_{q_{A}} \sum_{q_{B}} P_{q_{A}} P_{q_{B}} \ln \left(P_{q_{A}} P_{q_{B}}\right) \\
& -\epsilon_{1, A}\left(\sum_{q_{A}} P_{q_{A}}-1\right)-\epsilon_{1, B}\left(\sum_{q_{B}} P_{q_{B}}-1\right) \\
& -\epsilon_{2}\left(\sum_{q_{A}} P_{q_{A}} E_{q_{A}}^{S}+\sum_{q_{B}} P_{q_{B}} E_{q_{B}}^{S}-E\right)
\end{aligned}
$$

$F$ can be simplified by taking apart the logarithm and noting that the probabilities $P_{q_{A}}$ and $P_{q_{B}}$ sum to one to give

$$
\begin{aligned}
F= & -k_{\mathrm{B}} \sum_{q_{A}} P_{q_{A}} \ln \left(P_{q_{A}}\right)-k_{\mathrm{B}} \sum_{q_{B}} P_{q_{B}} \ln \left(P_{q_{B}}\right) \\
& -\epsilon_{1, A}\left(\sum_{q_{A}} P_{q_{A}}-1\right)-\epsilon_{1, B}\left(\sum_{q_{B}} P_{q_{B}}-1\right) \\
& -\epsilon_{2}\left(\sum_{q_{A}} P_{q_{A}} E_{q_{A}}^{\mathrm{S}}+\sum_{q_{B}} P_{q_{B}} E_{q_{B}}^{\mathrm{S}}-E\right)
\end{aligned}
$$

Differentiation now produces

$$
\begin{aligned}
& -k_{\mathrm{B}} \ln \left(P_{q_{A}}\right)-k_{\mathrm{B}}-\epsilon_{1, A}-\epsilon_{2} E_{q_{A}}^{\mathrm{S}}=0 \\
& -k_{\mathrm{B}} \ln \left(P_{q_{B}}\right)-k_{\mathrm{B}}-\epsilon_{1, B}-\epsilon_{2} E_{q_{B}}^{\mathrm{S}}=0
\end{aligned}
$$

which produces $P_{q_{A}}=C_{1, A} e^{-E_{q_{A}}^{\mathrm{S}} / C_{2}}$ and $P_{q_{B}}=C_{1, B} e^{-E_{q_{B}}^{\mathrm{S}} / C_{2}}$ and the common constant $C_{2}$ then implies that the two systems have the same temperature.

## D. 61 Chemical potential in the distributions

The following convoluted derivation of the distribution functions comes fairly straightly from Baierlein [4, pp. 170-]. Let it not deter you from reading the rest of this otherwise very clearly written and engaging little book. Even a nonengineering author should be allowed one mistake.

The derivations of the Maxwell-Boltzmann, Fermi-Dirac, and Bose-Einstein distributions given previously, $\{\mathrm{D} .57\}$ and $\{\mathrm{D} .58\}$, were based on finding the most numerous or most probable distribution. That implicitly assumes that significant deviations from the most numerous/probable distributions will be so rare that they can be ignored. This note will bypass the need for such an assumption since it will directly derive the actual expectation values of the singleparticle state occupation numbers $\iota$. In particular for fermions, the derivation will be solid as a rock.

The mission is to derive the expectation number $t_{n}$ of particles in an arbitrary single-particle state $\psi_{n}^{\mathrm{p}}$. This expectation value, as any expectation value, is given by the possible values times their probability:

$$
\iota_{n}=\sum_{q} i_{n} P_{q}
$$

where $i_{n}$ is the number of particles that system energy eigenfunction $\psi_{q}^{\mathrm{S}}$ has in single-particle state $\psi_{n}^{\mathrm{p}}$, and $P_{q}$ the probability of the eigenfunction. Since thermal equilibrium is assumed, the canonical probability value $e^{-E_{q}^{\mathrm{S}} / k_{\mathrm{B}} T} / Z$ can be substituted for $P_{q}$. Then, if the energy $E_{q}^{\mathrm{S}}$ is written as the sum of the ones of the single particle states times the number of particles in that state, it gives:

$$
\iota_{n}=\frac{1}{Z} \sum_{q} i_{n} e^{-\left(i_{1} E_{1}^{\mathrm{p}}+i_{2} E_{2}^{\mathrm{p}}+\ldots+i_{n-1} E_{n-1}^{\mathrm{p}}+i_{n} E_{n}^{\mathrm{p}}+i_{n+1} E_{n+1}^{\mathrm{p}}+\ldots\right) / k_{\mathrm{B}} T}
$$

Note that $i_{n}$ is the occupation number of single-particle state $\psi_{n}^{\mathrm{p}}$, just like $I_{s}$ was the occupation number of shelf $s$. Dealing with single-particle state occupation numbers has an advantage over dealing with shelf numbers: you do not have to figure out how many system eigenfunctions there are. For a given set of single-particle state occupation numbers $\vec{\imath}=\left|i_{1}, i_{2}, \ldots\right\rangle$, there is exactly one system energy eigenfunction. Compare figures 11.2 and 11.3: if you know how many particles there are in each single-particle state, you know everything there is to know about the eigenfunction depicted. (This does not apply to distinguishable particles, figure 11.1, because for them the numbers on the particles can still vary for given occupation numbers, but as noted in chapter 11.11, there is no such thing as identical distinguishable particles anyway.)

It has the big consequence that the sum over the eigenfunctions can be
replaced by sums over all sets of occupation numbers:

$$
\begin{aligned}
& \iota_{n}=\frac{1}{Z} \underbrace{\sum_{i_{1}} \sum_{i_{2}} \ldots \sum_{i_{n-1}} \sum_{i_{n}} \sum_{i_{n+1}} \ldots}_{i_{1}+i_{2}+\ldots+i_{n-1}+i_{n}+i_{n+1}+\ldots=I} \\
& i_{n} e^{-\left(i_{1} E_{1}^{\mathrm{p}}+i_{2} E_{2}^{\mathrm{p}}+\ldots+i_{n-1} E_{n-1}^{\mathrm{p}}+i_{n} E_{n}^{\mathrm{p}}+i_{n+1} E_{n+1}^{\mathrm{p}}+\ldots\right) / k_{\mathrm{B}} T}
\end{aligned}
$$

Each set of single-particle state occupation numbers corresponds to exactly one eigenfunction, so each eigenfunction is still counted exactly once. Of course, the occupation numbers do have to add up to the correct number of particles in the system.

Now consider first the case of $I$ identical bosons. For them the occupation numbers may have values up to a maximum of I:

$$
\iota_{n}=\frac{1}{Z} \underbrace{\sum_{i_{1}=0}^{I} \sum_{i_{2}=0}^{I} \ldots \sum_{i_{n-1}=0}^{I} \sum_{i_{n}=0}^{I} \sum_{i_{n+1}=0}^{I} \ldots}_{i_{1}+i_{2}+\ldots+i_{n-1}+i_{n}+i_{n+1}+\ldots=I}
$$

$$
i_{n} e^{-\left(i_{1} E_{1}^{\mathrm{p}}+i_{2} E_{2}^{\mathrm{p}}+\ldots+i_{n-1} E_{n-1}^{\mathrm{p}}+i_{n} E_{n}^{\mathrm{p}}+i_{n+1} E_{n+1}^{\mathrm{p}}+\ldots\right) / k_{\mathrm{B}} T}
$$

One simplification that is immediately evident is that all the terms that have $i_{n}$ $=0$ are zero and can be ignored. Now apply a trick that only a mathematician would think of: define a new summation index $i_{n}^{\prime}$ by setting $i_{n}=1+i_{n}^{\prime}$. Then the summation over $i_{n}^{\prime}$ can start at 0 and will run up to $I-1$. Plugging $i_{n}=$ $1+i_{n}^{\prime}$ into the sum above gives

$$
\begin{aligned}
& \iota_{n}=\frac{1}{Z} \underbrace{\sum_{i_{1}+\ldots+i_{n-1}+i_{n}^{\prime}+i_{n+1}+\ldots}^{I} \ldots \sum_{i_{n-1}=0}^{I} \sum_{i_{n}^{\prime}=0}^{I-1} \sum_{i_{n+1}=0}^{I} \ldots}_{i_{1}=0} \\
&\left(1+i_{n}^{\prime}\right) e^{-\left(i_{1} E_{1}^{\mathrm{p}}+\ldots+i_{n-1} E_{n-1}^{\mathrm{p}}+E_{n}^{\mathrm{p}}+i_{n}^{\prime} E_{n}^{\mathrm{p}}+i_{n+1} E_{n+1}^{\mathrm{p}}+\ldots\right) / k_{\mathrm{B}} T}
\end{aligned}
$$

This can be simplified by taking the constant part of the exponential out of the summation. Also, the constraint in the bottom shows that the occupation numbers can no longer be any larger than $I-1$ (since the original $i_{n}$ is at least one), so the upper limits can be reduced to $I-1$. Finally, the prime on $i_{n}^{\prime}$ may as well be dropped, since it is just a summation index and it does not make a difference what name you give it. So, altogether,

$$
\iota_{n}=\frac{1}{Z} e^{-E_{n}^{\mathrm{p}} / k_{\mathrm{B}} T} \underbrace{\sum_{i_{1}=0}^{I-1} \ldots \sum_{i_{n-1}=0}^{I-1} \sum_{i_{n}=0}^{I-1} \sum_{i_{n+1}=0}^{I-1} \ldots}_{i_{1}+\ldots+i_{n-1}+i_{n}+i_{n+1}+\ldots=I-1}
$$

$$
\left(1+i_{n}\right) e^{-\left(i_{1} E_{1}^{\mathrm{p}}+\ldots+i_{n-1} E_{n-1}^{\mathrm{p}}+i_{n} E_{n}^{\mathrm{p}}+i_{n+1} E_{n+1}^{\mathrm{p}}+\ldots\right) / k_{\mathrm{B}} T}
$$

The right hand side falls apart into two sums: one for the 1 in $1+i_{n}$ and one for the $i_{n}$ in $1+i_{n}$. The first sum is essentially the partition function $Z^{-}$ for a system with $I-1$ particles instead of $I$. The second sum is essentially $Z^{-}$ times the expectation value $\iota_{n}^{-}$for such a system. To be precise

$$
\iota_{n}=\frac{1}{Z} e^{-E_{n}^{\mathrm{p}} / k_{\mathrm{B}} T} Z^{-}\left[1+\iota_{n}^{-}\right]
$$

This equation is exact, no approximations have been made yet.
The system with $I-1$ particles is the same in all respects to the one for $I$ particles, except that it has one less particle. In particular, the single-particle energy eigenfunctions are the same, which means the volume of the box is the same, and the expression for the canonical probability is the same, meaning that the temperature is the same.

But when the system is macroscopic, the occupation counts for $I-1$ particles must be virtually identical to those for $I$ particles. Clearly the physics should not change noticeably depending on whether $10^{20}$ or $10^{20}+1$ particles are present. If $\iota_{n}^{-}=\iota_{n}$, then the above equation can be solved to give:

$$
\iota_{n}=1 /\left[\frac{Z}{Z^{-}} e^{E_{n}^{\mathrm{p}} / k_{\mathrm{B}} T}-1\right]
$$

The final formula is the Bose-Einstein distribution with

$$
e^{-\mu / k_{\mathrm{B}} T}=\frac{Z}{Z^{-}}
$$

Solve for $\mu$ :

$$
\mu=-k_{\mathrm{B}} T \ln \left(\frac{Z}{Z^{-}}\right)=\frac{-k_{\mathrm{B}} T \ln (Z)+k_{\mathrm{B}} T \ln \left(Z^{-}\right)}{I-(I-1)}
$$

The final fraction is a difference quotient approximation for the derivative of the Helmholtz free energy with respect to the number of particles. Now a single particle change is an extremely small change in the number of particles, so the difference quotient will be to very great accuracy be equal to the derivative of the Helmholtz free energy with respect to the number of particles. And as noted earlier, in the obtained expressions, volume and temperature are held constant. So, $\mu=(\partial F / \partial I)_{T, V}$, and (11.39) identified that as the chemical potential. Do note that $\mu$ is on a single-particle basis, while $\bar{\mu}$ was taken to be on a molar basis. The Avogadro number $I_{\mathrm{A}}=6.022110^{26}$ particles per kmol converts between the two.

Now consider the case of $I$ identical fermions. Then, according to the exclusion principle, there are only two allowed possibilities for the occupation numbers: they can be zero or one:

$$
\iota_{n}=\frac{1}{Z} \underbrace{\sum_{i_{1}=0}^{1} \ldots \sum_{i_{n-1}=0}^{1} \sum_{i_{n}=0}^{1} \sum_{i_{n+1}=0}^{1} \ldots}_{i_{1}+\ldots+i_{n}+i_{n}+i_{n+1}+\ldots=I} i_{n} e^{-\left(i_{1} E_{1}^{\mathrm{p}}+\ldots+i_{n-1} E_{n-1}^{\mathrm{p}}+i_{n} E_{n}^{\mathrm{p}}+i_{n+1} E_{n+1}^{\mathrm{p}}+\ldots\right) / k_{\mathrm{B}} T}
$$

Again, all terms with $i_{n}=0$ are zero, so you can set $i_{n}=1+i_{n}^{\prime}$ and get

$$
\begin{aligned}
& \iota_{n}=\frac{1}{Z} \underbrace{\sum_{i_{1}+\ldots+i_{n-1}+i_{n}^{\prime}+i_{n+1}+\ldots}^{1} \ldots \sum_{i_{n-1}=0}^{1} \sum_{i_{n}^{\prime}=0}^{0} \sum_{i_{n+1}=0}^{1} \ldots}_{i_{1}=0} \\
&\left(1+i_{n}^{\prime}\right) e^{-\left(i_{1} E_{1}^{\mathrm{p}}+\ldots+i_{n-1} E_{n-1}^{\mathrm{p}}+E_{n}^{\mathrm{p}}+i_{n}^{\prime} E_{n}^{\mathrm{p}}+i_{n+1} E_{n+1}^{\mathrm{p}}+\ldots\right) / k_{\mathrm{B}} T}
\end{aligned}
$$

But now there is a difference: even for a system with $I-1$ particles $i_{n}^{\prime}$ can still have the value 1 but the upper limit is zero. Fortunately, since the above sum only sums over the single value $i_{n}^{\prime}=0$, the factor $\left(1+i_{n}^{\prime}\right)$ can be replaced by $\left(1-i_{n}^{\prime}\right)$ without changing the answer. And then the summation can include $i_{n}^{\prime}$ $=1$ again, because $\left(1-i_{n}^{\prime}\right)$ is zero when $i_{n}^{\prime}=1$. This sign change produces the sign change in the Fermi-Dirac distribution compared to the Bose-Einstein one; the rest of the analysis is the same.

Here are some additional remarks about the only approximation made, that the systems with $I$ and $I-1$ particles have the same expectation occupation numbers. For fermions, this approximation is justified to the gills, because it can be easily be seen that the obtained value for the occupation number is in between those of the systems with $I-1$ and $I$ particles. Since nobody is going to count whether a macroscopic system has $10^{20}$ particles or $10^{20}+1$, this is truly as good as any theoretical prediction can possibly get.

But for bosons, it is a bit trickier because of the possibility of condensation. Assume, reasonably, that when a particle is added, the occupation numbers will not go down. Then the derived expression overestimates both expectation occupation numbers $\iota_{n}$ and $\iota_{n}^{-}$. However, it could at most be wrong, (i.e. have a finite relative error) for a finite number of states, and the number of singleparticle states will be large. (In the earlier derivation using shelf numbers, the actual $\iota_{n}$ was found to be lower than the Bose-Einstein value by a factor $\left(N_{s}-1\right) / N_{s}$ with $N_{s}$ the number of states on the shelf.)

If the factor $Z e^{E_{1}^{\mathrm{p}} / k_{\mathrm{B}} T} / Z^{-}$is one exactly, which definitely means Bose-Einstein condensation, then $i_{1}=1+i_{1}^{-}$. In that case, the additional particle that the system with $I$ particles has goes with certainty into the ground state. So the ground state better be unique then; the particle cannot go into two ground states.

## D. 62 Fermi-Dirac integrals at low temperature

This note finds the basic Fermi-Dirac integrals for the free-electron gas at low temperature. To summarize the main text, the number of particles and total energy per unit volume are to be found from

$$
\frac{I}{\mathcal{V}}=\int_{0}^{\infty}{ }_{\iota^{\mathrm{f}}} \mathcal{D} \mathrm{~d} E^{\mathrm{p}} \quad \frac{E}{\mathcal{V}}=\int_{0}^{\infty} E^{\mathrm{p}} \iota^{\mathrm{f}} \mathcal{D} \mathrm{~d} E^{\mathrm{p}}
$$

where the Fermi-Dirac distribution and the density of states are:

$$
\iota^{\mathrm{f}}=\frac{1}{e^{\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T}+1} \quad \mathcal{D}=\frac{n_{s}}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \sqrt{E^{\mathrm{p}}}
$$

and the number of spin states $n_{s}=2 s+1=2$ for systems of electrons. This may be rewritten in terms of the scaled energies

$$
u=\frac{E^{\mathrm{p}}}{k_{\mathrm{B}} T} \quad u_{0}=\frac{\mu}{k_{\mathrm{B}} T}
$$

to give

$$
\begin{aligned}
& \frac{I}{\mathcal{V}}=\frac{n_{s}}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \mu^{3 / 2} \int_{u=0}^{\infty} \frac{\left(u / u_{0}\right)^{1 / 2}}{e^{u-u_{0}}+1} \mathrm{~d}\left(u / u_{0}\right) \\
& \frac{E}{\mathcal{V}}=\frac{n_{s}}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \mu^{5 / 2} \int_{u=0}^{\infty} \frac{\left(u / u_{0}\right)^{3 / 2}}{e^{u-u_{0}}+1} \mathrm{~d}\left(u / u_{0}\right)
\end{aligned}
$$

To find the number of particles per unit volume for small but nonzero temperature, in the final integral change integration variable to $v=\left(u / u_{0}\right)-1$, then take the integral apart as

$$
\int_{-1}^{0} \sqrt{1+v} \mathrm{~d} v-\int_{-1}^{0} \frac{\sqrt{1+v} e^{u_{0} v} \mathrm{~d} v}{e^{u_{0} v}+1}+\int_{0}^{\infty} \frac{\sqrt{1+v} \mathrm{~d} v}{e^{u_{0} v}+1}
$$

and clean it up, by dividing top and bottom of the center integral by the exponential and then inverting the sign of $v$ in the integral, to give

$$
\int_{-1}^{0} \sqrt{1+v} \mathrm{~d} v+\int_{0}^{1} \frac{(\sqrt{1+v}-\sqrt{1-v}) \mathrm{d} v}{e^{u_{0} v}+1}+\int_{1}^{\infty} \frac{\sqrt{1+v} \mathrm{~d} v}{e^{u_{0} v}+1}
$$

In the second integral, the range that is not killed off by the exponential in the bottom is very small for large $u_{0}$ and you can therefore approximate $\sqrt{1+v}-\sqrt{1-v}$ as $v$, or using a Taylor series if still higher precision is required. (Note that the Taylor series only includes odd terms. That makes the final expansions proceed in powers of $1 / u_{0}^{2}$.) The range of integration can be extended to infinity, since the exponential in the bottom is exponentially large beyond $v=1$. For the same reason, the third integral can be ignored completely. Note that $\int_{0}^{\infty} x \mathrm{~d} x /\left(e^{x}+1\right)=\pi^{2} / 12$, see [41, 18.81-82, p. 132] for this and additional integrals.

Finding the number of particles per unit volume $I / \mathcal{V}$ this way and then solving the expression for the Fermi level $\mu$ gives

$$
\begin{equation*}
\mu=E_{\mathrm{F}}^{\mathrm{p}}-\frac{\pi^{2}}{12}\left(\frac{k_{\mathrm{B}} T}{E_{\mathrm{F}}^{\mathrm{p}}}\right)^{2} E_{\mathrm{F}}^{\mathrm{p}}+\ldots \quad E_{\mathrm{F}}^{\mathrm{p}}=\left(\frac{6 \pi^{2}}{n_{s}}\right)^{2 / 3} \frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3} \tag{D.39}
\end{equation*}
$$

This used the approximations that $\mu \approx E_{\mathrm{F}}^{\mathrm{p}}$ and $u_{0}^{-2}$ is small, so

$$
u_{0}^{-2}=\left(\frac{k_{\mathrm{B}} T}{\mu}\right)^{2} \approx\left(\frac{k_{\mathrm{B}} T}{E_{\mathrm{F}}^{\mathrm{p}}}\right)^{2} \quad\left(1+\frac{\pi^{2}}{8} u_{0}^{-2}\right)^{-2 / 3} \approx 1-\frac{2}{3} \frac{\pi^{2}}{8} u_{0}^{-2}
$$

The integral in the expression for the total energy per unit volume goes exactly the same way. That gives the average energy per particle as

$$
\begin{equation*}
\frac{E}{I}=E_{\mathrm{ave}}^{\mathrm{p}}=\frac{3}{5} E_{\mathrm{F}}^{\mathrm{p}}+\frac{\pi^{2}}{4}\left(\frac{k_{\mathrm{B}} T}{E_{\mathrm{F}}^{\mathrm{p}}}\right)^{2} E_{\mathrm{F}}^{\mathrm{p}}+\ldots \tag{D.40}
\end{equation*}
$$

To get the specific heat at constant volume, divide by $m$ and differentiate with respect to temperature:

$$
C_{v}=\frac{\pi^{2}}{2} \frac{k_{\mathrm{B}} T}{E_{\mathrm{F}}^{\mathrm{p}}} \frac{k_{\mathrm{B}}}{m}+\ldots
$$

## D. 63 Angular momentum uncertainty

Suppose that an eigenstate, call it $|m\rangle$, of $\widehat{J}_{z}$ is also an eigenstate of $\widehat{J}_{x}$. Then $\left[\widehat{J}_{z}, \widehat{J}_{x}\right]|m\rangle$ must be zero, and the commutator relations say that this is equivalent to $\widehat{J}_{y}|m\rangle=0$, which makes $|m\rangle$ also an eigenvector of $\widehat{J}_{y}$, and with the eigenvalue zero to boot. So the angular momentum in the $y$-direction must be zero. Repeating the same argument using the $\left[\widehat{J}_{x}, \widehat{J}_{y}\right]$ and $\left[\widehat{J}_{y}, \widehat{J}_{z}\right]$ commutator pairs shows that the angular momentum in the other two directions is zero too. So there is no angular momentum at all, $|m\rangle$ is an $|00\rangle$ state.

## D. 64 Spherical harmonics by ladder operators

One application of ladder operators is to find the spherical harmonics, which as noted in chapter 4.2.3 is not an easy problem. To do it with ladder operators, show that

$$
\widehat{L}_{x}=\frac{\hbar}{\mathrm{i}}\left(-\sin \phi \frac{\partial}{\partial \theta}-\frac{\cos \theta \cos \phi}{\sin \theta} \frac{\partial}{\partial \phi}\right) \quad \widehat{L}_{y}=\frac{\hbar}{\mathrm{i}}\left(\cos \phi \frac{\partial}{\partial \theta}-\frac{\cos \theta \sin \phi}{\sin \theta} \frac{\partial}{\partial \phi}\right)
$$

then that

$$
\begin{equation*}
L^{+}=\hbar e^{\mathrm{i} \phi}\left(\frac{\partial}{\partial \theta}+\mathrm{i} \frac{\cos \theta}{\sin \theta} \frac{\partial}{\partial \phi}\right) \quad L^{-}=\hbar e^{-\mathrm{i} \phi}\left(-\frac{\partial}{\partial \theta}+\mathrm{i} \frac{\cos \theta}{\sin \theta} \frac{\partial}{\partial \phi}\right) \tag{D.42}
\end{equation*}
$$

Note that the spherical harmonics are of the form $Y_{l}^{m}=e^{\mathrm{i} m \phi} \Theta_{l}^{m}(\theta)$, so

$$
L^{+} Y_{l}^{m}=\hbar e^{\mathrm{i}(m+1) \phi} \sin ^{m} \theta \frac{\mathrm{~d}\left(\Theta_{l}^{m} / \sin ^{m} \theta\right)}{\mathrm{d} \theta}
$$

$$
L^{-} Y_{l}^{m}=-\hbar e^{\mathrm{i}(m-1) \phi} \frac{1}{\sin ^{m} \theta} \frac{\mathrm{~d}\left(\Theta_{l}^{m} \sin ^{m} \theta\right)}{\mathrm{d} \theta}
$$

Find the $Y_{l}^{l}$ harmonic from $\widehat{L}^{+} Y_{l}^{l}=0$. That gives

$$
\begin{equation*}
Y_{l}^{l}=\sqrt{\frac{1}{4 \pi} \frac{(2 l+1)!}{\left(2^{l} l!\right)^{2}}} e^{\mathrm{i} l \phi} \sin ^{l} \theta=\sqrt{\frac{1}{4 \pi} \frac{135 \ldots(2 l+1)}{246 \ldots 2 l}}(x+\mathrm{i} y)^{l} \tag{D.43}
\end{equation*}
$$

Now apply $\widehat{L}^{-}$to find the rest of the ladder.
Interestingly enough, the solution of the one-dimensional harmonic oscillator problem can also be found using ladder operators. It turns out that, in the notation of that problem,

$$
H^{+}=-\mathrm{i} \widehat{p}+m \omega \widehat{x} \quad H^{-}=\mathrm{i} \widehat{p}+m \omega \widehat{x}
$$

are commutator eigenoperators of the harmonic oscillator Hamiltonian, with eigenvalues $\pm \hbar \omega$. So, you can play the same games of constructing ladders. Easier, really, since there is no equivalent to square angular momentum to worry about in that problem: there is only one ladder. See [25, pp. 42-47] for details. An equivalent derivation is given in addendum \{A.15.5\} based on quantum field theory.

## D. 65 How to make Clebsch-Gordan tables

The procedure of finding the Clebsch-Gordan coefficients for the combination of any two spin ladders is exactly the same as for electron ones, so it is simple enough to program.

To further simplify things, it turns out that the coefficients are all square roots of rational numbers (i.e. ratios of integers such as $102 / 38$.) The stepup and step-down operators by themselves produce square roots of rational numbers, so at first glance it would appear that the individual Clebsch-Gordan coefficients would be sums of square roots. But the square roots of a given coefficient are all compatible and can be summed into one. To see why, consider the coefficients that result from applying the combined step down ladder $\widehat{J}_{a b}^{-}$ a few times on the top of the ladder $|j j\rangle_{a}|j j\rangle_{b}$. Every contribution to the coefficient of a state $|j m\rangle_{a}|j m\rangle_{b}$ comes from applying $\widehat{J}_{a}^{-}$for $j_{a}-m_{a}$ times and $\widehat{J}_{b}^{-}$for $j_{b}-m_{b}$ times, so all contributions have compatible square roots. $\widehat{J}_{a b}^{-}$ merely adds an $m_{a b}$ dependent normalization factor.

You might think this pattern would be broken when you start defining the tops of lower ladders, since that process uses the step up operators. But because $\widehat{J}^{+} \widehat{J}^{-}$and $\widehat{J^{-}} \widehat{J}^{+}$are rational numbers (not square roots), applying the up operators is within a rational number the same as applying the down ones, and the pattern turns out to remain.

Additional note: There is also a direct expression for the Clebsch-Gordan coefficients:

$$
\begin{aligned}
& \left\langle j m \mid j_{1} m_{1}\right\rangle\left|j_{2} m_{2}\right\rangle= \\
& \quad \delta_{m_{1}+m_{2} m} \\
& \quad \sqrt{(2 j+1)\left(j_{1}+j_{2}-j\right)!\left(j_{1}-j_{2}+j\right)!\left(-j_{1}+j_{2}+j\right)!/\left(j_{1}+j_{2}+j+1\right)!} \\
& \quad \sqrt{\left(j_{1}+m_{1}\right)!\left(j_{1}-m_{1}\right)!\left(j_{2}+m_{2}\right)!\left(j_{2}-m_{2}\right)!(j+m)!(j-m)!} \\
& \quad \sum_{z=z_{1}}^{z_{\mathrm{h}}} \frac{(-1)^{z}}{\prod_{i=1}^{3}\left(z-z_{1 i}\right)!\left(z_{\mathrm{h} i}-z\right)!}
\end{aligned}
$$

where $\delta$ is the Kronecker delta and

$$
\begin{gathered}
z_{11}=0 \quad z_{12}=j_{1}+m_{2}-j \quad z_{13}=j_{2}-m_{1}-j \quad z_{1}=\min \left(z_{11}, z_{12}, z_{13}\right) \\
z_{\mathrm{h} 1}=j_{1}+j_{2}-j \quad z_{\mathrm{h} 2}=j_{1}-m_{1} \quad z_{\mathrm{h} 2}=j_{2}+m_{2} \quad z_{\mathrm{h}}=\min \left(z_{\mathrm{h} 1}, z_{\mathrm{h} 2}, z_{\mathrm{h} 3}\right)
\end{gathered}
$$

Carefully coded, this one seems to be numerically superior at larger angular momenta. Either way, these coefficients will overflow pretty quickly.

There are also resources on the web to compute these coefficients. See \{N.13\} for additional information.

## D. 66 The triangle inequality

The normal triangle inequality continues to apply for expectation values in quantum mechanics.

The way to show that is, like other triangle inequality proofs, rather curious: examine the combination of $\widehat{\vec{J}}_{a}$, not with $\hat{\vec{J}}_{b}$, but with an arbitrary multiple $\lambda$ of $\widehat{\vec{J}}_{b}$ :

$$
\left\langle\left(\vec{J}_{a}+\lambda \vec{J}_{b}\right)^{2}\right\rangle=\left\langle\left(J_{x, a}+\lambda J_{x, b}\right)^{2}\right\rangle+\left\langle\left(J_{y, a}+\lambda J_{y, b}\right)^{2}\right\rangle+\left\langle\left(J_{z, a}+\lambda J_{z, b}\right)^{2}\right\rangle
$$

For $\lambda=1$ this produces the expectation value of $\left(\vec{J}_{a}+\vec{J}_{b}\right)^{2}$, for $\lambda=-1$, the one for $\left(\vec{J}_{a}-\vec{J}_{b}\right)^{2}$. In addition, it is positive for all values of $\lambda$, since it consists of expectation values of square Hermitian operators. (Just examine each term in terms of its own eigenstates.)

If you multiply out, you get

$$
\left\langle\left(\vec{J}_{a}+\lambda \vec{J}_{b}\right)^{2}\right\rangle=J_{a}^{2}+2 M \lambda+J_{b}^{2} \lambda^{2}
$$

where $J_{a} \equiv \sqrt{\left\langle J_{x a}^{2}+J_{y a}^{2}+J_{z a}^{2}\right\rangle}, J_{b} \equiv \sqrt{\left\langle J_{x b}^{2}+J_{y b}^{2}+J_{z b}^{2}\right\rangle}$, and $M$ represents mixed terms that do not need to be written out. In order for this quadratic form in $\lambda$ to always be positive, the discriminant must be negative:

$$
M^{2}-J_{a}^{2} J_{b}^{2} \leqslant 0
$$

which means, taking square roots,

$$
-J_{a} J_{b} \leqslant M \leqslant J_{a} J_{b}
$$

and so
or

$$
J_{a}^{2}-2 J_{a} J_{b}+J_{b}^{2} \leqslant\left\langle\left(\vec{J}_{a}+\vec{J}_{b}\right)^{2}\right\rangle \leqslant J_{a}^{2}+2 J_{a} J_{b}+J_{b}^{2}
$$

$$
\left|J_{a}-J_{b}\right|^{2} \leqslant\left\langle\left(\vec{J}_{a}+\vec{J}_{b}\right)\right\rangle^{2} \leqslant\left|J_{a}+J_{b}\right|^{2}
$$

and taking square roots gives the triangle inequality.
Note that this derivation does not use any properties specific to angular momentum and does not require the simultaneous existence of the components. With a bit of messing around, the azimuthal quantum number relation $\left|j_{a}-j_{b}\right|$ $\leqslant j_{a b} \leqslant j_{a}+j_{b}$ can be derived from it if a unique value for $j_{a b}$ exists; the key is to recognize that $J=j+\delta$ where $\delta$ is an increasing function of $j$ that stays below $1 / 2$, and the $j$ values must be half integers. This derivation is not as elegant as using the ladder operators, but the result is the same.

## D. 67 Momentum of shells

Table 12.1 was originally taken from [36], who in turn took it from the book of Mayer and Jensen. However, the final table contains three typos, as can be seen from the fact that in three cases the numbers of states do not add up to the correct total. (The errors are: for 3 particles with spin $9 / 2$, the $13 / 2$ combined state is omitted, for 4 particles with spin $9 / 2$, the spin 8 state should be double, and for 4 particles with spin $11 / 2$, a spin 7 (double) state is missing. Similarly, [5, p. 140] has the same missing 13/2 combined state, and in addition for 3 particles with spin $7 / 2$, there is a $1 / 2$ state that should not be there.)

So table 12.1 was instead computer-generated, and should therefore be free of typos. Since the program had to be written anyway, some more values were generated and are in table D.1.

Deducing the table using Clebsch-Gordan coefficients would be a messy exercise indeed. A simpler procedure, [31], will here be illustrated for the example that the number of fermions is $I=3$ and the angular momentum of the singleparticle states is $j^{\mathrm{p}}=5 / 2$. Then the possibilities for the single-particle angular momentum in the $z$-direction are $m^{\mathrm{p}}=5 / 2,3 / 2,1 / 2,-1 / 2,-3 / 2$, and $-5 / 2$. So there

Table D.1: Additional combined angular momentum values.
are 6 different one particle states, and these will give rise to $6!/ 3!(6-3)!=20$ different antisymmetric states for 3 particles, chapter 5.7.

The combination states can be chosen to have definite values of the combined angular momentum $j$ and momentum in the $z$-direction $m$. In the absence of any antisymmetrization requirements, that can be seen from the way that states combine using Clebsch-Gordan coefficients. And these states of definite combined angular momentum must either be antisymmetric and allowable, or symmetric and not allowed. The reason is that exchanging fermions does not do anything physically, since the fermions are identical. So the angular momentum and particle exchange operators commute. Therefore, the eigenstates of the angular momentum operators can also be taken to be eigenstates of the particle exchange operators, which means either symmetric (eigenvalue 1) or antisymmetric (eigenvalue -1 ).

Let $m$ be the total magnetic quantum number of the 3 fermions in any combination of $j^{\mathrm{p}}=5 / 2$ single-particle states. First note that $m$ is the sum of the three $m^{\mathrm{p}}$ values of the individual particles. Next, the highest that $\mathrm{m}^{\mathrm{p}}$ can be is $5 / 2$, but the fermions cannot all three be in the same $m^{p}=5 / 2$ state, only one can. Three fermions need three different states, so the highest the combined $m$ can be is $5 / 2+3 / 2+1 / 2$. This triplet of values of $m^{\mathrm{p}}$ gives exactly one antisymmetric combination of states with $m=9 / 2$. (There is only one Slater determinant for three different given states, chapter 5.7). Since the combined angular momentum of this state in any arbitrary direction can never be observed to be more than $9 / 2$, because that would violate the above argument in a rotated coordinate system, it must be a $j=9 / 2$ state. The first conclusion is therefore that the angular momenta cannot combine into a total greater than $j=9 / 2$. And since $j$ cannot be less than $m$, there must be states with $j=9 / 2$.

But note that if $j=m=9 / 2$ is a valid combination of single-particle states, then so should be the states with $j=9 / 2$ for the other values of $m$; these can be thought of as fully equivalent states simply oriented under a different angle. That means that there are a total of 10 combination states with $j=9 / 2$, in which $m$ is any one of $9 / 2,7 / 2, \ldots,-9 / 2$.

Next consider what combinations have $m=7 / 2$. The only combination of three different $m^{\mathrm{p}}$ values that adds up to $7 / 2$ is $5 / 2+3 / 2-1 / 2$. So there is only one combined state with $m=7 / 2$. Since it was already inferred above that there must be one such state with $j=9 / 2$, that must be the only one. So apparently there is no state with $j=7 / 2$ : such a state would show up as a second $m=7 / 2$ state under the right orientation.

There are two independent possibilities to create a triplet of different states with $m=5 / 2: 5 / 2+3 / 2-3 / 2$ or $5 / 2+1 / 2-1 / 2$. One combination of such a type is already identified as being a $j=9 / 2$ state, so the second must correspond to a $j=5 / 2$ state. Since the orientation should again not make a difference, there must be a total of 6 such states, one for each of the different values of $m$ in the range from $5 / 2$ to $-5 / 2$.

There are three ways to create a triplet of states with $m=3 / 2: 5 / 2+3 / 2-5 / 2$, $5 / 2+1 / 2-3 / 2$, and $3 / 2+1 / 2-1 / 2$. Two of these are already identified as being $j=$ $9 / 2$ and $j=5 / 2$, so there must be one set of 4 states with $j=3 / 2$.

That makes a total of 20 states, so there must not be any states with $j=1 / 2$. Indeed, there are only three ways to produce $m=1 / 2: 5 / 2+1 / 2-5 / 2,5 / 2-1 / 2-3 / 2$, and $3 / 2+1 / 2-3 / 2$, and each of these three states is already assigned to a value of $j$.

It is tricky, but it works. And it is easily put on a computer.
For bosons, the idea is the same, except that states with equal values of $m^{p}$ can no longer be excluded.

## D. 68 Awkward questions about spin

Now of course you ask: how do you know how the mathematical expressions for spin states change when the coordinate system is rotated around some axis? Darn.

If you did a basic course in linear algebra, they will have told you how the components of normal vectors change when the coordinate system is rotated, but not spin vectors, or spinors, which are two-dimensional vectors in three-dimensional space.

You need to go back to the fundamental meaning of angular momentum. The effect of rotations of the coordinate system around the $z$-axis was discussed in addendum \{A.19\}. The expressions given there can be straightforwardly generalized to rotations around a line in the direction of an arbitrary unit vector $\left(n_{x}, n_{y}, n_{z}\right)$. Rotation by an angle $\varphi$ multiplies the $n$-direction angular momentum eigenstates by $e^{\mathrm{i} m \varphi}$ if $m \hbar$ is the angular momentum in the $n$-direction. For electron spin, the values for $m$ are $\pm \frac{1}{2}$, so, using the Euler formula (2.5) for the exponential, the eigenstates change by a factor

$$
\cos \left(\frac{1}{2} \varphi\right) \pm \mathrm{i} \sin \left(\frac{1}{2} \varphi\right)
$$

For arbitrary combinations of the eigenstates, the first of the two terms above still represents multiplication by the number $\cos \left(\frac{1}{2} \varphi\right)$.

The second term may be compared to the effect of the $n$-direction angular momentum operator $\widehat{J}_{n}$, which multiplies the angular momentum eigenstates by $\pm \frac{1}{2} \hbar$; it is seen to be $2 \mathrm{i} \sin \left(\frac{1}{2} \varphi\right) \widehat{J}_{n} / \hbar$. So the operator that describes rotation of the coordinate system over an angle $\varphi$ around the $n$-axis is

$$
\begin{equation*}
\mathcal{R}_{n, \varphi}=\cos \left(\frac{1}{2} \varphi\right)+\mathrm{i} \sin \left(\frac{1}{2} \varphi\right) \frac{2}{\hbar} \widehat{J}_{n} \tag{D.44}
\end{equation*}
$$

Further, in terms of the $x, y$, and $z$ angular momentum operators, the angular momentum in the $n$-direction is

$$
\widehat{J}_{n}=n_{x} \widehat{J}_{x}+n_{y} \widehat{J}_{y}+n_{z} \widehat{J}_{z}
$$

If you put it in terms of the Pauli spin matrices, $\hbar$ drops out:

$$
\mathcal{R}_{n, \varphi}=\cos \left(\frac{1}{2} \varphi\right)+\mathrm{i} \sin \left(\frac{1}{2} \varphi\right)\left(n_{x} \sigma_{x}+n_{y} \sigma_{y}+n_{z} \sigma_{z}\right)
$$

Using this operator, you can find out how the spin-up and spin-down states are described in terms of correspondingly defined basis states along the $x$ - or $y$ axis, and then deduce these correspondingly defined basis states in terms of the $z$ ones.

Note however that the very idea of defining the positive $x$ and $y$ angular momentum states from the $z$ ones by rotating the coordinate system over $90^{\circ}$ is somewhat specious. If you rotate the coordinate system over $450^{\circ}$ instead, you get a different answer! Off by a factor -1 , to be precise. But that is as bad as the indeterminacy gets; whatever way you rotate the axis system to the new position, the basis vectors you get will either be the same or only a factor -1 different $\{\mathrm{D} .69\}$.

More awkwardly, the negative momentum states obtained by rotation do not lead to real positive numerical factors for the corresponding ladder operators. Presumably, this reflects the fact that at the wave function level, nature does not have the rotational symmetry that it has for observable quantities. Anyway, if nature does not bother to obey such symmetry, then there seems no point in pretending it does. Especially since the nonpositive ladder factors would mess up various formulae. The negative spin states found by rotation go out of the window. Bye, bye.

## D. 69 More awkwardness about spin

How about that? A note on a note.
The previous note brought up the question: why can you only change the spin states you find in a given direction by a factor -1 by rotating your point of view? Why not by i, say?

With a bit of knowledge of linear algebra and some thought, you can see that this question is really: how can you change the spin states if you perform an arbitrary number of coordinate system rotations that end up in the same orientation as they started?

One way to answer this is to show that the effect of any two rotations of the coordinate system can be achieved by a single rotation over a suitably chosen net angle around a suitably chosen net axis. (Mathematicians call this showing the "group" nature of the rotations.) Applied repeatedly, any set of rotations of the starting axis system back to where it was becomes a single rotation around a single axis, and then it is easy to check that at most a change of sign is possible.
(To show that any two rotations are equivalent to one, just crunch out the multiplication of two rotations, which shows that it takes the algebraic form of a single rotation, though with a unit vector $\vec{n}$ not immediately evident to be of
length one. By noting that the determinant of the rotation matrix must be one, it follows that the length is in fact one.)

## D. 70 Emergence of spin from relativity

This note will give a (relatively) simple derivation of the Dirac equation to show how relativity naturally gives rise to spin. The equation will be derived without ever mentioning the word spin while doing it, just to prove it can be done. Only Dirac's assumption that Einstein's square root disappears,

$$
\sqrt{\left(m c^{2}\right)^{2}+\sum_{i=1}^{3}\left(\widehat{p}_{i} c\right)^{2}}=\alpha_{0} m c^{2}+\sum_{i=1}^{3} \alpha_{i} \widehat{p}_{i} c,
$$

will be used and a few other assumptions that have nothing to do with spin.
The conditions on the coefficient matrices $\alpha_{i}$ for the linear combination to equal the square root can be found by squaring both sides in the equation above and then comparing sides. They turn out to be:

$$
\begin{equation*}
\alpha_{i}^{2}=1 \text { for every } i \quad \alpha_{i} \alpha_{j}+\alpha_{j} \alpha_{i}=0 \text { for } i \neq j \tag{D.45}
\end{equation*}
$$

Now assume that the matrices $\alpha_{i}$ are Hermitian, as appropriate for measurable energies, and choose to describe the wave function vector in terms of the eigenvectors of matrix $\alpha_{0}$. Under those conditions $\alpha_{0}$ will be a diagonal matrix, and its diagonal elements must be $\pm 1$ for its square to be the unit matrix. So, choosing the order of the eigenvectors suitably,

$$
\alpha_{0}=\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)
$$

where the sizes of the positive and negative unit matrices in $\alpha_{0}$ are still undecided; one of the two could in principle be of zero size.

However, since $\alpha_{0} \alpha_{i}+\alpha_{i} \alpha_{0}$ must be zero for the three other Hermitian $\alpha_{i}$ matrices, it is seen from multiplying that out that they must be of the form

$$
\alpha_{1}=\left(\begin{array}{cc}
0 & \sigma_{1}^{\dagger} \\
\sigma_{1} & 0
\end{array}\right) \quad \alpha_{2}=\left(\begin{array}{cc}
0 & \sigma_{2}^{\dagger} \\
\sigma_{2} & 0
\end{array}\right) \quad \alpha_{3}=\left(\begin{array}{cc}
0 & \sigma_{3}^{\dagger} \\
\sigma_{3} & 0
\end{array}\right)
$$

The $\sigma_{i}$ matrices, whatever they are, must be square in size or the $\alpha_{i}$ matrices would be singular and could not square to one. This then implies that the positive and negative unit matrices in $\alpha_{0}$ must be the same size.

Now try to satisfy the remaining conditions on $\alpha_{1}, \alpha_{2}$, and $\alpha_{3}$ using just complex numbers, rather than matrices, for the $\sigma_{i}$. By multiplying out the conditions (D.45), you see that

$$
\alpha_{i} \alpha_{i}=1 \Longrightarrow \sigma_{i}^{\dagger} \sigma_{i}=\sigma_{i} \sigma_{i}^{\dagger}=1
$$

$$
\alpha_{i} \alpha_{j}+\alpha_{j} \alpha_{i}=0 \Longrightarrow \sigma_{i}^{\dagger} \sigma_{j}+\sigma_{j}^{\dagger} \sigma_{i}=\sigma_{i} \sigma_{j}^{\dagger}+\sigma_{j} \sigma_{i}^{\dagger}=0
$$

The first condition above would require each $\sigma_{i}$ to be a number of magnitude one, in other words, a number that can be written as $e^{\mathrm{i} \phi_{i}}$ for some real angle $\phi_{i}$. The second condition is then according to the Euler formula (2.5) equivalent to the requirement that

$$
\cos \left(\phi_{i}-\phi_{j}\right)=0 \text { for } i \neq j ;
$$

this implies that all three angles would have to be 90 degrees apart. That is impossible: if $\phi_{2}$ and $\phi_{3}$ are each 90 degrees apart from $\phi_{1}$, then $\phi_{2}$ and $\phi_{3}$ are either the same or apart by 180 degrees; not by 90 degrees.

It follows that the components $\sigma_{i}$ cannot be numbers, and must be matrices too. Assume, reasonably, that they correspond to some measurable quantity and are Hermitian. In that case the conditions above on the $\sigma_{i}$ are the same as those on the $\alpha_{i}$, with one critical difference: there are only three $\sigma_{i}$ matrices, not four. And so the analysis repeats.

Choose to describe the wave function in terms of the eigenvectors of the $\sigma_{3}$ matrix; this does not conflict with the earlier choice since all half wave function vectors are eigenvectors of the positive and negative unit matrices in $\alpha_{0}$. So you have

$$
\sigma_{3}=\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)
$$

and the other two matrices must then be of the form

$$
\sigma_{1}=\left(\begin{array}{cc}
0 & \tau_{1}^{\dagger} \\
\tau_{1} & 0
\end{array}\right) \quad \sigma_{2}=\left(\begin{array}{cc}
0 & \tau_{2}^{\dagger} \\
\tau_{2} & 0
\end{array}\right)
$$

But now the components $\tau_{1}$ and $\tau_{2}$ can indeed be just complex numbers, since there are only two, and two angles can be apart by 90 degrees. You can take $\tau_{1}$ $=e^{\mathrm{i} \phi_{1}}$ and then $\tau_{2}=e^{\mathrm{i}\left(\phi_{1}+\pi / 2\right)}$ or $e^{\mathrm{i}\left(\phi_{1}-\pi / 2\right)}$. The existence of two possibilities for $\tau_{2}$ implies that on the wave function level, nature is not mirror symmetric; momentum in the positive $y$-direction interacts differently with the $x$ and $z$ momenta than in the opposite direction. Since the observable effects are mirror symmetric, do not worry about it and just take the first possibility.

So, the goal of finding a formulation in which Einstein's square root falls apart has been achieved. However, you can clean up some more, by redefining the value of $\tau_{1}$ away. If the four-dimensional wave function vector takes the form $\left(a_{1}, a_{2}, a_{3}, a_{4}\right)$, define $\bar{a}_{1}=e^{\mathrm{i} \phi_{1} / 2} a_{1}, \bar{a}_{2}=e^{-\mathrm{i} \phi_{1} / 2} a_{2}$ and similar for $\bar{a}_{3}$ and $\bar{a}_{4}$.

In that case, the final cleaned-up $\sigma$ matrices are

$$
\sigma_{3}=\left(\begin{array}{rr}
1 & 0  \tag{D.46}\\
0 & -1
\end{array}\right) \quad \sigma_{1}=\left(\begin{array}{ll}
0 & 1 \\
1 & 0
\end{array}\right) \quad \sigma_{2}=\left(\begin{array}{rr}
0 & -\mathrm{i} \\
\mathrm{i} & 0
\end{array}\right)
$$

The "s" word has not been mentioned even once in this derivation. So, now please express audible surprise that the $\sigma_{i}$ matrices turn out to be the Pauli (it can now be said) spin matrices of chapter 12.10.

But there is more. Suppose you define a new coordinate system rotated 90 degrees around the $z$-axis. This turns the old $y$-axis into a new $x$-axis. Since $\tau_{2}$ has an additional factor $e^{\mathrm{i} \pi / 2}$, to get the normalized coefficients, you must include an additional factor $e^{\mathrm{i} \pi / 4}$ in $\bar{a}_{1}$, which by the fundamental definition of angular momentum discussed in addendum \{A.19\} means that it describes a state with angular momentum $1 / 2 \hbar$. Similarly $a_{3}$ corresponds to a state with angular momentum $1 / 2 \hbar$ and $a_{2}$ and $a_{4}$ to ones with $-1 / 2 \hbar$.

For nonzero momentum, the relativistic evolution of spin and momentum becomes coupled. But still, if you look at the eigenstates of positive energy, they take the form:

$$
\binom{\vec{a}}{\varepsilon(\vec{p} \cdot \vec{\sigma}) \vec{a}}
$$

where $\varepsilon$ is a small number in the nonrelativistic limit and $\vec{a}$ is the two-component vector $\left(a_{1}, a_{2}\right)$. The operator corresponding to rotation of the coordinate system around the momentum vector commutes with $\vec{p} \cdot \vec{\sigma}$, hence the entire four-dimensional vector transforms as a combination of a spin $\frac{1}{2} \hbar$ state and a spin $-\frac{1}{2} \hbar$ state for rotation around the momentum vector.

## D. 71 Electromagnetic commutators

The purpose of this note is to identify the two commutators of chapter 13.1; the one that produces the velocity (or rather, the rate of change in expectation position), and the one that produces the force (or rather the rate of change in expectation linear momentum). All basic properties of commutators used in the derivations below are described in chapter 4.5.4.

The Hamiltonian is

$$
H=\frac{1}{2 m}(\widehat{\vec{p}}-q \vec{A}) \cdot(\widehat{\vec{p}}-q \vec{A})+q \varphi=\frac{1}{2 m} \sum_{j=1}^{3}\left(\widehat{p}_{j}-q A_{j}\right)^{2}+q \varphi
$$

when the dot product is written out in index notation.
The rate of change in the expectation value of a position vector component $r_{i}$ is according to chapter 7.2 given by

$$
\frac{\mathrm{d}\left\langle r_{i}\right\rangle}{\mathrm{d} t}=\left\langle\frac{\mathrm{i}}{\hbar}\left[H, r_{i}\right]\right\rangle
$$

so you need the commutator

$$
\left[H, r_{i}\right]=\left[\frac{1}{2 m} \sum_{j=1}^{3}\left(\widehat{p}_{j}-q A_{j}\right)^{2}+q \varphi, r_{i}\right]
$$

Now the term $q \varphi$ can be dropped, since functions of position commute with each other. On the remainder, use the fact that each of the two factors $\widehat{p}_{j}-q A_{j}$ comes out at its own side of the commutator, to give

$$
\left[H, r_{i}\right]=\frac{1}{2 m} \sum_{j=1}^{3}\left\{\left(\widehat{p}_{j}-q A_{j}\right)\left[\widehat{p}_{j}-q A_{j}, r_{i}\right]+\left[\widehat{p}_{j}-q A_{j}, r_{i}\right]\left(\widehat{p}_{j}-q A_{j}\right)\right\}
$$

and then again, since the vector potential is just a function of position too, the $q A_{j}$ can be dropped from the commutators. What is left is zero unless $j$ is the same as $i$, since different components of position and momentum commute, and when $j=i$, it is minus the canonical commutator, (minus since the order of $r_{i}$ and $\widehat{p}_{i}$ is inverted), and the canonical commutator has value $\mathrm{i} \hbar$, so

$$
\left[H, r_{i}\right]=-\frac{1}{m} \mathrm{i} \hbar\left(\widehat{p}_{i}-q A_{i}\right)
$$

Plugging this in the time derivative of the expectation value of position, you get

$$
\frac{\mathrm{d}\left\langle r_{i}\right\rangle}{\mathrm{d} t}=\frac{1}{m}\left\langle\widehat{p}_{i}-q A_{i}\right\rangle
$$

so the normal momentum $m v_{i}$ is indeed given by the operator $\widehat{p}_{i}-q A_{i}$.
On to the other commutator! The $i$-th component of Newton's second law in expectation form,

$$
m \frac{\mathrm{~d}\left\langle v_{i}\right\rangle}{\mathrm{d} t}=\left\langle\frac{\mathrm{i}}{\hbar}\left[H, \widehat{p}_{i}-q A_{i}\right]\right\rangle-q\left\langle\frac{\partial A_{i}}{\partial t}\right\rangle
$$

requires the commutator

$$
\left[H, \widehat{p}_{i}-q A_{i}\right]=\left[\frac{1}{2 m} \sum_{j=1}^{3}\left(\widehat{p}_{j}-q A_{j}\right)^{2}+q \varphi, p_{i}-q A_{i}\right]
$$

The easiest is the term $q \varphi$, since both $\varphi$ and $A_{i}$ are functions of position and commute. And the commutator with $\widehat{p}_{i}$ is the generalized fundamental operator of chapter 4.5.4,

$$
\left[q \varphi, p_{i}\right]=\mathrm{i} \hbar q \frac{\partial \varphi}{\partial r_{i}}
$$

and plugging that into Newton's equation, you can verify that the electric field term of the Lorentz law has already been obtained.

In what is left of the desired commutator, again take each factor $\widehat{p}_{j}-q A_{j}$ to its own side of the commutator:

$$
\frac{1}{2 m} \sum_{j=1}^{3}\left\{\left(\widehat{p}_{j}-q A_{j}\right)\left[\widehat{p}_{j}-q A_{j}, p_{i}-q A_{i}\right]+\left[\widehat{p}_{j}-q A_{j}, p_{i}-q A_{i}\right]\left(\widehat{p}_{j}-q A_{j}\right)\right\}
$$

Work out the simpler commutator appearing here first:

$$
\left[\widehat{p}_{j}-q A_{j}, p_{i}-q A_{i}\right]=-q\left[p_{j}, A_{i}\right]-q\left[A_{j}, p_{i}\right]=\mathrm{i} \hbar q \frac{\partial A_{i}}{\partial r_{j}}-\mathrm{i} \hbar q \frac{\partial A_{j}}{\partial r_{i}}
$$

the first equality because momentum operators and functions commute, and the second equality is again the generalized fundamental commutator.

Note that by assumption the derivatives of $\vec{A}$ are constants, so the side of $\widehat{p}_{j}-q A_{j}$ that this result appears is not relevant and what is left of the Hamiltonian becomes

$$
\frac{q \mathrm{i} \hbar}{m} \sum_{j=1}^{3}\left\{\frac{\partial A_{i}}{\partial r_{j}}-\frac{\partial A_{j}}{\partial r_{i}}\right\}\left(\widehat{p}_{j}-q A_{j}\right)
$$

Now let $\bar{\imath}$ be the index following $i$ in the sequence $123123 \ldots$ and $\overline{\bar{\imath}}$ the one preceding it (or the second following). Then the sum above will have a term where $j=i$, but that term is seen to be zero, a term where $j=\bar{\imath}$, and a term where $j=\overline{\bar{\imath}}$. The total is then:

$$
\frac{q i \hbar}{m}\left\{\left(\widehat{p}_{\bar{\imath}}-q A_{\bar{\imath}}\right)\left(\frac{\partial A_{i}}{\partial r_{\bar{\imath}}}-\frac{\partial A_{\bar{\imath}}}{\partial r_{i}}\right)-\left(\widehat{p}_{\overline{\bar{\imath}}}-q A_{\overline{\bar{\imath}}}\right)\left(\frac{\partial A_{\overline{\bar{\imath}}}}{\partial r_{i}}-\frac{\partial A_{i}}{\partial r_{\overline{\bar{\imath}}}}\right)\right\}
$$

and that is

$$
-\frac{q \mathrm{i} \hbar}{m}\left\{\left(\widehat{p}_{\bar{\imath}}-q A_{\bar{\imath}}\right)(\nabla \times \vec{A})_{\bar{\imath}}-\left(\widehat{p}_{\overline{\bar{\imath}}}-q A_{\overline{\bar{\imath}}}\right)(\nabla \times \vec{A})_{\bar{\imath}}\right\}
$$

and the expression in brackets is the $i$-th component of $(\hat{\vec{p}}-q \vec{A}) \times(\nabla \times \vec{A})$ and produces the $q \vec{v} \times \overrightarrow{\mathcal{B}}$ term in Newton's equation provided that $\overrightarrow{\mathcal{B}}=\nabla \times \vec{A}$.

## D. 72 Various electrostatic derivations.

This section gives various derivations for the electromagnetostatic solutions of chapter 13.3.

## D.72.1 Existence of a potential

This subsection shows that if the curl of the electric field $\overrightarrow{\mathcal{E}}$ (or of any other vector field, like the magnetic one or a force field), is zero, it is minus the gradient of some potential.

That potential can be defined to be

$$
\begin{equation*}
\varphi(\vec{r})=-\int_{\vec{r}_{0}}^{\vec{r}} \overrightarrow{\mathcal{E}}(\underline{\vec{r}}) \mathrm{d} \underline{\vec{r}} \tag{D.47}
\end{equation*}
$$

where $\vec{r}_{0}$ is some arbitrarily chosen reference point. You might think that the value of $\varphi(\vec{r})$ would depend on what integration path you took from the reference point to $\vec{r}$, but the Stokes' theorem of calculus says that the difference between integrals leading to the same path must be zero since $\nabla \times \overrightarrow{\mathcal{E}}$ is zero.

Now if you evaluate $\varphi$ at a neighboring point $\vec{r}+\hat{\imath} \partial x$ by a path first going to $\vec{r}$ and from there straight to $\vec{r}+\hat{\imath} \partial x$, the difference in integrals is just the integral over the final segment:

$$
\begin{equation*}
\varphi(\vec{r}+\hat{\imath} \partial x)-\varphi(\vec{r})=-\int_{\vec{r}}^{\vec{r}+\hat{\imath} \partial x} \overrightarrow{\mathcal{E}}(\underline{\vec{r}}) \mathrm{d} \underline{\vec{r}} \tag{D.48}
\end{equation*}
$$

Dividing by $\partial x$ and then taking the limit $\partial x \rightarrow 0$ shows that minus the $x$ derivative of $\varphi$ gives the $x$-component of the electric field. The same of course for the other components, since the $x$-direction is arbitrary.

Note that if regions are multiply connected, the potential may not be quite unique. The most important example of that is the magnetic potential of an infinite straight electric wire. Since the curl of the magnetic field is nonzero inside the wire, the path of integration must stay clear of the wire. It then turns out that the value of the potential depends on how many times the chosen integration path wraps around the wire. Indeed, the magnetic potential is $\varphi_{m}$ $=-I \theta / 2 \pi \epsilon_{0} c^{2}$. and as you know, an angle like $\theta$ is indeterminate by any integer multiple of $2 \pi$.

## D.72.2 The Laplace equation

The homogeneous Poisson equation,

$$
\begin{equation*}
\nabla^{2} \varphi=0 \tag{D.49}
\end{equation*}
$$

for some unknown function $\varphi$ is called the Laplace equation. It is very important in many areas of physics and engineering. This note derives some of its generic properties.

The so-called mean-value property says that the average of $\varphi$ over the surface of any sphere in which the Laplace equation holds is the value of $\varphi$ at the center of the sphere. To see why, for convenience take the center of the sphere as the origin of a spherical coordinate system. Now

$$
\begin{aligned}
0 & =\int_{\text {sphere }} \nabla^{2} \varphi \mathrm{~d}^{3} \vec{r} \\
& =\iiint \frac{\partial \varphi}{\partial r} r^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \\
& =\frac{1}{4 \pi} \iint \frac{\partial \varphi}{\partial r} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi \\
& =\frac{\partial}{\partial r} \frac{1}{4 \pi} \iint \varphi \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi
\end{aligned}
$$

the first equality since $\varphi$ satisfies the Laplace equation, the second because of the divergence theorem, the third because the integral is zero, so a constant factor does not make a difference, and the fourth by changing the order of integration and differentiation. It follows that the average of $\varphi$ is the same on all spherical surfaces centered around the origin. Since this includes as a limiting case the origin and the average of $\varphi$ over the single point at the origin is just $\varphi$ at the origin, the mean value property follows.

The so called maximum-minimum principle says that either $\varphi$ is constant everywhere or its maximum and minimum are on a boundary or at infinity. The reason is the mean-value property above. Suppose there is an absolute maximum in the interior of the region in which the Laplace equation applies. Enclose the maximum by a small sphere. Since the values of $\varphi$ would be less than the maximum on the surface of the sphere, the average value on the surface must be less than the maximum too. But the mean value theorem says it must be the same. The only way around that is if $\varphi$ is completely constant in the sphere, but then the "maximum" is not a true maximum. And then you can start "sphere-hopping" to show that $\varphi$ is constant everywhere. Minima go the same way.

The only solution of the Laplace equation in all of space that is zero at infinity is zero everywhere. In more general regions, as long as the solution is zero on all boundaries, including infinity where relevant, then the solution is zero everywhere. The reason is the maximum-minimum principle: if there was a point where the solution was positive/negative, then there would have to be an interior maximum/minimum somewhere.

The solution of the Laplace equation for given boundary values is unique. The reason is that the difference between any two solutions must satisfy the Laplace equation with zero boundary values, hence must be zero.

## D.72.3 Egg-shaped dipole field lines

The egg shape of the ideal dipole field lines can be found by assuming that the dipole is directed along the $z$-axis. Then the field lines in the $x z$-plane satisfy

$$
\frac{\mathrm{d} z}{\mathrm{~d} x}=\frac{\mathcal{E}_{z}}{\mathcal{E}_{x}}=\frac{2 z^{2}-x^{2}}{3 z x}
$$

Change to a new variable $u$ by replacing $z$ by $x u$ to get:

$$
x \frac{\mathrm{~d} u}{\mathrm{~d} x}=-\frac{1+u^{2}}{3 u} \Longrightarrow \int \frac{3 u \mathrm{~d} u}{1+u^{2}}=-\int \frac{\mathrm{d} x}{x}
$$

Integrating and replacing $u$ again by $z / x$ gives

$$
\left(x^{2}+z^{2}\right)^{3 / 2}=C x^{2}
$$

where $C$ represents the integration constant from the integration. Near the origin, $x \sim z^{3 / 2} / C$; therefore the field line has infinite curvature at the origin, explaining the pronounced egg shape. Rewritten in spherical coordinates, the field lines are given by $r=C \sin ^{2} \theta$ and $\phi$ constant, and that is also valid outside the $x z$-plane.

## D.72.4 Ideal charge dipole delta function

Next is the delta function in the electric field generated by a charge distribution that is contracted to an ideal dipole. To find the precise delta function, the electric field can be integrated over a small sphere, but still large enough that on its surface the ideal dipole potential is valid. The integral will give the strength of the delta function. Since the electric field is minus the gradient of the potential, an arbitrary component $\mathcal{E}_{i}$ integrates to

$$
\int_{\text {sphere }} \mathcal{E}_{i} \mathrm{~d}^{3} \vec{r}=-\int_{\text {sphere }} \nabla \cdot\left(\varphi \hat{\imath}_{i}\right) \mathrm{d}^{3} \vec{r}=-\int_{\text {sphere surface }} \varphi n_{i} \mathrm{~d} A
$$

where $\hat{\imath}_{i}$ is the unit vector in the $i$-direction and the divergence theorem of calculus was used to convert the integral to an integral over the surface area $A$ of the sphere. Noting that the vector $\vec{n}$ normal to the surface of the sphere equals $\vec{r} / r$, and that the potential is the ideal dipole one, you get

$$
\int_{\text {sphere }} \mathcal{E}_{i} \mathrm{~d}^{3} \vec{r}=-\frac{1}{4 \pi \epsilon_{0}} \int_{\text {sphere surface }} \frac{\vec{\gamma} \cdot \vec{r}}{r^{3}} \frac{r_{i}}{r} \mathrm{~d} A
$$

For simplicity, take the $z$-axis along the dipole moment; then $\vec{\wp} \cdot \vec{r}=\wp z$. For the $x$-component $\mathcal{E}_{x}, r_{i}=x$ so that the integrand is proportional to $x z$, and that integrates to zero over the surface of the sphere because the negative $x$ values cancel the positive ones at the same $z$. The same for the $y$-component of the field, so only the $z$-component, or more generally, the component in the same direction as $\vec{\wp}$, has a delta function. For $\mathcal{E}_{z}$, you are integrating $z^{2}$, and by symmetry that is the same as integrating $x^{2}$ or $y^{2}$, so it is the same as integrating $\frac{1}{3} r^{2}$. Since the surface of the sphere equals $4 \pi r^{2}$, the delta function included in the expression for the field of a dipole as listed in table 13.2 is obtained.

## D.72.5 Integrals of the current density

In subsequent derivations, various integrals of the current density $\vec{\jmath}$ are needed. In all cases it is assumed that the current density vanishes strongly outside some region. Of course, normally an electric motor or electromagnet has electrical leads going towards and away from of it; it is assumed that these are stranded so tightly together that their net effect can be ignored.

Consider an integral like $\int r_{i}{ }^{m} r_{\bar{\imath}}^{n} j_{i} \mathrm{~d}^{3} \vec{r}$ where $j_{i}$ is any component $j_{1}$, $j_{2}$, or $j_{3}$ of the current density, $\bar{\imath}$ is the index following $i$ in the sequence $\ldots 123123 \ldots$,
$m$ and $n$ are nonnegative integers, and the integration is over all of space. By integration by parts in the $i$-direction, and using the fact that the current densities vanish at infinity,

$$
\int r_{i}^{m} r_{\bar{\imath}}^{n} j_{i} \mathrm{~d}^{3} \vec{r}=-\int \frac{r_{i}^{m+1}}{m+1} r_{\bar{\imath}}^{n} \frac{\partial j_{i}}{\partial r_{i}} \mathrm{~d}^{3} \vec{r}
$$

Now use the fact that the divergence of the current density is zero since the charge density is constant for electromagnetostatic solutions:

$$
\int r_{i}^{m} r_{\bar{\imath}}^{n} j_{i} \mathrm{~d}^{3} \vec{r}=\int \frac{r_{i}^{m+1}}{m+1} r_{\bar{\imath}}^{n} \frac{\partial j_{\bar{\imath}}}{\partial r_{\bar{\imath}}} \mathrm{d}^{3} \vec{r}+\int \frac{r_{i}^{m+1}}{m+1} r_{\bar{\imath}}^{n} \frac{\partial j_{\overline{\bar{\imath}}}}{\partial r_{\bar{\imath}}} \mathrm{d}^{3} \vec{r}
$$

where $\overline{\bar{\imath}}$ is the index preceding $i$ in the sequence $\ldots 123123 \ldots$... The final integral can be integrated in the $\overline{\bar{\imath}}$-direction and is then seen to be zero because $\vec{\jmath}$ vanishes at infinity.

The first integral in the right hand side can be integrated by parts in the $\bar{\imath}$ direction to give the final result:

$$
\begin{equation*}
\int r_{i}^{m} r_{\bar{\imath}}^{n} j_{i} \mathrm{~d}^{3} \vec{r}=-\int \frac{r_{i}^{m+1}}{m+1} n r_{\bar{\imath}}^{n-1} j_{\bar{\imath}} \mathrm{d}^{3} \vec{r} \tag{D.50}
\end{equation*}
$$

It follows from this equation with $m=0, n=1$ that

$$
\begin{equation*}
\int r_{i} j_{\bar{\imath}} \mathrm{d}^{3} \vec{r}=-\int r_{\bar{\imath}} j_{i} \mathrm{~d}^{3} \vec{r}=\mu_{\overline{\bar{\imath}}} \quad \vec{\mu} \equiv \frac{1}{2} \int \vec{r} \times \vec{\jmath} \mathrm{d}^{3} \vec{r} \tag{D.51}
\end{equation*}
$$

with $\vec{\mu}$ the current distribution's dipole moment. In these expressions, you can swap indices as

$$
(i, \bar{\imath}, \overline{\bar{\imath}}) \rightarrow(\bar{\imath}, \overline{\bar{\imath}}, i) \quad \text { or } \quad(i, \bar{\imath}, \overline{\bar{\imath}}) \rightarrow(\overline{\bar{\imath}}, i, \bar{\imath})
$$

because only the relative ordering of the indices in the sequence ... 123123... is relevant.

In quantum applications, it is often necessary to relate the dipole moment to the angular momentum of the current carriers. Since the current density is the charge per unit volume times its velocity, you get the linear momentum per unit volume by multiplying by the ratio $m_{\mathrm{c}} / q_{\mathrm{c}}$ of current carrier mass over charge. Then the angular momentum is

$$
\vec{L}=\int \vec{r} \times \frac{m_{\mathrm{c}}}{q_{\mathrm{c}}} \vec{\jmath} \mathrm{~d}^{3} \vec{r}=\frac{2 m_{\mathrm{c}}}{q_{\mathrm{c}}} \vec{\mu}
$$

## D.72.6 Lorentz forces on a current distribution

Next is the derivation of the Lorentz forces on a given current distribution $\vec{\jmath}$ in a constant external magnetic field $\overrightarrow{\mathcal{B}}_{\text {ext }}$. The Lorentz force law says that the force $\vec{F}$ on a charge $q$ moving with speed $\vec{v}$ equals

$$
\vec{F}=q \vec{v} \times \overrightarrow{\mathcal{B}}_{\mathrm{ext}}
$$

In terms of a current distribution, the moving charge per unit volume times its velocity is the current density, so the force on a volume element $\mathrm{d}^{3} \vec{r}$ is:

$$
\mathrm{d} \vec{F}=\vec{\jmath} \times \overrightarrow{\mathcal{B}}_{\mathrm{ext}} \mathrm{~d}^{3} \vec{r}
$$

The net force on the current distribution is therefore zero, because according to (D.50) with $m=n=0$, the integrals of the components of the current distribution are zero.

The moment is not zero, however. It is given by

$$
\vec{M}=\int \vec{r} \times\left(\vec{\jmath} \times \overrightarrow{\mathcal{B}}_{\mathrm{ext}}\right) \mathrm{d}^{3} \vec{r}
$$

According to the vectorial triple product rule, that is

$$
\vec{M}=\int\left(\vec{r} \cdot \overrightarrow{\mathcal{B}}_{\text {ext }}\right) \vec{\jmath} \mathrm{d}^{3} \vec{r}-\int(\vec{r} \cdot \vec{\jmath}) \overrightarrow{\mathcal{B}}_{\text {ext }} \mathrm{d}^{3} \vec{r}
$$

The second integral is zero because of (D.50) with $m=1, n=0$. What is left is can be written in index notation as

$$
M_{i}=\int r_{i} \mathcal{B}_{\text {ext }, \mathrm{i}} j_{i} \mathrm{~d}^{3} \vec{r}+\int r_{\bar{\imath}} \mathcal{B}_{\text {ext }, \bar{i}} j_{i} \mathrm{~d}^{3} \vec{r}+\int r_{\bar{\imath}} \mathcal{B}_{\text {ext }, \bar{i}} j_{i} \mathrm{~d}^{3} \vec{r}
$$

The first of the three integrals is zero because of (D.50) with $m=1, n=0$. The other two can be rewritten using (D.51):

$$
M_{i}=-\mu_{\overline{\bar{\imath}}} \mathcal{B}_{\mathrm{ext}, \bar{\imath}}+\mu_{\bar{\imath}} \mathcal{B}_{\mathrm{ext}, \overline{\overline{1}}}
$$

and in vector notation that reads

$$
\vec{M}=\vec{\mu} \times \overrightarrow{\mathcal{B}}_{\mathrm{ext}}
$$

When the (frozen) current distribution is slowly rotated around the axis aligned with the moment vector, the work done is

$$
-M \mathrm{~d} \alpha=-\mu \mathcal{B}_{\text {ext }} \sin \alpha \mathrm{d} \alpha=\mathrm{d}\left(\mu \mathcal{B}_{\text {ext }} \cos \alpha\right)
$$

where $\alpha$ is the angle between $\vec{\mu}$ and $\overrightarrow{\mathcal{B}}_{\text {ext }}$. By integration, it follows that the work done corresponds to a change in energy for an energy given by

$$
E_{\mathrm{ext}}=-\vec{\mu} \cdot \overrightarrow{\mathcal{B}}_{\mathrm{ext}}
$$

## D.72.7 Field of a current dipole

A current density $\vec{\jmath}$ creates a magnetic field because of Maxwell's second and fourth equations for the divergence and curl of the magnetic field:

$$
\nabla \cdot \overrightarrow{\mathcal{B}}=0 \quad \nabla \times \overrightarrow{\mathcal{B}}=\frac{1}{\epsilon_{0} c^{2}} \vec{\jmath}
$$

where $\overrightarrow{\mathcal{B}}$ vanishes at infinity assuming there is no additional ambient magnetic field.

A magnetic vector potential $\vec{A}$ will now be defined as the solution of the Poisson equation

$$
\nabla^{2} \vec{A}=-\frac{1}{\epsilon_{0} c^{2}} \vec{\jmath}
$$

that vanishes at infinity. Taking the divergence of this equation shows that the divergence of the vector potential satisfies a homogeneous Poisson equation, because the divergence of the current density is zero, with zero boundary conditions at infinity. Therefore the divergence of the vector potential is zero. It then follows that

$$
\overrightarrow{\mathcal{B}}=\nabla \times \vec{A}
$$

because it satisfies the equations for $\overrightarrow{\mathcal{B}}$ : the divergence of any curl is zero, and the curl of the curl of the vector potential is according to the vectorial triple product its Laplacian, hence the correct curl of the magnetic field.

You might of course wonder whether there might not be more than one magnetic field that has the given divergence and curl and is zero at infinity. The answer is no. The difference between any two such fields must have zero divergence and curl. Therefore the curl of the curl of the difference is zero too, and the vectorial triple product shows that equal to minus the Laplacian of the difference. If the Laplacian of the difference is zero, then the difference is zero, since the difference is zero at infinity (subsection 2). So the solutions must be the same.

Since the integrals of the current density are zero, (D.50) with $m=n=0$, the asymptotic expansion (13.31) of the Green's function integral shows that at large distances, the components of $\vec{A}$ behave as a dipole potential. Specifically,

$$
A_{i} \sim \frac{1}{4 \pi \epsilon_{0} c^{2} r^{3}} \sum_{\underline{i}=1}^{3} r_{\underline{i}} \int \underline{r}_{\underline{i}} j_{i} \mathrm{~d}^{3} \overrightarrow{\underline{r}}
$$

Now the term $\underline{i}=i$ in the sum does not give a contribution, because of (D.50) with $m=1, n=0$. The other two terms are

$$
A_{i} \sim \frac{1}{4 \pi \epsilon_{0} c^{2} r^{3}}\left[r_{\bar{\imath}} \int \underline{r}_{\bar{\imath}} j_{i} \mathrm{~d}^{3} \underline{\vec{r}}+r_{\overline{\bar{\imath}}} \int \underline{r}_{\bar{\imath}} j_{i} \mathrm{~d}^{3} \underline{\vec{r}}\right]
$$

with $\bar{\imath}$ following $i$ in the sequence $\ldots 123123 \ldots$ and $\overline{\bar{\imath}}$ preceding it. These two integrals can be rewritten using (D.51) to give

$$
A_{i} \sim-\frac{1}{4 \pi \epsilon_{0} c^{2} r^{3}}\left[r_{\bar{i}} \mu_{\overline{\bar{z}}}-r_{\overline{\bar{z}}} \mu_{\overline{\mathrm{z}}}\right]
$$

Note that the expression between brackets is just the $i$-th component of $\vec{r} \times \vec{\mu}$.
The magnetic field is the curl of $\vec{A}$, so

$$
\mathcal{B}_{i}=\frac{\partial A_{\overline{\bar{\imath}}}}{\partial r_{\bar{\imath}}}-\frac{\partial A_{\overline{\bar{\imath}}}}{\partial r_{\overline{\bar{\imath}}}}
$$

and substituting in for the vector potential from above, differentiating, and cleaning up produces

$$
\mathcal{B}_{i}=\frac{3(\vec{\mu} \cdot \vec{r}) \vec{r}-\vec{\mu} r^{2}}{4 \pi \epsilon_{0} c^{2} r^{5}}
$$

This is the same asymptotic field as a charge dipole with strength $\vec{\mu}$ would have.
However, for an ideal current dipole, the delta function at the origin will be different than that derived for a charge dipole in the first subsection. Integrate the magnetic field over a sphere large enough that on its surface, the asymptotic field is accurate:

$$
\int \mathcal{B}_{i} \mathrm{~d}^{3} \vec{r}=\int \frac{\partial A_{\overline{\bar{z}}}}{\partial r_{\bar{\imath}}} \mathrm{d}^{3} \vec{r}-\int \frac{\partial A_{\bar{\imath}}}{\partial r_{\bar{\imath}}} \mathrm{d}^{3} \vec{r}
$$

Using the divergence theorem, the right hand side becomes an integral over the surface of the sphere:

$$
\int \mathcal{B}_{i} \mathrm{~d}^{3} \vec{r}=\int A_{\overline{\bar{\imath}}} \frac{r_{\bar{z}}}{r} \mathrm{~d} A-\int A_{\bar{\imath}} \frac{r_{\overline{\overline{\overline{ }}}}}{r} \mathrm{~d} A
$$

Substituting in the asymptotic expression for $A_{i}$ above,

$$
\int \mathcal{B}_{i} \mathrm{~d}^{3} \vec{r}=-\frac{1}{4 \pi \epsilon_{0} c^{2} r^{4}}\left[\int\left(r_{i} \mu_{\bar{\imath}}-r_{\bar{\imath}} \mu_{i}\right) r_{\bar{\imath}} \mathrm{d} A-\int\left(r_{\overline{\bar{\imath}}} \mu_{i}-r_{i} \mu_{\overline{\bar{\imath}}}\right) r_{\overline{\bar{\imath}}} \mathrm{d} A\right]
$$

The integrals of $r_{i} r_{\bar{\imath}}$ and $r_{i} r_{\overline{\bar{\imath}}}$ are zero, for one because the integrand is odd in $r_{i}$. The integrals of $r_{\bar{\imath}} r_{\bar{\imath}}$ and $r_{\overline{\bar{\imath}}} r_{\overline{\bar{\imath}}}$ are each one third of the integral of $r^{2}$ because of symmetry. So, noting that the surface area $A$ of the spherical surface is $4 \pi r^{2}$,

$$
\int \mathcal{B}_{i} \mathrm{~d}^{3} \vec{r}=\frac{2}{3 \epsilon_{0} c^{2}} \mu_{i}
$$

That gives the strength of the delta function for an ideal current dipole.

## D.72.8 Biot-Savart law

In the previous section, it was noted that the magnetic field of a current distribution is the curl of a vector potential $\vec{A}$. This vector potential satisfies the Poisson equation

$$
\nabla^{2} \vec{A}=-\frac{1}{\epsilon_{0} c^{2}} \vec{\jmath}
$$

The solution for the vector potential can be written explicitly in terms of the current density using the Green's function integral (13.29):

$$
A_{i}=\frac{1}{4 \pi \epsilon_{0} c^{2}} \int \frac{1}{|\vec{r}-\underline{\vec{r}}|} j_{i}(\overrightarrow{\underline{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}}
$$

The magnetic field is the curl of $\vec{A}$,

$$
\mathcal{B}_{i}=\frac{\partial A_{\overline{\bar{\imath}}}}{\partial r_{\bar{\imath}}}-\frac{\partial A_{\bar{\imath}}}{\partial r_{\overline{\bar{\imath}}}}
$$

or substituting in and differentiating under the integral

$$
\mathcal{B}_{i}=-\frac{1}{4 \pi \epsilon_{0} c^{2}} \int \frac{r_{\bar{\imath}}-\underline{r}_{\bar{\imath}}}{|\vec{r}-\underline{\vec{r}}|^{3}} j_{\overline{\bar{\imath}}}(\underline{\vec{r}})-\frac{r_{\overline{\overline{ }}}-\underline{r}_{\overline{\bar{\imath}}}}{|\vec{r}-\underline{\vec{r}}|^{3}} j_{\bar{\imath}}(\overrightarrow{\vec{r}}) \mathrm{d}^{3} \underline{\vec{r}}
$$

In vector notation that gives the Biot-Savart law

$$
\overrightarrow{\mathcal{B}}=-\frac{1}{4 \pi \epsilon_{0} c^{2}} \int \frac{\vec{r}-\underline{\vec{r}}}{|\vec{r}-\underline{\vec{r}}|^{3}} \times \vec{\jmath} \mathrm{d}^{3} \underline{\underline{r}}
$$

Now assume that the current distribution is limited to one or more thin wires, as it usually is. In that case, a volume element of nonzero current distribution can be written as

$$
\vec{\jmath}^{3}{ }^{3} \underline{\vec{r}}=I \mathrm{~d} \overrightarrow{\vec{r}}
$$

where in the right hand side $\underline{\vec{r}}$ describes the position of the centerline of the wire and $I$ is the current through the wire. More specifically, $I$ is the integral of the current density over the cross section of the wire. The Biot-Savart law becomes

$$
\overrightarrow{\mathcal{B}}=-\frac{1}{4 \pi \epsilon_{0} c^{2}} \int \frac{\vec{r}-\vec{r}}{|\vec{r}-\underline{\vec{r}}|^{3}} \times I(\underline{\vec{r}}) \mathrm{d} \underline{\vec{r}}
$$

where the integration is over all infinitesimal segments $\mathrm{d} \overrightarrow{\vec{r}}$ of the wires.

## D. 73 Orbital motion in a magnetic field

This note derives the energy of a charged particle in an external magnetic field. The field is assumed constant.

According to chapter 13.1, the Hamiltonian is

$$
H=\frac{1}{2 m}(\widehat{\vec{p}}-q \vec{A})^{2}+V
$$

where $m$ and $q$ are the mass and charge of the particle and the vector potential $\vec{A}$ is related to the magnetic field $\overrightarrow{\mathcal{B}}$ by $\overrightarrow{\mathcal{B}}=\nabla \times \vec{A}$. The potential energy $V$ is of no particular interest in this note. The first term is, and it can be multiplied out as:

$$
H=\frac{1}{2 m} \widehat{\vec{p}}^{2}-\frac{q}{2 m}(\widehat{\vec{p}} \cdot \vec{A}+\vec{A} \cdot \widehat{\vec{p}})+\frac{q^{2}}{2 m}(\vec{A})^{2}+V
$$

The middle two terms in the right hand side are the changes in the Hamiltonian due to the magnetic field; they will be denoted as:

$$
H_{\mathcal{B} L} \equiv-\frac{q}{2 m}(\widehat{\vec{p}} \cdot \vec{A}+\vec{A} \cdot \widehat{\vec{p}}) \quad H_{\mathcal{B} D} \equiv \frac{q^{2}}{2 m}(\vec{A})^{2}
$$

Now to simplify the analysis, align the $z$-axis with $\overrightarrow{\mathcal{B}}$ so that $\overrightarrow{\mathcal{B}}=\hat{k} \mathcal{B}_{z}$. Then an appropriate vector potential $\vec{A}$ is

$$
\vec{A}=-\hat{\imath} \frac{1}{2} y \mathcal{B}_{z}+\hat{\jmath} \frac{1}{2} x \mathcal{B}_{z}
$$

The vector potential is not unique, but a check shows that indeed $\nabla \times \vec{A}=$ $\hat{k} \mathcal{B}_{z}=\overrightarrow{\mathcal{B}}$ for the one above. Also, the canonical momentum is

$$
\widehat{\vec{p}}=\frac{\hbar}{\mathrm{i}} \nabla=\hat{\imath} \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial y}+\hat{k} \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial z}
$$

Therefore, in the term $H_{\mathcal{B L}}$ above,

$$
H_{\mathcal{B} L}=-\frac{q}{2 m}(\widehat{\vec{p}} \cdot \vec{A}+\vec{A} \cdot \widehat{\vec{p}})=-\frac{q}{2 m} \mathcal{B}_{z}\left(x \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial y}-y \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial x}\right)=-\frac{q}{2 m} \mathcal{B}_{z} \widehat{L}_{z}
$$

the latter equality being true because of the definition of angular momentum as $\vec{r} \times \widehat{\vec{p}}$. Because the $z$-axis was aligned with $\overrightarrow{\mathcal{B}}, \mathcal{B}_{z} \widehat{L}_{z}=\overrightarrow{\mathcal{B}} \cdot \widehat{\vec{L}}$, so, finally,

$$
H_{\mathcal{B} L}=-\frac{q}{2 m} \overrightarrow{\mathcal{B}} \cdot \widehat{\vec{L}}
$$

Similarly, in the part $H_{\mathcal{B} D}$ of the Hamiltonian, substitution of the expression for $\vec{A}$ produces

$$
\frac{q^{2}}{2 m}(\vec{A})^{2}=\frac{q^{2}}{8 m} \mathcal{B}_{z}^{2}\left(x^{2}+y^{2}\right)
$$

or writing it so that it is independent of how the $z$-axis is aligned,

$$
H_{\mathcal{B} D}=\frac{q^{2}}{8 m}(\overrightarrow{\mathcal{B}} \times \vec{r})^{2}
$$

## D. 74 Electron spin in a magnetic field

If you are curious how the magnetic dipole strength of the electron can just pop out of the relativistic Dirac equation, this note gives a quick derivation.

First, a problem must be addressed. Dirac's equation, chapter 12.12, assumes that Einstein's energy square root falls apart in a linear combination of terms:

$$
H=\sqrt{\left(m c^{2}\right)^{2}+\sum_{i=1}^{3}\left(\widehat{p}_{i} c\right)^{2}}=\alpha_{0} m c^{2}+\sum_{i=1}^{3} \alpha_{i} \widehat{p}_{i} c
$$

which works for the $4 \times 4 \alpha$ matrices given in that section. For an electron in a magnetic field, according to chapter 13.1 you want to replace $\widehat{\vec{p}}$ with $\widehat{\vec{p}}-q \vec{A}$ where $\vec{A}$ is the magnetic vector potential. But where should you do that, in the square root or in the linear combination? It turns out that the answer you get for the electron energy is not the same.

If you believe that the Dirac linear combination is the way physics really works, and its description of spin leaves little doubt about that, then the answer is clear: you need to put $\widehat{\vec{p}}-q \vec{A}$ in the linear combination, not in the square root.

So, what are now the energy levels? That would be hard to say directly from the linear form, so square it down to $H^{2}$, using the properties of the $\alpha$ matrices, as given in chapter 12.12 and its note. You get, in index notation,

$$
H^{2}=\left(m c^{2}\right)^{2} I+\sum_{i=1}^{3}\left(\left(\widehat{p}_{i}-q A_{i}\right) c\right)^{2} I+\sum_{i=1}^{3}\left[\widehat{p}_{\bar{\imath}}-q A_{\bar{\imath}}, \widehat{p}_{\overline{\bar{\imath}}}-q A_{\overline{\bar{l}}} c^{2} \alpha_{\bar{\imath}} \alpha_{\overline{\bar{\imath}}}\right.
$$

where $I$ is the four by four unit matrix, $\bar{\imath}$ is the index following $i$ in the sequence $123123 \ldots$, and $\overline{\bar{\imath}}$ is the one preceding $i$. The final sum represents the additional squared energy that you get by substituting $\widehat{\vec{p}}-q \vec{A}$ in the linear combination instead of the square root. The commutator arises because $\alpha_{\bar{\imath}} \alpha_{\overline{\bar{\imath}}}+\alpha_{\overline{\bar{\imath}}} \alpha_{\bar{\imath}}=0$, giving the terms with the indices reversed the opposite sign. Working out the commutator using the formulae of chapter 4.5.4, and the definition of the vector potential $\vec{A}$,

$$
H^{2}=\left(m c^{2}\right)^{2} I+\sum_{i=1}^{3}\left(\left(\widehat{p}_{i}-q A_{i}\right) c\right)^{2} I+q \hbar c^{2} \mathrm{i} \sum_{i=1}^{3} \mathcal{B}_{i} \alpha_{\bar{\imath}} \alpha_{\overline{\bar{\imath}}} .
$$

By multiplying out the expressions for the $\alpha_{i}$ of chapter 12.12, using the fundamental commutation relation for the Pauli spin matrices that $\sigma_{\bar{\imath}} \sigma_{\overline{\bar{\imath}}}=\mathrm{i} \sigma_{i}$,

$$
H^{2}=\left(m c^{2}\right)^{2} I+\sum_{i=1}^{3}\left(\left(\widehat{p}_{i}-q A_{i}\right) c\right)^{2} I-q \hbar c^{2} \sum_{i=1}^{3} \mathcal{B}_{i}\left(\begin{array}{cc}
\sigma_{i} & 0 \\
0 & \sigma_{i}
\end{array}\right)
$$

It it seen that due to the interaction of the spin with the magnetic field, the square energy changes by an amount $-q h c^{2} \sigma_{i} \mathcal{B}_{i}$. Since $\frac{1}{2} \hbar$ times the Pauli spin matrices gives the spin $\widehat{S}$, the square energy due to the magnetic field acting on the spin is $-2 q c^{2} \widehat{\vec{S}} \cdot \overrightarrow{\mathcal{B}}$.

In the nonrelativistic case, the rest mass energy $m c^{2}$ is much larger than the other terms, and in that case, if the change in square energy is $-2 q c^{2} \widehat{\vec{S}} \cdot \overrightarrow{\mathcal{B}}$, the change in energy itself is smaller by a factor $2 m c^{2}$, so the energy due to the magnetic field is

$$
\begin{equation*}
H_{\mathcal{B} S}=-\frac{q}{m} \widehat{\vec{S}} \cdot \overrightarrow{\mathcal{B}} \tag{D.52}
\end{equation*}
$$

which is what was to be proved.

## D. 75 Solving the NMR equations

To solve the two coupled ordinary differential equations for the spin up and down probabilities, first get rid of the time dependence of the right-hand-side matrix by defining new variables $A$ and $B$ by

$$
a=A e^{\mathrm{i} \omega t / 2}, \quad b=B e^{-\mathrm{i} \omega t / 2}
$$

Then find the eigenvalues and eigenvectors of the now constant matrix. The eigenvalues can be written as $\pm \mathrm{i} \omega_{1} / f$, where $f$ is the resonance factor given in the main text. The solution is then

$$
\binom{A}{B}=C_{1} \vec{v}_{1} e^{\mathrm{i} \omega_{1} t / f}+C_{2} \vec{v}_{2} e^{-\mathrm{i} \omega_{1} t / f}
$$

where $\vec{v}_{1}$ and $\vec{v}_{2}$ are the eigenvectors. To find the constants $C_{1}$ and $C_{2}$, apply the initial conditions $A(0)=a(0)=a_{0}$ and $B(0)=b(0)=b_{0}$ and clean up as well as possible, using the definition of the resonance factor and the Euler formula.

It's a mess.

## D. 76 Harmonic oscillator revisited

This note rederives the harmonic oscillator solution, but in spherical coordinates. The reason to do so is to obtain energy eigenfunctions that are also eigenfunctions of square angular momentum and of angular momentum in the $z$-direction. The derivation is very similar to the one for the hydrogen atom given in derivation $\{\mathrm{D} .15\}$, so the discussion will mainly focus on the differences.

The solutions are again in the form $R(r) Y_{l}^{m}(\theta, \phi)$ with the $Y_{l}^{m}$ the spherical harmonics. However, the radial functions $R$ are different; the equation for them is now

$$
-\frac{1}{R} \frac{\mathrm{~d}}{\mathrm{~d} r}\left(r^{2} \frac{\mathrm{~d} R}{\mathrm{~d} r}\right)+l(l+1)+\frac{2 m_{\mathrm{e}}}{\hbar^{2}} \frac{1}{2} m_{\mathrm{e}} \omega^{2} r^{4}=\frac{2 m_{e}}{\hbar^{2}} r^{2} E
$$

The difference from $\{\mathrm{D} .15\}$ is that a harmonic oscillator potential $\frac{1}{2} m_{e} \omega^{2} r^{2}$ has replaced the Coulomb potential. A suitable rescaling is now $r=\rho \sqrt{\hbar / m_{\mathrm{e}} \omega}$, which produces

$$
-\frac{1}{R} \frac{\mathrm{~d}}{\mathrm{~d} \rho}\left(\rho^{2} \frac{\mathrm{~d} R}{\mathrm{~d} \rho}\right)+l(l+1)+\rho^{4}=\rho^{2} \epsilon
$$

where $\epsilon=E / \frac{1}{2} \hbar \omega$ is the energy in half quanta.
Split off the expected asymptotic behavior for large $\rho$ by defining

$$
R=e^{-\rho^{2} / 2} f
$$

Then $f$ satisfies

$$
\rho^{2} f^{\prime \prime}+2 \rho f^{\prime}-l(l+1) f=2 \rho^{3} f^{\prime}+(3-\epsilon) \rho^{2} f
$$

Plug in a power series $f=\sum_{p} c_{p} \rho^{p}$, then the coefficients must satisfy:

$$
[p(p+1)-l(l+l)] c_{p}=[2(p-2)+3-\epsilon] c_{p-2}
$$

From that it is seen that the lowest power in the series is $p_{\text {min }}=l, p_{\text {min }}=-l-1$ not being acceptable. Also the series must terminate, or blow up will occur. That requires that $\epsilon=2 p_{\max }+3$. So the energy must be $\left(p_{\max }+\frac{3}{2}\right) \hbar \omega$ with $p_{\max }$ an integer no smaller than $l$, so at least zero.

Therefore, numbering the energy levels from $n=1$ like for the hydrogen level gives the energy levels as

$$
E_{n}=\left(n+\frac{1}{2}\right) \hbar \omega
$$

That are the same energy levels as derived in Cartesian coordinates, as they should be. However, the eigenfunctions are different. They are of the form

$$
\psi_{n l m}=e^{-\rho^{2} / 2} P_{n l}(\rho) Y_{l}^{m}(\theta, \phi)
$$

where $P_{n l}$ is some polynomial of degree $n-1$, whose lowest power of $\rho$ is $\rho^{l}$. The value of the azimuthal quantum number $l$ must run up to $n-1$ like for the hydrogen atom. However, in this case $l$ must be odd or even depending on whether $n-1$ is odd or even, or the power series will not terminate.

Note that for even $l$, the power series proceed in even powers of $r$. These eigenfunctions are said to have even parity: if you replace $r$ by $-r$, they are unchanged. Similarly, the eigenfunctions for odd $l$ expand in odd powers of $r$. They are said to have odd parity; if you replace $r$ by $-r$, they change sign.

## D. 77 Impenetrable spherical shell

To solve the problem of particles stuck inside an impenetrable shell of radius $a$, refer to addendum \{A.6\}. According to that addendum, the solutions without unacceptable singularities at the center are of the form

$$
\begin{equation*}
\psi_{E l m}(r, \theta, \phi) \propto j_{l}\left(p_{r m c} r / \hbar\right) Y_{l}^{m}(\theta, \phi) \quad p_{r m c} \equiv \sqrt{2 m(E-V)} \tag{D.53}
\end{equation*}
$$

where the $j_{l}$ are the spherical Bessel functions of the first kind, the $Y_{l}^{m}$ the spherical harmonics, and $p_{r m c}$ is the classical momentum of a particle with energy $E . V_{0}$ is the constant potential inside the shell, which can be taken to be zero without fundamentally changing the solution.

Because the wave function must be zero at the shell $r=a, p_{r m c} a / \hbar$ must be one of the zero-crossings of the spherical Bessel functions. Therefore the allowable energy levels are

$$
\begin{equation*}
E_{\bar{n} l}=\frac{h b a r^{2}}{2 m a^{2}} \beta_{\bar{n} l}^{2}+V_{0} \tag{D.54}
\end{equation*}
$$

where $\beta_{\bar{n} l}$ is the $\bar{n}$-th zero-crossing of spherical Bessel function $j_{l}$ (not counting the origin). Those crossings can be found tabulated in for example [1], (under the guise of the Bessel functions of half-integer order.)

In terms of the count $n$ of the energy levels of the harmonic oscillator, $\bar{n}=$ 1 corresponds to energy level $n=l+1$, and each next value of $\bar{n}$ increases the energy levels by two, so

$$
n=l-1+2 \bar{n}
$$

## D. 78 Shell model quadrupole moment

The result for one proton is readily available in literature and messy to derive yourself. If you want to give it a try anyway, one way is the following. Note that in spherical coordinates

$$
3 z^{2}-r^{2}=2 r^{2}-3 r^{2} \sin ^{2} \theta
$$

and the first term produces $2\left\langle r^{2}\right\rangle$ simply by the definition of expectation value. The problem is to get rid of the $\sin ^{2} \theta$ in the second expectation value.

To do so, use chapter 12.8, 2. That shows that the second term is essentially $3\left\langle r^{2}\right\rangle$ modified by factors of the form

$$
\left\langle Y_{l}^{l} \mid \sin ^{2} \theta Y_{l}^{l}\right\rangle \quad \text { and } \quad\left\langle Y_{l}^{l-1} \mid \sin ^{2} \theta Y_{l}^{l-1}\right\rangle
$$

where the integration is over the unit sphere. If you use the representation of the spherical harmonics as given in \{D.64\}, you can relate these inner products to the unit inner products

$$
\left\langle Y_{l+1}^{l+1} \mid Y_{l+1}^{l+1}\right\rangle \quad \text { and } \quad\left\langle Y_{l+1}^{l} \mid Y_{l+1}^{l}\right\rangle
$$

Have fun.
The expression for the quadrupole moment if there are an odd number $i \geqslant$ 3 of protons in the shell would seem to be a very messy exercise. Some text books suggest that the odd-particle shell model implies that the one-proton value applies for any odd number of protons in the shell. However, it is clear from the state with a single hole that this is untrue. The cited result that the quadrupole moment varies linearly with the odd number of protons in the shell comes directly from Krane, [31, p. 129]. No derivation or reference is given. In fact, the restriction to an odd number of protons is not even stated. If you have a reference or a simple derivation, let me know and I will add it here.

## D. 79 Derivation of perturbation theory

This note derives the perturbation theory results for the solution of the eigenvalue problem $\left(H_{0}+H_{1}\right) \psi=E \psi$ where $H_{1}$ is small. The considerations for degenerate problems use linear algebra.

First, "small" is not a valid mathematical term. There are no small numbers in mathematics, just numbers that become zero in some limit. Therefore, to mathematically analyze the problem, the perturbation Hamiltonian will be written as

$$
H_{1} \equiv \varepsilon H_{\varepsilon}
$$

where $\varepsilon$ is some chosen number that physically indicates the magnitude of the perturbation potential. For example, if the perturbation is an external electric field, $\varepsilon$ could be taken as the reference magnitude of the electric field. In perturbation analysis, $\varepsilon$ is assumed to be vanishingly small.

The idea is now to start with a good eigenfunction $\psi_{\vec{n}, 0}$ of $H_{0}$, (where "good" is still to be defined), and correct it so that it becomes an eigenfunction of $H$ $=H_{0}+H_{1}$. To do so, both the desired energy eigenfunction and its energy eigenvalue are expanded in a power series in terms of $\varepsilon$ :

$$
\begin{aligned}
& \psi_{\vec{n}}=\psi_{\vec{n}, 0}+\varepsilon \psi_{\vec{n}, \varepsilon}+\varepsilon^{2} \psi_{\vec{n}, \varepsilon^{2}}+\ldots \\
& E_{\vec{n}}=E_{\vec{n}, 0}+\varepsilon E_{\vec{n}, \varepsilon}+\varepsilon^{2} E_{\vec{n}, \varepsilon^{2}}+\ldots
\end{aligned}
$$

If $\varepsilon$ is a small quantity, then $\varepsilon^{2}$ will be much smaller still, and can probably be ignored. If not, then surely $\varepsilon^{3}$ will be so small that it can be ignored. A result that forgets about powers of $\varepsilon$ higher than one is called first order perturbation theory. A result that also includes the quadratic powers, but forgets about powers higher than two is called second order perturbation theory, etcetera.

Before proceeding with the practical application, a disclaimer is needed. While it is relatively easy to see that the eigenvalues expand in whole powers of $\varepsilon$, (note that they must be real whether $\varepsilon$ is positive or negative), it is much more messy to show that the eigenfunctions must expand in whole powers. In
fact, for degenerate energies $E_{\vec{n}, 0}$ they only do if you choose good states $\psi_{\vec{n}, 0}$. See Rellich's lecture notes on Perturbation Theory [Gordon \& Breach, 1969] for a proof. As a result the problem with degeneracy becomes that the good unperturbed eigenfunction $\psi_{\vec{n}, 0}$ is initially unknown. It leads to lots of messiness in the procedures for degenerate eigenvalues described below.

When the above power series are substituted into the eigenvalue problem to be solved,

$$
\left(H_{0}+\varepsilon H_{\varepsilon}\right) \psi_{\vec{n}}=E_{\vec{n}} \psi_{\vec{n}}
$$

the net coefficient of every power of $\varepsilon$ must be equal in the left and right hand sides. Collecting these coefficients and rearranging them appropriately produces:

$$
\begin{array}{ll}
\varepsilon^{0}: & \left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 0}=0 \\
\varepsilon^{1}: & \left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, \varepsilon}=-H_{\varepsilon} \psi_{\vec{n}, 0}+E_{\vec{n}, \varepsilon} \psi_{\vec{n}, 0} \\
\varepsilon^{2}: & \left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, \varepsilon^{2}}=-H_{\varepsilon} \psi_{\vec{n}, \varepsilon}+E_{\vec{n}, \varepsilon} \psi_{\vec{n}, \varepsilon}+E_{\vec{n}, \varepsilon^{2}} \psi_{\vec{n}, 0} \\
\varepsilon^{3}:\left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, \varepsilon^{3}}=-H_{\varepsilon} \psi_{\vec{n}, \varepsilon^{2}}+E_{\vec{n}, \varepsilon} \psi_{\vec{n}, \varepsilon^{2}}+E_{\vec{n}, \varepsilon^{2}} \psi_{\vec{n}, \varepsilon}+E_{\vec{n}, \varepsilon^{3}} \psi_{\vec{n}, 0}
\end{array}
$$

These are the equations to be solved in succession to give the various terms in the expansion for the wave function $\psi_{\vec{n}}$ and the energy $E_{\vec{n}}$. The further you go down the list, the better your combined result should be.

Note that all it takes is to solve problems of the form

$$
\left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, \ldots}=\ldots
$$

The equations for the unknown functions are in terms of the unperturbed Hamiltonian $H_{0}$, with some additional but in principle knowable terms.

For difficult perturbation problems like you find in engineering, the use of a small parameter $\varepsilon$ is essential to get the mathematics right. But in the simple applications in quantum mechanics, it is usually overkill. So most of the time the expansions are written without, like

$$
\begin{aligned}
& \psi_{\vec{n}}=\psi_{\vec{n}, 0}+\psi_{\vec{n}, 1}+\psi_{\vec{n}, 2}+\ldots \\
& E_{\vec{n}}=E_{\vec{n}, 0}+E_{\vec{n}, 1}+E_{\vec{n}, 2}+\ldots
\end{aligned}
$$

where you are assumed to just imagine that $\psi_{\vec{n}, 1}$ and $E_{\vec{n}, 1}$ are "first order small," $\psi_{\vec{n}, 2}$ and $E_{\vec{n}, 2}$ are "second order small," etcetera. In those terms, the successive equations to solve are:

$$
\begin{equation*}
\left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 0}=0 \tag{D.55}
\end{equation*}
$$

$$
\begin{align*}
& \left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 1}=-H_{1} \psi_{\vec{n}, 0}+E_{\vec{n}, 1} \psi_{\vec{n}, 0}  \tag{D.56}\\
& \left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 2}=-H_{1} \psi_{\vec{n}, 1}+E_{\vec{n}, 1} \psi_{\vec{n}, 1}+E_{\vec{n}, 2} \psi_{\vec{n}, 0}  \tag{D.57}\\
& \left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 3}=-H_{1} \psi_{\vec{n}, 2}+E_{\vec{n}, 1} \psi_{\vec{n}, 2}+E_{\vec{n}, 2} \psi_{\vec{n}, 1}+E_{\vec{n}, 3} \psi_{\vec{n}, 0} \tag{D.58}
\end{align*}
$$

Now consider each of these equations in turn. First, (D.55) is just the Hamiltonian eigenvalue problem for $H_{0}$ and is already satisfied by the chosen unperturbed solution $\psi_{\vec{n}, 0}$ and its eigenvalue $E_{\vec{n}, 0}$. However, the remaining equations are not trivial. To solve them, write their solutions in terms of the other eigenfunctions $\psi_{\vec{n}, 0}$ of the unperturbed Hamiltonian $H_{0}$. In particular, to solve (D.56), write

$$
\psi_{\vec{n}, 1}=\sum_{\underline{\vec{n}} \neq \vec{n}} c_{\underline{\vec{n}}, 1} \psi_{\underline{\vec{n}}, 0}
$$

where the coefficients $c_{\vec{n}, 1}$ are still to be determined. The coefficient of $\psi_{\vec{n}, 0}$ is zero on account of the normalization requirement. (And in fact, it is easiest to take the coefficient of $\psi_{\vec{n}, 0}$ also zero for $\psi_{\vec{n}, 2}, \psi_{\vec{n}, 3}, \ldots$, even if it means that the resulting wave function will no longer be normalized.)

The problem (D.56) becomes

$$
\sum_{\underline{\vec{n}} \neq \vec{n}} c_{\underline{\vec{n}}, 1}\left(E_{\underline{\vec{n}}, 0}-E_{\vec{n}, 0}\right) \psi_{\underline{\vec{n}}, 0}=-H_{1} \psi_{\vec{n}, 0}+E_{\vec{n}, 1} \psi_{\vec{n}, 0}
$$

where the left hand side was cleaned up using the fact that the $\psi_{\underline{n}, 0}$ are eigenfunctions of $H_{0}$. To get the first order energy correction $E_{\vec{n}, 1}$, the trick is now to take an inner product of the entire equation with $\left\langle\psi_{\vec{n}, 0}\right|$. Because of the fact that the energy eigenfunctions of $H_{0}$ are orthonormal, this inner product produces zero in the left hand side, and in the right hand side it produces:

$$
0=-H_{\vec{n} \vec{n}, 1}+E_{\vec{n}, 1} \quad H_{\vec{n} \vec{n}, 1}=\left\langle\psi_{\vec{n}, 0} \mid H_{1} \psi_{\vec{n}, 0}\right\rangle
$$

And that is exactly the first order correction to the energy claimed in $\{\mathrm{A} .38 .1\}$; $E_{\vec{n}, 1}$ equals the Hamiltonian perturbation coefficient $H_{\vec{n} \vec{n}, 1}$. If the problem is not degenerate or $\psi_{\vec{n}, 0}$ is good, that is.

To get the coefficients $c_{\vec{n}, 1}$, so that you know what is the first order correction $\psi_{\vec{n}, 1}$ to the wave function, just take an inner product with each of the other eigenfunctions $\left\langle\psi_{\underline{\vec{n}}, 0}\right|$ of $H_{0}$ in turn. In the left hand side it only leaves the coefficient of the selected eigenfunction because of orthonormality, and for the same reason, in the right hand side the final term drops out. The result is

$$
c_{\vec{n}, 1}\left(E_{\underline{\vec{n}}, 0}-E_{\vec{n}, 0}\right)=-H_{\underline{\vec{n}} \vec{n}, 1} \quad \text { for } \quad \underline{\vec{n}} \neq \vec{n} \quad H_{\underline{\vec{n}} \vec{n}, 1}=-\left\langle\psi_{\underline{\vec{n}}, 0} \mid H_{1} \psi_{\vec{n}, 0}\right\rangle
$$

The coefficients $c_{\underline{\underline{n}}, 1}$ can normally be computed from this.

Note however that if the problem is degenerate, there will be eigenfunctions $\psi_{\vec{n}, 0}$ that have the same energy $E_{\vec{n}, 0}$ as the eigenfunction $\psi_{\vec{n}, 0}$ being corrected. For these the left hand side in the equation above is zero, and the equation cannot in general be satisfied. If so, it means that the assumption that an eigenfunction $\psi_{\vec{n}}$ of the full Hamiltonian expands in a power series in $\varepsilon$ starting from $\psi_{\vec{n}, 0}$ is untrue. Eigenfunction $\psi_{\vec{n}, 0}$ is bad. And that means that the first order energy correction derived above is simply wrong. To fix the problem, what needs to be done is to identify the submatrix of all Hamiltonian perturbation coefficients in which both unperturbed eigenfunctions have the energy $E_{\vec{n}, 0}$, i.e. the submatrix

$$
\text { all } H_{\vec{n}_{i} \vec{n}_{j}, 1} \quad \text { with } \quad E_{\vec{n}_{i}, 0}=E_{\vec{n}_{j}, 0}=E_{\vec{n}, 0}
$$

The eigenvalues of this submatrix are the correct first order energy changes. So, if all you want is the first order energy changes, you can stop here. Otherwise, you need to replace the unperturbed eigenfunctions that have energy $E_{\vec{n}, 0}$. For each orthonormal eigenvector $\left(c_{1}, c_{2}, \ldots\right)$ of the submatrix, there is a corresponding replacement unperturbed eigenfunction

$$
c_{1} \psi_{\vec{n}_{1}, 0, \mathrm{old}}+c_{2} \psi_{\vec{n}_{2}, 0, \mathrm{old}}+\ldots
$$

You will need to rewrite the Hamiltonian perturbation coefficients in terms of these new eigenfunctions. (Since the replacement eigenfunctions are linear combinations of the old ones, no new integrations are needed.) You then need to reselect the eigenfunction $\psi_{\vec{n}, 0}$ whose energy to correct from among these replacement eigenfunctions. Choose the first order energy change (eigenvalue of the submatrix) $E_{\vec{n}, 1}$ that is of interest to you and then choose $\psi_{\vec{n}, 0}$ as the replacement eigenfunction corresponding to a corresponding eigenvector. If the first order energy change $E_{\vec{n}, 1}$ is not degenerate, the eigenvector is unique, so $\psi_{\vec{n}, 0}$ is now good. If not, the good eigenfunction will be some combination of the replacement eigenfunctions that have that first order energy change, and the good combination will have to be figured out later in the analysis. In any case, the problem with the equation above for the $c_{\vec{n}, 1}$ will be fixed, because the new submatrix will be a diagonal one: $H_{\vec{n} \vec{n}, 1}$ will be zero when $E_{\vec{n}, 0}=E_{\vec{n}, 0}$ and $\underline{\vec{n}} \neq \vec{n}$. The coefficients $c_{\vec{n}, 1}$ for which $E_{\vec{n}, 0}=E_{\vec{n}, 0}$ remain indeterminate at this stage. They will normally be found at a later stage in the expansion.

With the coefficients $c_{\underline{n}, 1}$ as found, or not found, the sum for the first order perturbation $\psi_{\vec{n}, 1}$ in the wave function becomes

$$
\psi_{\vec{n}, 1}=-\sum_{E_{\vec{n}, 0} \neq E_{\vec{n}, 0}} \frac{H_{\overrightarrow{\underline{n}} \vec{n}, 1}}{E_{\vec{n}, 0}-E_{\vec{n}, 0}} \psi_{\overrightarrow{\vec{n}}, 0}+\sum_{E_{E_{\vec{n}, 0}, E_{\vec{n}} \neq \vec{n}}} c_{\vec{n}, 1} \psi_{\overrightarrow{\vec{n}}, 0}
$$

The entire process repeats for higher order. In particular, to second order
(D.57) gives, writing $\psi_{\vec{n}, 2}$ also in terms of the unperturbed eigenfunctions,

$$
\begin{aligned}
\sum_{\overrightarrow{\vec{n}}} c_{\overrightarrow{\vec{n}}, 2}\left(E_{\vec{n}, 0}-E_{\vec{n}, 0}\right) \psi_{\overrightarrow{\vec{n}}, 0}= & \sum_{E_{\overrightarrow{\vec{n}}, 0} \neq E_{\vec{n}, 0}} \frac{H_{\vec{n} \vec{n}, 1}}{E_{\vec{n}, 0}-E_{\vec{n}, 0}}\left(H_{1}-E_{\vec{n}, 1}\right) \psi_{\vec{n}, 0} \\
& -\sum_{\substack{E_{\vec{n}, 0}=E_{\vec{n}, 0} \\
\vec{n} \neq \vec{n}}} c_{\vec{n}, 1}\left(H_{1}-E_{\vec{n}, 1}\right) \psi_{\vec{n}, 0}+E_{\vec{n}, 2} \psi_{\vec{n}, 0}
\end{aligned}
$$

To get the second order contribution to the energy, take again an inner product with $\left\langle\psi_{\vec{n}, 0}\right|$. That produces, again using orthonormality, (and diagonality of the submatrix discussed above if degenerate),

$$
0=\sum_{E_{\overrightarrow{\vec{r}}, 0} \neq E_{\vec{n}, 0}} \frac{H_{\vec{n} \vec{n}, 1} H_{\vec{n} \vec{n}, 1}}{E_{\vec{n}, 0}-E_{\vec{n}, 0}}+E_{\vec{n}, 2}
$$

This gives the second order change in the energy stated in $\left\{\right.$ A.38.1\}, if $\psi_{\vec{n}, 0}$ is good. Note that since $H_{1}$ is Hermitian, the product of the two Hamiltonian perturbation coefficients in the expression is just the square magnitude of either.

In the degenerate case, when taking an inner product with a $\left\langle\psi_{\vec{n}, 0}\right|$ for which $E_{\vec{n}, 0}=E_{\vec{n}, 0}$, the equation can be satisfied through the still indeterminate $c_{\vec{n}, 1}$ provided that the corresponding diagonal coefficient $H_{\overrightarrow{\underline{n}} \vec{n}, 1}$ of the diagonalized submatrix is unequal to $E_{\vec{n}, 1}=H_{\vec{n} \vec{n}, 1}$. In other words, provided that the first order energy change is not degenerate. If that is untrue, the higher order submatrix

$$
\text { all } \sum_{E_{\vec{n}, 0} \neq E_{\vec{n}, 0}} \frac{H_{\vec{n}_{i}, \vec{n}, 1} H_{\vec{n} \vec{n}}^{\vec{n}_{j}, 1}}{}-E_{\vec{n}, 0} \quad \text { with } \quad E_{\vec{n}_{i}, 0}=E_{\vec{n}_{j}, 0}=E_{\vec{n}, 0} \quad E_{\vec{n}_{i}, 1}=E_{\vec{n}_{j}, 1}=E_{\vec{n}, 1}
$$

will need to be diagonalized, (the rest of the equation needs to be zero). Its eigenvalues give the correct second order energy changes. To proceed to still higher energy, reselect the eigenfunctions following the same general lines as before. Obviously, in the degenerate case the entire process can become very messy. And you may never become sure about the good eigenfunction.

This problem can often be eliminated or greatly reduced if the eigenfunctions of $H_{0}$ are also eigenfunctions of another operator $A$, and $H_{1}$ commutes with $A$. Then you can arrange the eigenfunctions $\psi_{\vec{n}, 0}$ into sets that have the same value for the "good" quantum number $a$ of $\bar{A}$. You can analyze the perturbed eigenfunctions in each of these sets while completely ignoring the existence of eigenfunctions with different values for quantum number $a$.

To see why, consider two example eigenfunctions $\psi_{1}$ and $\psi_{2}$ of $A$ that have different eigenvalues $a_{1}$ and $a_{2}$. Since $H_{0}$ and $H_{1}$ both commute with $A$, their sum $H$ does, so

$$
0=\left\langle\psi_{2} \mid(H A-A H) \psi_{1}\right\rangle=\left\langle\psi_{2} \mid H A \psi_{1}\right\rangle+\left\langle A \psi_{2} \mid H \psi_{1}\right\rangle=\left(a_{1}-a_{2}\right)\left\langle\psi_{2}\right| H\left|\psi_{1}\right\rangle
$$

and since $a_{1}-a_{2}$ is not zero, $\left\langle\psi_{2}\right| H\left|\psi_{1}\right\rangle$ must be. Now $\left\langle\psi_{2}\right| H\left|\psi_{1}\right\rangle$ is the amount of eigenfunction $\psi_{2}$ produced by applying $H$ on $\psi_{1}$. It follows that applying $H$ on an eigenfunction with an eigenvalue $a_{1}$ does not produce any eigenfunctions with different eigenvalues $a$. Thus an eigenfunction of $H$ satisfying

$$
H\left(\sum_{a=a_{1}} c_{\vec{n}} \psi_{\vec{n}, 0}+\sum_{a \neq a_{1}} c_{\vec{n}} \psi_{\vec{n}, 0}\right)=E_{\vec{n}}\left(\sum_{a=a_{1}} c_{\vec{n}} \psi_{\vec{n}, 0}+\sum_{a \neq a_{1}} c_{\vec{n}} \psi_{\vec{n}, 0}\right)
$$

can be replaced by just $\sum_{a=a_{1}} c_{\vec{n}} \psi_{\vec{n}, 0}$, since this by itself must satisfy the eigenvalue problem: the Hamiltonian of the second sum does not produce any amount of eigenfunctions in the first sum and vice-versa. (There must always be at least one value of $a_{1}$ for which the first sum at $\varepsilon=0$ is independent of the other eigenfunctions of $H$.) Reduce every eigenfunction of $H$ to an eigenfunction of $A$ in this way. Now the existence of eigenfunctions with different values of $a$ than the one being analyzed can be ignored since the Hamiltonian does not produce them. In terms of linear algebra, the Hamiltonian has been reduced to block diagonal form, with each block corresponding to a set of eigenfunctions with a single value of $a$. If the Hamiltonian also commutes with another operator $B$ that the $\psi_{\vec{n}, 0}$ are eigenfunctions of, the argument repeats for the subsets with a single value for $b$.

The Hamiltonian perturbation coefficient $\left\langle\psi_{2}\right| H_{1}\left|\psi_{1}\right\rangle$ is zero whenever two good quantum numbers $a_{1}$ and $a_{2}$ are unequal. The reason is the same as for $\left\langle\psi_{2}\right| H\left|\psi_{1}\right\rangle$ above. Only perturbation coefficients for which all good quantum numbers are the same can be nonzero.

## D. 80 Hydrogen ground state Stark effect

This note derives the Stark effect on the hydrogen ground state. Since spin is irrelevant for the Stark effect, it will be ignored.

The unperturbed ground state of hydrogen was derived in chapter 4.3. Following the convention in perturbation theory to append a subscript zero to the unperturbed state, it can be summarized as:

$$
H_{0} \psi_{100,0}=E_{100,0} \psi_{100,0} \quad H_{0}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla^{2}+V \quad \psi_{100,0}=\frac{1}{\sqrt{\pi a_{0}^{3}}} e^{-r / a_{0}}
$$

where $H_{0}$ is the unperturbed hydrogen atom Hamiltonian, $\psi_{100,0}$ the unperturbed ground state wave function, $E_{100,0}$ the unperturbed ground state energy, 13.6 eV , and $a_{0}$ is the Bohr radius, $0.53 \AA$.

The Stark perturbation produces a change $\psi_{100,1}$ in this wave function that satisfies, from (A.243),

$$
\left(H_{0}-E_{100,0}\right) \psi_{100,1}=-\left(H_{1}-E_{100,1}\right) \psi_{100,0} \quad H_{1}=e \mathcal{E}_{\mathrm{ext}} z
$$

The first order energy change $E_{100,1}$ is zero and can be dropped. The solution for $\psi_{100,1}$ will now simply be guessed to be $\psi_{100,0}$ times some spatial function $f$ still to be found:

$$
\left(H_{0}-E_{100,0}\right)\left(f \psi_{100,0}\right)=-e \mathcal{E}_{\mathrm{ext}} z \psi_{100,0} \quad H_{0}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla^{2}+V
$$

Differentiating out the Laplacian $\nabla^{2}$ of the product $f \psi_{100,0}$ into individual terms using Cartesian coordinates, the equation becomes

$$
f\left(H_{0}-E_{100,0}\right) \psi_{100,0}-\frac{\hbar^{2}}{m_{\mathrm{e}}}(\nabla f) \cdot\left(\nabla \psi_{100,0}\right)-\frac{\hbar^{2}}{2 m_{\mathrm{e}}}\left(\nabla^{2} f\right) \psi_{100,0}=-e \mathcal{E}_{\mathrm{ext}} z \psi_{100,0}
$$

The first term in this equation is zero since $H_{0} \psi_{100,0}=E_{100,0} \psi_{100,0}$. Also, now using spherical coordinates, the gradients are, e.g. [41, 20.74, 20.82],

$$
\nabla f=\frac{\partial f}{\partial r} \hat{\imath}_{r}+\frac{1}{r} \frac{\partial f}{\partial \theta} \hat{\imath}_{\theta}+\frac{1}{r \sin \theta} \frac{\partial f}{\partial \phi} \hat{\imath}_{\phi} \quad \nabla \psi_{100,0}=-\psi_{100,0} \frac{1}{a_{0}} \hat{\imath}_{r}
$$

Substituting that into the equation, it reduces to

$$
\frac{\hbar^{2}}{m_{\mathrm{e}}}\left(\frac{1}{a_{0}} \frac{\partial f}{\partial r}-\frac{1}{2} \nabla^{2} f\right) \psi_{100,0}=-e \mathcal{E}_{\mathrm{ext}} z \psi_{100,0}
$$

Now $z=r \cos \theta$ in polar coordinates, and for the $r$-derivative of $f$ to produce something that is proportional to $r, f$ must be proportional to $r^{2}$. (The Laplacian in the second term always produces lower powers of $r$ than the $r$ derivative and can for now be ignored.) So, to balance the right hand side, $f$ should contain a highest power of $r$ equal to:

$$
f=-\frac{m_{\mathrm{e}} e \mathcal{E}_{\mathrm{ext}} a_{0}}{2 \hbar^{2}} r^{2} \cos \theta+\ldots
$$

but then, using [41, 20.83], the $\nabla^{2} f$ term in the left hand side produces an $e \mathcal{E}_{\text {ext }} a_{0} \cos \theta$ term. So add another term to $f$ for its $r$-derivative to eliminate it:

$$
f=-\frac{m_{\mathrm{e}} e \mathcal{E}_{\mathrm{ext}} a_{0}}{2 \hbar^{2}} r^{2} \cos \theta-\frac{m_{\mathrm{e}} e \mathcal{E}_{\mathrm{ext}} a_{0}^{2}}{\hbar^{2}} r \cos \theta
$$

The Laplacian of $r \cos \theta=z$ is zero so no further terms need to be added. The change $f \psi_{100,0}$ in wave function is therefore

$$
\psi_{100,1}=-\frac{m_{\mathrm{e}} e \mathcal{E}_{\text {ext }} a_{0}}{2 \hbar^{2} \sqrt{\pi a_{0}^{3}}}\left(r^{2}+2 a_{0} r\right) e^{-r / a_{0}} \cos \theta
$$

(This "small perturbation" becomes larger than the unperturbed wave function far from the atom because of the growing value of $r^{2}$. It is implicitly assumed that the electric field terminates before a real problem arises. This is related
to the possibility of the electron tunneling out of the atom if the potential far from the atom is less than its energy in the atom: if the electron can tunnel out, there is strictly speaking no bound state.)

Now according to (A.243), the second order energy change can be found as

$$
E_{100,2}=\left\langle\psi_{100,0} \mid H_{1} \psi_{100,1}\right\rangle \quad H_{1}=e \mathcal{E}_{\mathrm{ext}} r \cos \theta
$$

Doing the inner product integration in spherical coordinates produces

$$
E_{100,2}=-\frac{9 m_{\mathrm{e}} e^{2} \mathcal{E}_{\mathrm{ext}}^{2} a_{0}^{4}}{4 \hbar^{2}}
$$

## D. 81 Dirac fine structure Hamiltonian

This note derives the fine structure Hamiltonian of the hydrogen atom. This Hamiltonian fixes up the main relativistic errors in the classical solution of chapter 4.3. The derivation is based on the relativistic Dirac equation from chapter 12.12 and uses nontrivial linear algebra.

According to the Dirac equation, the relativistic Hamiltonian and wave function take the form
$H_{D}=m_{\mathrm{e}} c^{2}\left(\begin{array}{rr}1 & 0 \\ 0 & -1\end{array}\right)+\sum_{i=1}^{3} c \widehat{p}_{i}\left(\begin{array}{cc}0 & \sigma_{i} \\ \sigma_{i} & 0\end{array}\right)+V\left(\begin{array}{ll}1 & 0 \\ 0 & 1\end{array}\right) \quad \vec{\psi}_{D}=\binom{\vec{\psi}^{p}}{\vec{\psi}^{n}}$
where $m_{\mathrm{e}}$ is the mass of the electron when at rest, $c$ the speed of light, and the $\sigma_{i}$ are the $2 \times 2$ Pauli spin matrices of chapter 12.10. Similarly the ones and zeros in the shown matrices are $2 \times 2$ unit and zero matrices. The wave function is a four-dimensional vector whose components depend on spatial position. It can be subdivided into the two-dimensional vectors $\vec{\psi}^{p}$ and $\vec{\psi}^{n}$. The two components of $\vec{\psi}^{p}$ correspond to the spin up and spin down components of the normal classical electron wave function; as noted in chapter 5.5.1, this can be thought of as a vector if you want. The two components of the other vector $\vec{\psi}^{n}$ are very small for the solutions of interest. These components would be dominant for states that would have negative rest mass. They are associated with the anti-particle of the electron, the positron.

The Dirac equation is solvable in closed form, but that solution is not something you want to contemplate if you can avoid it. And there is really no need for it, since the Dirac equation is not exact anyway. To the accuracy it has, it can easily be solved using perturbation theory in essentially the same way as in derivation \{D.79\}. In this case, the small parameter is $1 / c$ : if the speed of light is infinite, the nonrelativistic solution is exact. And if you ballpark a typical velocity for the electron in a hydrogen atom, it is only about one percent or so of the speed of light.

So, following derivation $\{\mathrm{D} .79\}$, take the Hamiltonian apart into successive powers of $1 / c$ as $H_{D}=H_{D, 0}+H_{D, 1}+H_{D, 2}$ with

$$
H_{D, 0}=\left(\begin{array}{cc}
m_{\mathrm{e}} c^{2} & 0 \\
0 & -m_{\mathrm{e}} c^{2}
\end{array}\right) \quad H_{D, 1}=\sum_{i=1}^{3}\left(\begin{array}{cc}
0 & c \widehat{p}_{i} \sigma_{i} \\
c \widehat{p}_{i} \sigma_{i} & 0
\end{array}\right) \quad H_{D, 2}=\left(\begin{array}{cc}
V & 0 \\
0 & V
\end{array}\right)
$$

and similarly for the wave function vector:

$$
\vec{\psi}_{D}=\binom{\vec{\psi}_{0}^{p}}{\vec{\psi}_{0}^{n}}+\binom{\vec{\psi}_{1}^{p}}{\vec{\psi}_{1}^{n}}+\binom{\vec{\psi}_{2}^{p}}{\vec{\psi}_{2}^{n}}+\binom{\vec{\psi}_{3}^{p}}{\vec{\psi}_{3}^{n}}+\binom{\vec{\psi}_{4}^{p}}{\vec{\psi}_{4}^{n}}+\ldots
$$

and the energy:

$$
E_{D}=E_{D, 0}+E_{D, 1}+E_{D, 2}+E_{D, 3}+E_{D, 4}+\ldots
$$

Substitution into the Hamiltonian eigenvalue problem $H_{D} \vec{\psi}_{D}=E_{D} \vec{\psi}_{D}$ and then collecting equal powers of $1 / c$ together produces again a system of successive equations, just like in derivation \{D.79\}:

$$
\begin{array}{cc}
c^{2}: & {\left[\left(\begin{array}{cc}
m_{\mathrm{e}} c^{2} & 0 \\
0 & -m_{\mathrm{e}} c^{2}
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 0} & 0 \\
0 & E_{D, 0}
\end{array}\right)\right]\binom{\vec{\psi}_{0}^{p}}{\vec{\psi}_{0}^{n}}=0} \\
c^{1}: \quad & {\left[\left(\begin{array}{cc}
m_{\mathrm{e}} c^{2} & 0 \\
0 & -m_{\mathrm{e}} c^{2}
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 0} & 0 \\
0 & E_{D, 0}
\end{array}\right)\right]\binom{\vec{\psi}_{1}^{p}}{\vec{\psi}_{1}^{n}}=} \\
& \left.-\left[\begin{array}{ll}
\left.\sum_{i=1}^{3}\left(\begin{array}{cc}
0 & c \widehat{p}_{i} \sigma_{i} \\
c \widehat{p_{i}} \sigma_{i} & 0
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 1} & 0 \\
0 & E_{D, 1}
\end{array}\right)\right]\binom{\vec{\psi}_{0}^{p}}{\vec{\psi}_{0}^{n}} \\
c^{0}: & {\left[\left(\begin{array}{cc}
m_{\mathrm{e}} c^{2} & 0 \\
0 & -m_{\mathrm{e}} c^{2}
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 0} & 0 \\
0 & E_{D, 0}
\end{array}\right)\right]\binom{\vec{\psi}_{2}^{p}}{\vec{\psi}_{2}^{n}}=} \\
& -\left[\begin{array}{cc}
\sum_{i=1}^{3}\left(\begin{array}{c}
0 \\
c \hat{p}_{i} \sigma_{i}
\end{array}\right. & \widehat{p}_{i} \sigma_{i} \\
0
\end{array}\right)-\left(\begin{array}{c}
E_{D, 1} \\
0
\end{array}\right. \\
E_{D, 1}
\end{array}\right)\right]\binom{\vec{\psi}_{1}^{p}}{\vec{\psi}_{1}^{n}} \\

V & 0 \\
0 & V
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 2} & 0 \\
0 & E_{D, 2}
\end{array}\right)\right]\binom{\vec{\psi}_{0}^{p}}{\vec{\psi}_{0}^{n}} \\
c^{-1}: \quad & {\left[\left(\begin{array}{cc}
m_{\mathrm{e}} c^{2} & 0 \\
0 & -m_{\mathrm{e}} c^{2}
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 0} & 0 \\
0 & E_{D, 0}
\end{array}\right)\right]\binom{\vec{\psi}_{3}^{p}}{\vec{\psi}_{3}^{n}}=}
\end{array}
$$

$$
\begin{aligned}
& -\left[\sum_{i=1}^{3}\left(\begin{array}{cc}
0 & c \widehat{p}_{i} \sigma_{i} \\
c \widehat{p}_{i} \sigma_{i} & 0
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 1} & 0 \\
0 & E_{D, 1}
\end{array}\right)\right]\binom{\vec{\psi}_{2}^{p}}{\vec{\psi}_{2}^{n}} \\
& -\left[\left(\begin{array}{cc}
V & 0 \\
0 & V
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 2} & 0 \\
0 & E_{D, 2}
\end{array}\right)\right]\binom{\vec{\psi}_{1}^{p}}{\vec{\psi}_{1}^{n}} \\
& +\left(\begin{array}{cc}
E_{D, 3} & 0 \\
0 & E_{D, 3}
\end{array}\right)\binom{\vec{\psi}_{0}^{p}}{\vec{\psi}_{0}^{n}} \\
& c^{-2}: \quad\left[\left(\begin{array}{cc}
m_{\mathrm{e}} c^{2} & 0 \\
0 & -m_{\mathrm{e}} c^{2}
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 0} & 0 \\
0 & E_{D, 0}
\end{array}\right)\right]\binom{\vec{\psi}_{4}^{p}}{\vec{\psi}_{4}^{n}}= \\
& -\left[\sum_{i=1}^{3}\left(\begin{array}{cc}
0 & c \widehat{p}_{i} \sigma_{i} \\
c \widehat{p}_{i} \sigma_{i} & 0
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 1} & 0 \\
0 & E_{D, 1}
\end{array}\right)\right]\binom{\vec{\psi}_{3}^{p}}{\vec{\psi}_{3}^{n}} \\
& -\left[\left(\begin{array}{cc}
V & 0 \\
0 & V
\end{array}\right)-\left(\begin{array}{cc}
E_{D, 2} & 0 \\
0 & E_{D, 2}
\end{array}\right)\right]\binom{\vec{\psi}_{2}^{p}}{\vec{\psi}_{2}^{n}} \\
& +\left(\begin{array}{cc}
E_{D, 3} & 0 \\
0 & E_{D, 3}
\end{array}\right)\binom{\vec{\psi}_{1}^{p}}{\vec{\psi}_{1}^{n}}+\left(\begin{array}{cc}
E_{D, 4} & 0 \\
0 & E_{D, 4}
\end{array}\right)\binom{\vec{\psi}_{0}^{p}}{\vec{\psi}_{0}^{n}} \\
& c^{-3}: \quad \ldots
\end{aligned}
$$

The first, order $c^{2}$, eigenvalue problem has energy eigenvalues $\pm m_{e} c^{2}$, in other words, plus or minus the rest mass energy of the electron. The solution of interest is the physical one with a positive rest mass, so the desired solution is

$$
E_{D, 0}=m_{\mathrm{e}} c^{2} \quad \vec{\psi}_{0}^{p}=\text { still arbitrary } \quad \vec{\psi}_{0}^{n}=0
$$

Plug that into the order $c^{1}$ equation to give, for top and bottom subvectors

$$
0=E_{D, 1} \vec{\psi}_{0}^{p} \quad-2 m_{\mathrm{e}} c^{2} \vec{\psi}_{1}^{n}=-\sum_{i} c \widehat{p}_{i} \sigma_{i} \vec{\psi}_{0}^{p}
$$

It follows from the first of those that the first order energy change must be zero because $\vec{\psi}_{0}^{p}$ cannot be zero; otherwise there would be nothing left. The second equation gives the leading order values of the secondary components, so in total

$$
E_{D, 1}=0 \quad \vec{\psi}_{1}^{p}=\text { still arbitrary } \quad \vec{\psi}_{1}^{n}=\sum_{j} \frac{1}{2 m_{\mathrm{e}} c} \widehat{p}_{j} \sigma_{j} \vec{\psi}_{0}^{p}
$$

where the summation index $i$ was renamed to $j$ to avoid ambiguity later.

Plug all that in the order $c^{0}$ equation to give

$$
0=-\frac{1}{2 m_{\mathrm{e}}} \sum_{i} \sum_{j} \widehat{p}_{i} \widehat{p}_{j} \sigma_{i} \sigma_{j} \vec{\psi}_{0}^{p}-V \vec{\psi}_{0}^{p}+E_{D, 2} \vec{\psi}_{0}^{p} \quad \vec{\psi}_{2}^{n}=\sum_{j} \frac{1}{2 m_{\mathrm{e}} c} \widehat{p}_{j} \sigma_{j} \vec{\psi}_{1}^{p}
$$

The first of these two equations is the nonrelativistic Hamiltonian eigenvalue problem of chapter 4.3. To see that, note that in the double sum the terms with $j \neq i$ pairwise cancel since for the Pauli matrices, $\sigma_{i} \sigma_{j}+\sigma_{j} \sigma_{i}=0$ when $j \neq$ $i$. For the remaining terms in which $j=i$, the relevant property of the Pauli matrices is that $\sigma_{i} \sigma_{i}$ is one (or the $2 \times 2$ unit matrix, really,) giving

$$
\frac{1}{2 m_{\mathrm{e}}} \sum_{i} \sum_{j} \widehat{p}_{i} \widehat{p}_{j} \sigma_{i} \sigma_{j}+V=\frac{1}{2 m_{\mathrm{e}}} \sum_{i} \widehat{p}_{i}^{2}+V \equiv H_{0}
$$

where $H_{0}$ is the nonrelativistic hydrogen Hamiltonian of chapter 4.3.
So the first part of the order $c^{0}$ equation takes the form

$$
H_{0} \vec{\psi}_{0}^{p}=E_{D, 2} \vec{\psi}_{0}^{p}
$$

The energy $E_{D, 2}$ will therefore have to be a Bohr energy level $E_{n}$ and each component of $\vec{\psi}_{0}^{p}$ will have to be a nonrelativistic energy eigenfunction with that energy:

$$
E_{D, 2}=E_{n} \quad \vec{\psi}_{0}^{p}=\sum_{l} \sum_{m} c_{l m+} \psi_{n l m} \uparrow+\sum_{l} \sum_{m} c_{l m-} \psi_{n l m} \downarrow
$$

The sum multiplying $\uparrow$ is the first component of vector $\vec{\psi}_{0}^{p}$ and the sum multiplying $\downarrow$ the second. The nonrelativistic analysis in chapter 4.3 was indeed correct as long as the speed of light is so large compared to the relevant velocities that $1 / c$ can be ignored.

To find out the error in it, the relativistic expansion must be taken to higher order. To order $c^{-1}$, you get for the top vector

$$
0=-\left(H_{0}-E_{n}\right) \vec{\psi}_{1}^{p}+E_{D, 3} \vec{\psi}_{0}^{p}
$$

Now if $\vec{\psi}_{1}^{p}$ is written as a sum of the eigenfunctions of $H_{0}$, including $\vec{\psi}_{0}^{p}$, the first term will produce zero times $\vec{\psi}_{0}^{p}$ since $\left(H_{0}-E_{n}\right) \vec{\psi}_{0}^{p}=0$. That means that $E_{D, 3}$ must be zero. The expansion must be taken one step further to identify the relativistic energy change. The bottom vector gives

$$
\vec{\psi}_{3}^{n}=\sum_{j} \frac{1}{2 m_{\mathrm{e}} c} \widehat{p}_{j} \sigma_{j} \vec{\psi}_{2}^{p}+\frac{V-E_{n}}{2 m_{\mathrm{e}} c^{2}} \sum_{j} \frac{1}{2 m_{\mathrm{e}} c} \widehat{p}_{j} \sigma_{j} \vec{\psi}_{0}^{p}
$$

To order $c^{-2}$, you get for the top vector

$$
0=-\left(H_{0}-E_{n}\right) \vec{\psi}_{2}^{p}-\sum_{i} \sum_{j} \widehat{p}_{i} \sigma_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{j} \sigma_{j} \vec{\psi}_{0}^{p}+E_{D, 4} \vec{\psi}_{0}^{p}
$$

and that determines the approximate relativistic energy correction.
Now recall from derivation $\{\mathrm{D} .79\}$ that if you do a nonrelativistic expansion of an eigenvalue problem $\left(H_{0}+H_{1}\right) \psi=E \psi$, the equations to solve are (D.55) and (D.56);

$$
\left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 0}=0 \quad\left(H_{0}-E_{\vec{n}, 0}\right) \psi_{\vec{n}, 1}=-\left(H_{1}-E_{\vec{n}, 1}\right) \psi_{\vec{n}, 0}
$$

The first equation was satisfied by the solution for $\vec{\psi}_{0}^{p}$ obtained above. However, the second equation presents a problem. Comparison with the final Dirac result suggests that the fine structure Hamiltonian correction $H_{1}$ should be identified as

$$
H_{1} \stackrel{?}{=} \sum_{i} \sum_{j} \widehat{p}_{i} \sigma_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{j} \sigma_{j}
$$

but that is not right, since $E_{n}$ is not a physical operator, but an energy eigenvalue for the selected eigenfunction. So mapping the Dirac expansion straightforwardly onto a classical one has run into a snag.

It is maybe not that surprising that a two-dimensional wave function cannot correctly represent a truly four-dimensional one. But clearly, whatever is selected for the fine structure Hamiltonian $H_{1}$ must at least get the energy eigenvalues right. To see how this can be done, the operator obtained from the Dirac equation will have to be simplified. Now for any given $i$, the sum over $j$ includes a term $j=i$, a term $j=\bar{\imath}$, where $\bar{\imath}$ is the number following $i$ in the cyclic sequence $\ldots 123123 \ldots$, and it involves a term $j=\overline{\bar{\imath}}$ where $\overline{\bar{\imath}}$ precedes $i$ in the sequence. So the Dirac operator falls apart into three pieces:

$$
H_{1} \stackrel{?}{=} \sum_{i} \widehat{p}_{i} \sigma_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{i} \sigma_{i}+\sum_{i} \widehat{p}_{i} \sigma_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{\bar{\imath}} \sigma_{\bar{\imath}}+\sum_{i} \widehat{p}_{i} \sigma_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{\bar{\imath}} \sigma_{\overline{\bar{\imath}}}
$$

or using the properties of the Pauli matrices that $\sigma_{i} \sigma_{i}=1, \sigma_{i} \sigma_{\bar{\imath}}=\mathrm{i} \sigma_{\overline{\bar{\imath}}}$, and $\sigma_{i} \sigma_{\overline{\bar{\imath}}}$ $=-\mathrm{i} \sigma_{\overline{\bar{\imath}}}$ for any $i$,

$$
\begin{equation*}
H_{1} \stackrel{?}{=} \sum_{i} \widehat{p}_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{i}+\mathrm{i} \sum_{i} \widehat{p}_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{\bar{\imath}} \sigma_{\overline{\bar{\imath}}}-\mathrm{i} \sum_{i} \widehat{p}_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{\bar{\imath}} \sigma_{\bar{\imath}} \tag{D.59}
\end{equation*}
$$

The approach will now be to show first that the final two terms are the spin-orbit interaction in the fine structure Hamiltonian. After that, the much more tricky first term will be discussed. Renotate the indices in the last two terms as follows:

$$
H_{1, \text { spin-orbit }}=\mathrm{i} \sum_{i} \widehat{p}_{\bar{\imath}} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{\bar{\imath}} \sigma_{i}-\mathrm{i} \sum_{i} \widehat{p}_{\overline{\bar{\imath}}} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{\bar{\imath}} \sigma_{i}
$$

Since the relative order of the subscripts in the cycle was maintained in the renotation, the sums still contain the exact same three terms, just in a different
order. Take out the common factors;

$$
H_{1, \text { spin-orbit }}=\frac{\mathrm{i}}{4 m_{\mathrm{e}}^{2} c^{2}} \sum_{i}\left[\widehat{p}_{\bar{\imath}}\left(V-E_{n}\right) \widehat{p}_{\overline{\bar{\imath}}}-\widehat{p}_{\bar{\imath}}\left(V-E_{n}\right) \widehat{p}_{\bar{\imath}}\right] \sigma_{i}
$$

Now according to the generalized canonical commutator of chapter 4.5.4:

$$
\widehat{p}_{i}\left(V-E_{n}\right)=\left(V-E_{n}\right) \widehat{p}_{i}-\mathrm{i} \hbar \frac{\partial\left(V-E_{n}\right)}{\partial r_{i}}
$$

where $E_{n}$ is a constant that produces a zero derivative. So $\widehat{p}_{\bar{\imath}}$, respectively $\widehat{p}_{\overline{\bar{\imath}}}$ can be taken to the other side of $V-E_{n}$ as long as the appropriate derivatives of $V$ are added. If that is done, $\left(V-E_{n}\right) \widehat{p}_{\bar{p}} \widehat{p}_{\overline{\bar{\imath}}}$ and $-\left(V-E_{n}\right) \widehat{p} \hat{p}_{\bar{i}}$ cancel since linear momentum operators commute. What is left are just the added derivative terms:

$$
H_{1, \text { spin-orbit }}=\frac{\hbar}{4 m_{\mathrm{e}}^{2} c^{2}} \sum_{i}\left[\frac{\partial V}{\partial r_{\bar{\imath}}} \widehat{p}_{\overline{\bar{\imath}}}-\frac{\partial V}{\partial r_{\overline{\bar{\imath}}}} \widehat{p}_{\bar{\imath}}\right] \sigma_{i}
$$

Note that the errant eigenvalue $E_{n}$ mercifully dropped out. Now the hydrogen potential $V$ only depends on the distance $r$ from the origin, as $1 / r$, so

$$
\frac{\partial V}{\partial r_{i}}=-\frac{V}{r^{2}} r_{i}
$$

and plugging that into the operator, you get

$$
H_{1, \text { spin-orbit }}=-\frac{\hbar V}{4 m_{\mathrm{e}}^{2} c^{2} r^{2}} \sum_{i}\left[r_{\widehat{\bar{z}}} \widehat{\bar{p}}_{\overline{\bar{\imath}}}-r_{\overline{\bar{z}}} \widehat{p}_{\bar{z}}\right] \sigma_{i}
$$

The term between the square brackets can be recognized as the $i$ th component of the angular momentum operator; also the Pauli spin matrix $\sigma_{i}$ is defined as $\widehat{S}_{i} / \frac{1}{2} \hbar$, so

$$
H_{1, \text { spin-orbit }}=-\frac{V}{2 m_{\mathrm{e}}^{2} c^{2} r^{2}} \sum_{i} \widehat{L}_{i} \widehat{S}_{i}
$$

Get rid of $c^{2}$ using $\left|E_{1}\right|=\frac{1}{2} \alpha^{2} m_{\mathrm{e}} c^{2}$, of $V$ using $V=-2\left|E_{1}\right| a_{0} / r$, and $m_{\mathrm{e}}$ using $\left|E_{1}\right|=\hbar^{2} / 2 m_{\mathrm{e}} a_{0}^{2}$ to get the spin-orbit interaction as claimed in the section on fine structure.

That leaves the term

$$
\sum_{i} \widehat{p}_{i} \frac{V-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{i}
$$

in (D.59). Since $V=H_{0}-\widehat{p}^{2} / 2 m_{\mathrm{e}}$, it can be written as

$$
\sum_{i} \widehat{p}_{i} \frac{H_{0}-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{i}-\frac{\left(\widehat{p}^{2}\right)^{2}}{8 m_{\mathrm{e}}^{3} c^{2}}
$$

The final term is the claimed Einstein correction in the fine structure Hamiltonian, using $\left|E_{1}\right|=\frac{1}{2} \alpha^{2} m_{\mathrm{e}} c^{2}$ to get rid of $c^{2}$.

The first term,

$$
H_{1, \text { Darwin }} \stackrel{?}{=} \sum_{i} \widehat{p_{i}} \frac{H_{0}-E_{n}}{4 m_{\mathrm{e}}^{2} c^{2}} \widehat{p}_{i}
$$

is the sole remaining problem. It cannot be transformed into a decent physical operator. The objective is just to get the energy correction right. And to achieve that requires only that the Hamiltonian perturbation coefficients are evaluated correctly at the $E_{n}$ energy level. Specifically, what is needed is that

$$
H_{\overrightarrow{\underline{\rightharpoonup}} \vec{n}, 1, \text { Darwin }} \equiv\left\langle\psi_{\underline{\vec{n}}, 0} \mid H_{1, \text { Darwin }} \psi_{\vec{n}, 0}\right\rangle=\frac{1}{4 m_{\mathrm{e}}^{2} c^{2}} \sum_{i}\left\langle\psi_{\overrightarrow{\underline{n}}, 0} \mid \widehat{p}_{i}\left(H_{0}-E_{n}\right) \widehat{p}_{i} \psi_{\vec{n}, 0}\right\rangle
$$

for any arbitrary pair of unperturbed hydrogen energy eigenfunctions $\psi_{\vec{n}, 0}$ and $\psi_{\vec{n}, 0}$ with energy $E_{n}$. To see what that means, the leading Hermitian operator $\widehat{p}_{i}$ can be taken to the other side of the inner product, and in half of that result, $H_{0}-E_{n}$ will also be taken to the other side:
$H_{\overrightarrow{\underline{n}}, 1, \text { Darwin }}=\frac{1}{8 m_{\mathrm{e}}^{2} c^{2}} \sum_{i}\left(\left\langle\widehat{p}_{i} \psi_{\vec{n}, 0} \mid\left(H_{0}-E_{n}\right) \widehat{p}_{i} \psi_{\vec{n}, 0}\right\rangle+\left\langle\left(H_{0}-E_{n}\right) \widehat{p}_{i} \psi_{\vec{n}, 0} \mid \widehat{p}_{i} \psi_{\vec{n}, 0}\right\rangle\right)$
Now if you simply swap the order of the factors in $\left(H_{0}-E_{n}\right) \widehat{p}_{i}$ in this expression, you get zero, because both eigenfunctions have energy $E_{n}$. However, swapping the order of $\left(H_{0}-E_{n}\right) \widehat{p}_{i}$ brings in the generalized canonical commutator [ $V, \widehat{p}_{i}$ ] that equals i$\hbar \partial V / \partial r_{i}$. Therefore, writing out the remaining inner product you get

$$
H_{\overrightarrow{\underline{r}} \vec{n}, 1, \text { Darwin }}=\frac{-\hbar^{2}}{8 m_{\mathrm{e}}^{2} c^{2}} \sum_{i} \int_{\text {all } \vec{r}} \frac{\partial V}{\partial r_{i}} \frac{\partial \psi_{\vec{n}, 0}^{*} \psi_{\vec{n}, 0}}{\partial r_{i}} \mathrm{~d}^{3} \vec{r}
$$

Now, the potential $V$ becomes infinite at $r=0$, and that makes mathematical manipulation difficult. Therefore, assume for now that the nuclear charge $e$ is not a point charge, but spread out over a very small region around the origin. In that case, the inner product can be rewritten as

$$
H_{\overrightarrow{\underline{n}} \vec{n}, 1, \text { Darwin }}=\frac{-\hbar^{2}}{8 m_{\mathrm{e}}^{2} c^{2}} \sum_{i} \int_{\text {all } \vec{r}}\left[\frac{\partial}{\partial r_{i}}\left(\frac{\partial V}{\partial r_{i}} \psi_{\overrightarrow{\vec{n}}, 0}^{*} \psi_{\vec{n}, 0}\right)-\frac{\partial^{2} V}{\partial r_{i}^{2}} \psi_{\overrightarrow{\vec{n}}, 0}^{*} \psi_{\vec{n}, 0}\right] \mathrm{d}^{3} \vec{r}
$$

and the first term integrates away since $\psi_{\vec{n}, 0}^{*} \psi_{\vec{n}, 0}$ vanishes at infinity. In the final term, use the fact that the derivatives of the potential energy $V$ give $e$ times the electric field of the nucleus, and therefore the second order derivatives give $e$ times the divergence of the electric field. Maxwell's first equation (13.5) says that that is $e / \epsilon_{0}$ times the nuclear charge density. Now if the region of nuclear charge is allowed to contract back to a point, the charge density must still integrate to the net proton charge $e$, so the charge density becomes $e \delta^{3}(\vec{r})$
where $\delta^{3}(\vec{r})$ is the three-dimensional delta function. Therefore the Darwin term produces Hamiltonian perturbation coefficients as if its Hamiltonian is

$$
H_{1, \text { Darwin }}=\frac{\hbar^{2} e^{2}}{8 m_{\mathrm{e}}^{2} c^{2} \epsilon_{0}} \delta^{3}(\vec{r})
$$

Get rid of $c^{2}$ using $\left|E_{1}\right|=\frac{1}{2} \alpha^{2} m_{\mathrm{e}} c^{2}$, of $e^{2} / \epsilon_{0}$ using $e^{2} / 4 \pi \epsilon_{0}=2\left|E_{1}\right| a_{0}$, and $m_{\mathrm{e}}$ using $\left|E_{1}\right|=\hbar^{2} / 2 m_{\mathrm{e}} a_{0}^{2}$ to get the Darwin term as claimed in the section on fine structure. It will give the right energy correction for the nonrelativistic solution. But you may rightly wonder what to make of the implied wave function.

## D. 82 Classical spin-orbit derivation

This note derives the spin-orbit Hamiltonian from a more intuitive, classical point of view than the Dirac equation mathematics.

Picture the magnetic electron as containing a pair of positive and negative magnetic monopoles of a large strength $q_{m}$. The very small distance from negative to positive pole is denoted by $\vec{d}$ and the product $\vec{\mu}=q_{m} \vec{d}$ is the magnetic dipole strength, which is finite.

Next imagine this electron smeared out in some orbit encircling the nucleus with a speed $\vec{v}$. The two poles will then be smeared out into two parallel "magnetic currents" that are very close together. The two currents have opposite directions because the velocity $\vec{v}$ of the poles is the same while their charges are opposite. These magnetic currents will be encircled by electric field lines just like the electric currents in figure 13.15 were encircled by magnetic field lines.

Now assume that seen from up very close, a segment of these currents will seem almost straight and two-dimensional, so that two-dimensional analysis can be used. Take a local coordinate system such that the $z$-axis is aligned with the negative magnetic current and in the direction of positive velocity. Rotate the $x y$-plane around the $z$-axis so that the positive current is to the right of the negative one. The picture is then just like figure 13.15, except that the currents are magnetic and the field lines electric. In this coordinate system, the vector from negative to positive pole takes the form $\vec{d}=d_{x} \hat{\imath}+d_{z} \hat{k}$.

The magnetic current strength is defined as $q_{m}^{\prime} v$, where $q_{m}^{\prime}$ is the moving magnetic charge per unit length of the current. So, according to table 13.2 the negative current along the $z$-axis generates a two-dimensional electric field whose potential is

$$
\varphi_{\ominus}=-\frac{q_{m}^{\prime} v}{2 \pi \epsilon_{0} c^{2}} \theta=-\frac{q_{m}^{\prime} v}{2 \pi \epsilon_{0} c^{2}} \arctan \left(\frac{y}{x}\right)
$$

To get the field of the positive current a distance $d_{x}$ to the right of it, shift $x$ and change sign:

$$
\varphi_{\oplus}=\frac{q_{m}^{\prime} v}{2 \pi \epsilon_{0} c^{2}} \arctan \left(\frac{y}{x-d_{x}}\right)
$$

If these two potentials are added, the difference between the two arctan functions can be approximated as $-d_{x}$ times the $x$ derivative of the unshifted arctan. That can be seen from either recalling the very definition of the partial derivative, or from expanding the second arctan in a Taylor series in $x$. The bottom line is that the monopoles of the moving electron generate a net electric field with a potential

$$
\varphi=\frac{q_{m}^{\prime} d_{x} v}{2 \pi \epsilon_{0} c^{2}} \frac{y}{x^{2}+y^{2}}
$$

Now compare that with the electric field generated by a couple of opposite electric line charges like in figure 13.12, a negative one along the $z$-axis and a positive one above it at a position $y=d_{\mathrm{c}}$. The electric dipole moment per unit length of such a pair of line charges is by definition $\vec{\wp}^{\prime}=q^{\prime} d_{\mathrm{c}} \hat{\jmath}$, where $q^{\prime}$ is the electric charge per unit length. According to table 13.1, a single electric charge along the $z$-axis creates an electric field whose potential is

$$
\varphi=\frac{q^{\prime}}{2 \pi \epsilon_{0}} \ln \frac{1}{r}=-\frac{q^{\prime}}{4 \pi \epsilon_{0}} \ln \left(x^{2}+y^{2}\right)
$$

For an electric dipole consisting of a negative line charge along the $z$-axis and a positive one above it at $y=d_{\mathrm{c}}$, the field is then

$$
\varphi=-\frac{q^{\prime}}{4 \pi \epsilon_{0}} \ln \left(x^{2}+(y-d)^{2}\right)+\frac{q^{\prime}}{4 \pi \epsilon_{0}} \ln \left(x^{2}+y^{2}\right)
$$

and the difference between the two logarithms can be approximated as $-d_{c}$ times the $y$-derivative of the unshifted one. That gives

$$
\varphi=\frac{q^{\prime} d_{\mathrm{c}}}{2 \pi \epsilon_{0}} \frac{y}{x^{2}+y^{2}}
$$

Comparing this with the potential of the monopoles, it is seen that the magnetic currents create an electric dipole in the $y$-direction whose strength $\vec{\wp}^{\prime}$ is $q_{m}^{\prime} d_{x} v / c^{2} \hat{\jmath}$. And since in this coordinate system the magnetic dipole moment is $\vec{\mu}^{\prime}=q_{m}^{\prime}\left(d_{x} \hat{\imath}+d_{z} \hat{k}\right)$ and the velocity $v \hat{k}$, it follows that the generated electric dipole strength is

$$
\vec{\wp}^{\prime}=-\vec{\mu}^{\prime} \times \vec{v} / c^{2}
$$

Since both dipole moments are per unit length, the same relation applies between the actual magnetic dipole strength of the electron and the electric dipole strength generated by its motion. The primes can be omitted.

Now the energy of the electric dipole is $-\widehat{\wp} \cdot \overrightarrow{\mathcal{E}}$ where $\overrightarrow{\mathcal{E}}$ is the electric field of the nucleus, $e \vec{r} / 4 \pi \epsilon_{0} r^{3}$ according to table 13.1. So the energy is:

$$
\frac{e}{4 \pi \epsilon_{0} c^{2}} \frac{1}{r^{3}} \vec{r} \cdot(\vec{\mu} \times \vec{v})
$$

and the order of the triple product of vectors can be changed and then the angular momentum can be substituted:

$$
-\frac{e}{4 \pi \epsilon_{0} c^{2}} \frac{1}{r^{3}} \vec{\mu} \cdot(\vec{r} \times \vec{v})=-\frac{e}{4 \pi \epsilon_{0} c^{2} m_{\mathrm{e}}} \frac{1}{r^{3}} \vec{\mu} \cdot \vec{L}
$$

To get the correct spin-orbit interaction, the magnetic dipole moment $\vec{\mu}$ used in this expression must be the classical one, $-e \vec{S} / 2 m_{\mathrm{e}}$. The additional factor $g_{e}=2$ for the energy of the electron in a magnetic field does not apply here. There does not seem to be a really good reason to give for that, except for saying that the same Dirac equation that says that the additional $g$-factor is there in the magnetic interaction also says it is not in the spin-orbit interaction. The expression for the energy becomes

$$
\frac{e^{2}}{8 \pi \epsilon_{0} m_{\mathrm{e}}^{2} c^{2}} \frac{1}{r^{3}} \vec{S} \cdot \vec{L}
$$

Getting rid of $c^{2}$ using $\left|E_{1}\right|=\frac{1}{2} \alpha^{2} m_{\mathrm{e}} c^{2}$, of $e^{2} / \epsilon_{0}$ using $e^{2} / 4 \pi \epsilon_{0}=2\left|E_{1}\right| a_{0}$, and of $m_{\mathrm{e}}$ using $\left|E_{1}\right|=\hbar^{2} / 2 m_{\mathrm{e}} a_{0}^{2}$, the claimed expression for the spin-orbit energy is found.

## D. 83 Expectation powers of $r$ for hydrogen

This note derives the expectation values of the powers of $r$ for the hydrogen energy eigenfunctions $\psi_{n l m}$. The various values to be be derived are:

$$
\begin{align*}
& \left\langle\psi_{n l m} \mid\left(a_{0} / r\right)^{3} \psi_{n l m}\right\rangle=\frac{1}{l\left(l+\frac{1}{2}\right)(l+1) n^{3}} \\
& \left\langle\psi_{n l m} \mid\left(a_{0} / r\right)^{2} \psi_{n l m}\right\rangle=\frac{1}{\left(l+\frac{1}{2}\right) n^{3}} \\
& \left\langle\psi_{n l m} \mid\left(a_{0} / r\right) \psi_{n l m}\right\rangle=\frac{1}{n^{2}}  \tag{D.60}\\
& \left\langle\psi_{n l m} \mid 1 \psi_{n l m}\right\rangle=1 \\
& \left\langle\psi_{n l m} \mid\left(r / a_{0}\right) \psi_{n l m}\right\rangle=\frac{3 n^{2}-l(l+1)}{2} \\
& \left\langle\psi_{n l m} \mid\left(r / a_{0}\right)^{2} \psi_{n l m}\right\rangle=\frac{n^{2}\left(5 n^{2}-3 l(l+1)+1\right)}{2}
\end{align*}
$$

where $a_{0}$ is the Bohr radius, about $0.53 \AA$. Note that you can get the expectation value of a more general function of $r$ by summing terms, provided that the
function can be expanded into a Laurent series. Also note that the value of $m$ does not make a difference: you can combine $\psi_{n l m}$ of different $m$ values together and it does not change the above expectation values. And watch it, when the power of $r$ becomes too negative, the expectation value will cease to exist. For example, for $l=0$ the expectation values of $\left(a_{0} / r\right)^{3}$ and higher powers are infinite.

The trickiest to derive is the expectation value of $\left(a_{0} / r\right)^{2}$, and that one will be done first. First recall the hydrogen Hamiltonian from chapter 4.3,

$$
H=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} r^{2}}\left\{\frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r}\right)+\frac{1}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)+\frac{1}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}}\right\}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r}
$$

Its energy eigenfunctions of given square and $z$ angular momentum and their energy are

$$
\psi_{n l m}=R_{n l}(r) Y_{l}^{m}(\theta, \phi) \quad E_{n}=-\frac{\hbar^{2}}{2 n^{2} m_{\mathrm{e}} a_{0}^{2}} \quad a_{0}=\frac{4 \pi \epsilon_{0} \hbar^{2}}{m_{\mathrm{e}} e^{2}}
$$

where the $Y_{l}^{m}$ are called the spherical harmonics.
When this Hamiltonian is applied to an eigenfunction $\psi_{n l m}$, it produces the exact same result as the following "dirty trick Hamiltonian" in which the angular derivatives have been replaced by $l(l+1)$ :

$$
H_{\mathrm{DT}}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} r^{2}}\left\{\frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r}\right)-l(l+1)\right\}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r}
$$

The reason is that the angular derivatives are essentially the square angular momentum operator of chapter 4.2.3. Now, while in the hydrogen Hamiltonian the quantum number $l$ has to be an integer because of its origin, in the dirty trick one $l$ can be allowed to assume any value. That means that you can differentiate the Hamiltonian and its eigenvalues $E_{n}$ with respect to $l$. And that allows you to apply the Hellmann-Feynman theorem of section A.38.1:

$$
\frac{\partial E_{n, \mathrm{DT}}}{\partial l}=\left\langle\psi_{n l m} \left\lvert\, \frac{\partial H_{\mathrm{DT}}}{\partial l} \psi_{n l m}\right.\right\rangle
$$

(Yes, the eigenfunctions $\psi_{n l m}$ are good, because the purely radial $H_{\text {DT }}$ commutes with both $\widehat{L}_{z}$ and $\widehat{L}^{2}$, which are angular derivatives.) Substituting in the dirty trick Hamiltonian,

$$
\frac{\partial E_{n, \mathrm{DT}}}{\partial l}=\frac{\hbar^{2}(2 l+1)}{2 m_{\mathrm{e}} a_{0}^{2}}\left\langle\psi_{n l m} \left\lvert\,\left(\frac{a_{0}}{r}\right)^{2} \psi_{n l m}\right.\right\rangle
$$

So, if you can figure out how the dirty trick energy changes with $l$ near some desired integer value $l=l_{0}$, the desired expectation value of $\left(a_{0} / r\right)^{2}$ at that integer value of $l$ follows. Note that the eigenfunctions of $H_{\mathrm{DT}}$ can still be taken
to be of the form $R_{n l}(r) Y_{l_{0}}^{m}(\theta, \phi)$, where $Y_{l_{0}}^{m}$ can be divided out of the eigenvalue problem to give $H_{\mathrm{DT}} R_{n l}=E_{D T} R_{n l}$. If you skim back through chapter 4.3 and its note, you see that that eigenvalue problem was solved in derivation $\{\mathrm{D} .15\}$. Now, of course, $l$ is no longer an integer, but if you skim through the note, it really makes almost no difference. The energy eigenvalues are still $E_{n, \mathrm{DT}}=$ $-\hbar^{2} / 2 n^{2} m_{\mathrm{e}} a_{0}^{2}$. If you look near the end of the note, you see that the requirement on $n$ is that $n=q+l+1$ where $q$ must remain an integer for valid solutions, hence must stay constant under small changes. So $\mathrm{d} n / \mathrm{d} l=1$, and then according to the chain rule the derivative of $E_{\mathrm{DT}}$ is $\hbar^{2} / n^{3} m_{\mathrm{e}} a_{0}^{2}$. Substitute it in and there you have that nasty expectation value as given in (D.60).

All other expectation values of $\left(r / a_{0}\right)^{q}$ for integer values of $q$ may be found from the "Kramers relation," or "(second) Pasternack relation:"

$$
\begin{equation*}
4(q+1)\langle q\rangle-4 n^{2}(2 q+1)\langle q-1\rangle+n^{2} q\left[(2 l+1)^{2}-q^{2}\right]\langle q-2\rangle=0 \tag{D.61}
\end{equation*}
$$

where $\langle q\rangle$ is shorthand for the expectation value $\left\langle\psi_{n l m} \mid\left(r / a_{0}\right)^{q} \psi_{n l m}\right\rangle$.
Substituting $q=0$ into the Kramers-Pasternack relation produces the expectation value of $a_{0} / r$ as in (D.60). It may be noted that this can instead be derived from the virial theorem of chapter 7.2, or from the Hellmann-Feynman theorem by differentiating the hydrogen Hamiltonian with respect to the charge $e$. Substituting in $q=1,2, \ldots$ produces the expectation values for $r / a_{0},\left(r / a_{0}\right)^{2}$,
. Substituting in $q=-1$ and the expectation value for $\left(a_{0} / r\right)^{2}$ from the Hellmann-Feynman theorem gives the expectation value for $\left(a_{0} / r\right)^{3}$. The remaining negative integer values $q=-2,-3, \ldots$ produce the remaining expectation values for the negative integer powers of $r / a_{0}$ as the $\langle q-2\rangle$ term in the equation.

Note that for a sufficiently negative powers of $r$, the expectation value becomes infinite. Specifically, since $\psi_{n l m}$ is proportional to $r^{l},\{\mathrm{D} .15\}$, it can be seen that $\langle q-2\rangle$ becomes infinite when $q=-2 l-1$. When that happens, the coefficient of the expectation value in the Kramers-Pasternack relation becomes zero, making it impossible to compute the expectation value. The relationship can be used until it crashes and then the remaining expectation values are all infinite.

The remainder of this note derives the Kramers-Pasternack relation. First note that the expectation values are defined as
$\langle q\rangle \equiv\left\langle\psi_{n l m} \mid\left(r / a_{0}\right)^{q} \psi_{n l m}\right\rangle=\int_{\text {all } \vec{r}}\left(r / a_{0}\right)^{q}\left|\psi_{n l m}\right|^{2} \mathrm{~d}^{3} \vec{r}=\int_{\text {all }}\left(r / a_{0}\right)^{q}\left|R_{n l} Y_{l}^{m}\right|^{2} \mathrm{~d}^{3} \vec{r}$
When this integral is written in spherical coordinates, the integration of the square spherical harmonic over the angular coordinates produces one. So, the expectation value simplifies to

$$
\langle q\rangle=\int_{r=0}^{\infty}\left(r / a_{0}\right)^{q} R_{n l}^{2} r^{2} \mathrm{~d} r
$$

To simplify the notations, a nondimensional radial coordinate $\rho=r / a_{0}$ will be used. Also, a new radial function $f \equiv \sqrt{a_{0}^{3}} \rho R_{n l}$ will be defined. In those terms, the expression above for the expectation value shortens to

$$
\langle q\rangle=\int_{0}^{\infty} \rho^{q} f^{2} \mathrm{~d} \rho
$$

To further shorten the notations, from now on the limits of integration and $\mathrm{d} \rho$ will be omitted throughout. In those notations, the expectation value of $\left(r / a_{0}\right)^{q}$ is

$$
\langle q\rangle=\int \rho^{q} f^{2}
$$

Also note that the integrals are improper. It is to be assumed that the integrations are from a very small value of $r$ to a very large one, and that only at the end of the derivation, the limit is taken that the integration limits become zero and infinity.

According to derivation $\left\{\right.$ D.15\}, the function $R_{n l}$ satisfies in terms of $\rho$ the ordinary differential equation.

$$
-\rho^{2} R_{n l}^{\prime \prime}-2 \rho R_{n l}^{\prime}+\left[l(l+1)-2 \rho+\frac{1}{n^{2}} \rho^{2}\right] R_{n l}=0
$$

where primes indicate derivatives with respect to $\rho$. Substituting in $R_{n l}=$ $f / \sqrt{a_{0}^{3}} \rho$, you get in terms of the new unknown function $f$ that

$$
\begin{equation*}
f^{\prime \prime}=\left[\frac{1}{n^{2}}-\frac{2}{\rho}+\frac{l(l+1)}{\rho^{2}}\right] f \tag{D.62}
\end{equation*}
$$

Since this makes $f^{\prime \prime}$ proportional to $f$, forming the integral $\int \rho^{q} f^{\prime \prime} f$ produces a combination of terms of the form $\int \rho^{\text {power }} f^{2}$, hence of expectation values of powers of $\rho$ :

$$
\begin{equation*}
\int \rho^{q} f^{\prime \prime} f=\frac{1}{n^{2}}\langle q\rangle-2\langle q-1\rangle+l(l+1)\langle q-2\rangle \tag{D.63}
\end{equation*}
$$

The idea is now to apply integration by parts on $\int \rho^{q} f^{\prime \prime} f$ to produce a different combination of expectation values. The fact that the two combinations must be equal will then give the Kramers-Pasternack relation.

Before embarking on this, first note that since

$$
\left.\int \rho^{q} f f^{\prime}=\int \rho^{q}\left(\frac{1}{2} f^{2}\right)^{\prime}=\rho^{q} \frac{1}{2} f^{2} \right\rvert\,-\int q \rho^{q-1} \frac{1}{2} f^{2}
$$

the latter from integration by parts, it follows that

$$
\begin{equation*}
\left.\int \rho^{q} f f^{\prime}=\frac{1}{2} \rho^{q} f^{2} \right\rvert\,-\frac{q}{2}\langle q-1\rangle \tag{D.64}
\end{equation*}
$$

This result will be used routinely in the manipulations below to reduce integrals of that form.

Now an obvious first integration by parts on $\int \rho^{q} f^{\prime \prime} f$ produces

$$
\int \rho^{q} f f^{\prime \prime}=\rho^{q} f f^{\prime}\left|-\int\left(\rho^{q} f\right)^{\prime} f^{\prime}=\rho^{q} f f^{\prime}\right|-\int q \rho^{q-1} f f^{\prime}-\int \rho^{q} f^{\prime} f^{\prime}
$$

The first of the two integrals reduces to an expectation value of $\rho^{q-2}$ using (D.64). For the final integral, use another integration by parts, but make sure you do not run around in a circle because if you do you will get a trivial expression. What works is integrating $\rho^{q}$ and differentiating $f^{\prime} f^{\prime}$ :

$$
\begin{equation*}
\left.\int \rho^{q} f f^{\prime \prime}=\rho^{q} f f^{\prime}\left|-\frac{q}{2} \rho^{q-1} f^{2}\right|+\frac{q(q-1)}{2}\langle q-2\rangle-\frac{\rho^{q+1}}{q+1} f^{\prime 2} \right\rvert\,+2 \int \frac{\rho^{q+1}}{q+1} f^{\prime} f^{\prime \prime} \tag{D.65}
\end{equation*}
$$

In the final integral, according to the differential equation (D.62), the factor $f^{\prime \prime}$ can be replaced by powers of $\rho$ times $f$ :

$$
2 \int \frac{\rho^{q+1}}{q+1} f^{\prime} f^{\prime \prime}=2 \int \frac{\rho^{q+1}}{q+1}\left[\frac{1}{n^{2}}-\frac{2}{\rho}+\frac{l(l+1)}{\rho^{2}}\right] f f^{\prime}
$$

and each of the terms is of the form (D.64), so you get

$$
\begin{aligned}
2 \int \frac{\rho^{q+1}}{q+1} f^{\prime} f^{\prime \prime} & \left.=\frac{1}{(q+1) n^{2}} \rho^{q+1} f^{2}\left|-\frac{2}{q+1} \rho^{q} f^{2}\right|+\frac{l(l+1)}{q+1} \rho^{q-1} f^{2} \right\rvert\, \\
& -\frac{1}{n^{2}}\langle q\rangle+\frac{2 q}{q+1}\langle q-1\rangle-\frac{l(l+1)(q-1)}{q+1}\langle q-2\rangle
\end{aligned}
$$

Plugging this into (D.65) and then equating that to (D.63) produces the Kramers-Pasternack relation. It also gives an additional right hand side

$$
\rho^{q} f f^{\prime}\left|-\frac{q \rho^{q-1}}{2} f^{2}\right|-\frac{\rho^{q+1}}{q+1} f^{\prime 2}\left|+\frac{\rho^{q+1}}{(q+1) n^{2}} f^{2}\right|-\frac{2 \rho^{q}}{q+1} f^{2}\left|+\frac{l(l+1) \rho^{q-1}}{q+1} f^{2}\right|
$$

but that term becomes zero when the integration limits take their final values zero and infinity. In particular, the upper limit values always become zero in the limit of the upper bound going to infinity; $f$ and its derivative go to zero exponentially then, beating out any power of $\rho$. The lower limit values also become zero in the region of applicability that $\langle q-2\rangle$ exists, because that requires that $\rho^{q-1} f^{2}$ is for small $\rho$ proportional to a power of $\rho$ greater than zero.

The above analysis is not valid when $q=-1$, since then the final integration by parts would produce a logarithm, but since the expression is valid for any other $q$, not just integer ones you can just take a limit $q \rightarrow-1$ to cover that case.

## D. 84 Band gap explanation derivations

To see mathematically how the results of note $\{\mathrm{N} .9\}$ were obtained requires knowledge of linear algebra. If you are unaware of it, definitely skip the below derivation.

First define the "growth matrix $G$ that gives the values of $\psi, \psi^{\prime}$ at $x=d_{x}$ given the values at $x=0$ :

$$
\binom{\psi\left(d_{x}\right)}{\psi^{\prime}\left(d_{x}\right)}=G\binom{\psi(0)}{\psi^{\prime}(0)}
$$

Simply take the initial conditions to be 1,0 and 0,1 respectively, and find the solutions at $d_{x}$ to find the two columns of $G$.

Since the potential is the same in all atomic cell, matrix $G$ describes the change over any cell, not just the first one. And for a periodic solution for a box with $N_{x}$ "atoms," after $N_{x}$ applications of $G$ the original values of $\psi, \psi^{\prime}$ must be obtained. According to linear algebra, and assuming that the two eigenvalues of $G$ are unequal, that means that at least one eigenvalue of $G$ raised to the power $N_{x}$ must be 1 .

Now matrix $G$ must have unit determinant, because for the two basic solutions with 1,0 and 0,1 initial conditions,

$$
\psi_{1} \psi_{2}^{\prime}-\psi_{1}^{\prime} \psi_{2}=\text { constant }=1
$$

for all $x$. The quantity in the left hand side is called the Wronskian of the solutions. To verify that it is indeed constant, take $\psi_{1}$ times the Hamiltonian eigenvalue problem for $\psi_{2}$ minus $\psi_{2}$ times the one for $\psi_{1}$ to get

$$
0=\psi_{1} \psi_{2}^{\prime \prime}-\psi_{2} \psi_{1}^{\prime \prime}=\left(\psi_{1} \psi_{2}^{\prime}-\psi_{2} \psi_{1}^{\prime}\right)^{\prime}
$$

According to linear algebra, if $G$ has unit determinant then the product of its two eigenvalues is 1 . Therefore, if its eigenvalues are unequal and real, their magnitude is unequal to 1 . One will be less than 1 in magnitude and the other greater than 1 . Neither can produce 1 when raised to the power $N_{x}$, so there are no periodic solutions. Energies that produce such matrices $G$ are in the band gaps.

If the eigenvalues of $G$ are complex conjugates, they must have magnitude 1. In that case, the eigenvalues can always be written in the form

$$
e^{\mathrm{i} k_{x} d_{x}} \text { and } e^{-\mathrm{i} k_{x} d_{x}}
$$

for some value of $k_{x}$. For either eigenvalue raised to the power $N_{x}$ to produce $1, N_{x} k_{x} d_{x}$ must be a whole multiple of $2 \pi$. That gives the same wave number values as for the free-electron gas.

To see when the eigenvalues of $G$ have the right form, consider the sum of the eigenvalues. This sum is called the trace. If the eigenvalues are real and
unequal, and their product is 1 , then the trace of $G$ must be greater than 2 in magnitude. (One way of seeing that for positive eigenvalues is to multiply out the expression $\left(\sqrt{\lambda_{1}}-\sqrt{\lambda_{2}}\right)^{2}>0$. For negative ones, add two minus signs in the square roots.) Conversely, when the eigenvalues are complex conjugates, their sum equals $2 \cos \left(k_{x} d_{x}\right)$ according to the Euler formula (2.5). That is less than 2 in magnitude. So the condition for valid periodic eigenfunctions becomes

$$
\operatorname{trace}(G)=2 \cos \left(k_{x} d_{x}\right) \quad k_{x} d_{x}=\frac{n_{x}}{N_{x}} 2 \pi
$$

From the fact that periodic solutions with twice the crystal period exist, (the ones at the band gaps), it is seen that the values of the trace must be such that the cosine runs through the entire gamut of values. Indeed when the trace is plotted as a function of the energy, it oscillates in value between minima less than -2 and maxima greater than 2. Each segment between adjacent minima and maxima produces one energy band. At the gap energies

$$
v_{x}^{\mathrm{p}}=\frac{\mathrm{d} E_{x}^{\mathrm{p}}}{\mathrm{~d} \hbar k_{x}}=\frac{1}{\hbar} \frac{\mathrm{~d} 2 \cos \left(k_{x} d_{x}\right)}{\mathrm{d} k_{x}} / \frac{\operatorname{dtrace}(G)}{\mathrm{d} E_{x}^{\mathrm{p}}}=0
$$

because the cosine is at its $\pm 1$ extrema at the gap energies. So the velocity becomes zero at the ends of the bands.

Identification of the eigenfunctions using the growth matrix $G$ is readily put on a computer. A canned zero finder can be used to find the energies corresponding to the allowed values of the trace.

## Appendix $\mathbf{N}$

## Notes

This appendix collects various notes on the material. This sort of material is often given in footnotes at the bottom of the text. However, such a footnote is distracting. You tend to read them even if they are probably not really that important to you. Also, footnotes have to be concise, or they make a mess of the main text.

## N. 1 Why this book?

With the current emphasis on nanotechnology, quantum mechanics is becoming increasingly essential to engineering students. Yet, the typical quantum mechanics texts for physics students are not written in a style that most engineering students would likely feel comfortable with. Furthermore, an engineering education provides very little real exposure to modern physics, and introductory quantum mechanics books do little to fill in the gaps. The emphasis tends to be on the computation of specific examples, rather than on discussion of the broad picture. Undergraduate physics students may have the luxury of years of further courses to pick up a wide physics background, engineering graduate students not really. In addition, the coverage of typical introductory quantum mechanics books does not emphasize understanding of the larger-scale quantum system that a density functional computation, say, would be used for.

Hence this book, written by an engineer for engineers. As an engineering professor with an engineering background, this is the book $I$ wish I would have had when I started learning real quantum mechanics a few years ago. The reason I like this book is not because I wrote it; the reason I wrote this book is because I like it.

This book is not a popular exposition: quantum mechanics can only be described properly in the terms of mathematics; suggesting anything else is crazy. But the assumed background in this book is just basic undergraduate calculus and physics as taken by all engineering undergraduates. There is no intention to
teach students proficiency in the clever manipulation of the mathematical machinery of quantum mechanics. For those engineering graduate students who may have forgotten some of their undergraduate calculus by now, there are some quick and dirty reminders in the notations. For those students who may have forgotten some of the details of their undergraduate physics, frankly, I am not sure whether it makes much of a difference. The ideas of quantum mechanics are that different from conventional physics. But the general ideas of classical physics are assumed to be known. I see no reason why a bright undergraduate student, having finished calculus and physics, should not be able to understand this book. A certain maturity might help, though. There are a lot of ideas to absorb.

My initial goal was to write something that would "read like a mystery novel." Something a reader would not be able to put down until she had finished it. Obviously, this goal was unrealistic. I am far from a professional writer, and this is quantum mechanics, after all, not a murder mystery. But I have been told that this book is very well written, so maybe there is something to be said for aiming high.

To prevent the reader from getting bogged down in mathematical details, I mostly avoid nontrivial derivations in the text. Instead I have put the outlines of these derivations in notes at the end of this document: personally, I enjoy checking the correctness of the mathematical exposition, and I would not want to rob my students of the opportunity to do so too. In fact, the chosen approach allows a lot of detailed derivations to be given that are skipped in other texts to reduce distractions. Some examples are the harmonic oscillator, orbital angular momentum, and radial hydrogen wave functions, Hund's first rule, and rotation of angular momentum. And then there are extensive derivations of material not even included in other introductory quantum texts.

While typical physics texts jump back and forward from issue to issue, I thought that would just be distracting for my audience. Instead, I try to follow a consistent approach, with as central theme the method of separation-ofvariables, a method that most mechanical graduate students have seen before already. It is explained in detail anyway. To cut down on the issues to be mentally absorbed at any given time, I purposely avoid bringing up new issues until I really need them. Such a just-in-time learning approach also immediately answers the question why the new issue is relevant, and how it fits into the grand scheme of things.

The desire to keep it straightforward is the main reason that topics such as Clebsch-Gordan coefficients (except for the unavoidable introduction of singlet and triplet states) and Pauli spin matrices have been shoved out of the way to a final chapter. My feeling is, if I can give my students a solid understanding of the basics of quantum mechanics, they should be in a good position to learn more about individual issues by themselves when they need them. On the other hand, if they feel completely lost in all the different details, they are not likely
to learn the basics either.
That does not mean the coverage is incomplete. All topics that are conventionally covered in basic quantum mechanics courses are present in some form. Some are covered in much greater depth. And there is a lot of material that is not usually covered. I include significant qualitative discussion of atomic and chemical properties, Pauli repulsion, the properties of solids, Bragg reflection, and electromagnetism, since many engineers do not have much background on them and not much time to pick it up. The discussion of thermal physics is much more elaborate than you will find in other books on quantum mechanics. It includes all the essentials of a basic course on classical thermodynamics, in addition to the quantum statistics. I feel one cannot be separated from the other, especially with respect to the second law. While mechanical engineering students will surely have had a course in basic thermodynamics before, a refresher cannot hurt. Unlike other books, this book also contains a chapter on numerical procedures, currently including detailed discussions of the Born-Oppenheimer approximation, the variational method, and the Hartree-Fock method. Hopefully, this chapter will eventually be completed with a section on density-functional theory. (The Lennard-Jones model is covered earlier in the section on molecular solids.) The motivation for including numerical methods in a basic exposition is the feeling that after a century of work, much of what can be done analytically in quantum mechanics has been done. That the greatest scope for future advances is in the development of improved numerical methods.

Knowledgeable readers may note that I try to stay clear of abstract mathematics when it is not needed. For example, I try to go slow on the more abstract vector notation permeating quantum mechanics, usually phrasing such issues in terms of a specific basis. Abstract notation may seem to be completely general and beautiful to a mathematician, but I do not think it is going to be intuitive to a typical engineer. The discussion of systems with multiple particles is centered around the physical example of the hydrogen molecule, rather than particles in boxes. The discussion of solids in chapter 10 avoids the highly abstract Dirac comb (delta functions) mathematical model in favor of a physical discussion of more realistic one-dimensional crystals. The Lennard-Jones potential is derived for two atoms instead of harmonic oscillators.

The book tries to be as consistent as possible. Electrons are grey tones at the initial introduction of particles, and so they stay through the rest of the book. Nuclei are red dots. Occupied quantum states are red, empty ones grey. That of course required all figures to be custom made. They are not intended to be fancy but consistent and clear. I also try to stay consistent in notations throughout the book, as much as is possible without deviating too much from established usage.

When I derive the first quantum eigenfunctions, for a pipe and for the harmonic oscillator, I make sure to emphasize that they are not supposed to look like anything that we told them before. It is only natural for students to want
to relate what we told them before about the motion to the completely different story we are telling them now. So it should be clarified that (1) no, they are not going crazy, and (2) yes, we will eventually explain how what they learned before fits into the grand scheme of things.

Another difference of approach in this book is the way it treats classical physics concepts that the students are likely unaware about, such as canonical momentum, magnetic dipole moments, Larmor precession, and Maxwell's equations. They are largely "derived" in quantum terms, with no appeal to classical physics. I see no need to rub in the student's lack of knowledge of specialized areas of classical physics if a satisfactory quantum derivation is readily given.

This book is not intended to be an exercise in mathematical skills. Review questions are targeted towards understanding the ideas, with the mathematics as simple as possible. I also try to keep the mathematics in successive questions uniform, to reduce the algebraic effort required. There is an absolute epidemic out there of quantum texts that claim that "the only way to learn quantum mechanics is to do the exercises," and then those exercises turn out to be, by and large, elaborate exercises in integration and linear algebra that take excessive time and have nothing to do with quantum mechanics. Or worse, they are often basic theory. (Lazy authors that claim that basic theory is an "exercise" avoid having to cover that material themselves and also avoid having to come up with a real exercise.) Yes, I too did waste a lot of time with these. And then, when you are done, the answer teaches you nothing because you are unsure whether there might not be an algebraic error in your endless mass of algebra, and even if there is no mistake, there is no hint that it means what you think it means. All that your work has earned you is a $75 / 25$ chance or worse that you now "know" something that is not true. Not in this book.

Finally, this document faces the very real conceptual problems of quantum mechanics head-on, including the collapse of the wave function, the indeterminacy, the nonlocality, and the symmetrization requirements. The usual approach, and the way I was taught quantum mechanics, is to shove all these problems under the table in favor of a good sounding, but upon examination self-contradictory and superficial story. Such superficiality put me off solidly when they taught me quantum mechanics, culminating in the unforgettable moment when the professor told us, seriously, that the wave function had to be symmetric with respect to exchange of bosons because they are all truly the same, and then, when I was popping my eyes back in, continued to tell us that the wave function is not symmetric when fermions are exchanged, which are all truly the same. I would not do the same to my own students. And I really do not see this professor as an exception. Other introductions to the ideas of quantum mechanics that I have seen left me similarly unhappy on this point. One thing that really bugs me, none had a solid discussion of the many worlds interpretation. This is obviously not because the results would be incorrect, (they have not been contradicted for half a century,) but simply because the
teachers just do not like these results. I do not like the results myself, but basing teaching on what the teacher would like to be true rather on what the evidence indicates is true remains absolutely unacceptable in my book.

## N. 2 History and wish list

- Aug. 26, 2018. Version 5.63 alpha.

The main new thing is a correction in section 6.23 on Semiconductors. In the detailed explanation of how $n$-type semiconductors work, I wrote somewhere "conduction band" where I meant "valence band." This of course does not improve clarity. Even after fixing, I thought the discussion was still confusing, so I rewrote the corresponding paragraphs from scratch.

- July 3, 2018. Version 5.62 alpha.

Mainly rewrites of Hartree-Fock derivation \{D.54\}. If I cannot follow my own reasoning, it is pretty bad.

- April 27, 2018. Version 5.61 alpha.

Rewrote section 9.1.1 for readability. Also rewrote addendum \{A.7\}. Other minor rewrites.
Reposting because an (ununderstood) latex2html bug appeared out of nothing with the (tricky) way -1 is formatted on the web pages. This bug is not repeatable and it did not happen for the colorized version nor for the remake. I am putting in some precautions anyway.

- April 20, 2018. Version 5.60 alpha.

Rewrote the introductory Hartree-Fock section 9.3.1 to be more readable and more independent of earlier chapters. Expanded on the description of Hartree-Fock correlation energy in 9.3.5.4 and its note N.18. Incomplete, but I am posting it now because I found and fixed some ugly errors.

- Mar. 4, 2018. Version 5.59 alpha.

Corrected a typo ( $j$ instead of $l$ for orbital angular momentum) at the start of section 12.8.
In Multiple-Particle Systems:
In the periodic table, added the recently assigned names for element numbers $113,115,117,118$. Now every element in the table has a real name.

In Macroscopic systems:
Completely rewrote note N. 9 explaining how band gaps arise if you add a bit of a periodic potential to the free electron gas. Corrected "the crystal spacing is a half-integer multiple of the [Bragg] wave
lengths" into "double the atom spacing is a whole multiple of the wave lengths". ("half-integer" seems to exclude "whole integer.")

## In Time Evolution:

Cleaned up the links in the pdf to the animations on the web. Also, weblinks now go to the same server as the pdf is downloaded from.
Completely rewrote addendum A. 17 on the virial theorem, as I now expect I will need it when I cover density functional theory.

In Classical and Quantum Thermodynamics:
More rewrites in "Specific Heats".
In Nuclei:
Added the $Z$ vs $N$ form of all $Z$ vs $\Delta N$ graphs as external pdf files.
Showed the nuclear decay processes first in a "Chart of the Nuclides" ( $Z$ vs $N$ ) form.
Explained how the $Z$ vs $\Delta N$ form clearly illustrates that nucleons of the same type like to pair up, while the $Z$ vs $N$ form does not.
In subsection 14.5.1, added a graph showing half-lifes in addition to the nuclear decay processes.
Changed spin colors to make the individual spins easier to recognize.
Left out the unused colors in the legends for the same reason.
In the spin plots, nuclei whose spin has reservations are now shown in the expected color instead of yellow, with a light check mark (a cross if none yet). That increases information content a lot. All nuclei now get a mark in the spin plots except those with unknown spin (yellow squares). Added a mark for nuclei in which an imperfect odd-nucleon model lowers the spin by one unit.
For the parity plots, used light colors instead of yellow crosses to indicate which parities with reservations are predicted OK or not. In the odd-even respectively even-odd parity graphs, shell model parity lines are now only shown at the odd-even, respectively evenodd locations. Both sets of odd $-A$ parity lines are now shown in the odd-odd parity graphs.
In the beta decay rate plots, added the stable nuclei to fill in the holes with known data.
In gamma decay, I converted subsection N. 36 into a note. Which it should always have been, as it is not part of standard theory but an hypothesis. Also rewrote it quite a bit to improve the presentation.

- Nov 1, 2016. Version 5.57 alpha. Corrected a number of errors and poor phrasings pointed out by various readers, as in the acknowledgements.

Corrected "molecular mass" in "The New Variables" into "molar mass". Cannot complain about others if I do it myself.
Yes, I need to get back to doing some more serious writing on this book.

- Feb 4, 2015. Version 5.57 alpha. Corrected some rather horrible typos pointed out by Rob Vossen.
- Nov 14, 2013. Version 5.56 alpha. The book has been converted to be processed by 12 h instead of $\mathrm{ETEX}^{2}$ HTML-FU. Web page hyphenation and bad-math-break prevention are now done by 12 h , instead of inside the latex source. And the Wordperfect and MS Word grammar checkers can now be applied. (In document pieces, to be sure. Not on all 1,600 pages at once!) Removed "we" from the notations. More rewriting of $\{\mathrm{A} .9\}$. Added Flerovium and Livermorium to the periodic table. Corrected some errors pointed out by kind readers.
- June 15, 2012. Version 5.55 alpha. Added hyperspheres to the notations. Finished $\{$ A. 8$\}$ and $\{$ D. 22$\}$. Rewrote $\{$ A. 9$\}$. These may need some more editing. The problems of the previous version with the index have been fixed. Various small problems fixed.
Various corrections of this version were posted the next few days. They only differ in formatting of the index and notations. Also some very minor editing, part of which may not have been posted. But now the formatting problems really seem fixed. I hope.
- June 11, 2012. Version 5.54 alpha. Added the screened Poisson equation to $\{$ D. 2$\}$. Rewrote $\{$ A. 8$\}$ on positive unique ground states and added an explanatory figure. Needs more work. Added an entry on spherical coordinates to the notations. Cleaned up and expanded \{D.14\} a bit. Editing of \{A.42\}. Improved the values of the physical constants in the notations. Improved alignment of inline math for Internet Explorer. Took inline equations apart and added tuned relation symbols. Created a better key image for key points. Improved appearance of the key point and question lists. Bolded math labels in the notations and added some space behind the labels. In the web version symbols are no longer on preceding lines. In the pdf, links are now enclosed by non-offensive thin grey lines. Urls are now enclosed by non-offensive thin black lines. In html, very long words, including all 14 characters long or more. will now hyphenate if needed. That includes one-dimensional, two-dimensional, three-dimensional, four-dimensional, $n$-dimensional. accomplishments, acknowledgments, anticommutators, antisymmetrically, antisymmetrization, ...Also in html, stupid line breaks at inline math images should no longer occur.
Please note that surely ten thousands of small changes have been made. Some are bound to have introduced a problem, especially
in formatting. I do think the esthetics of the web pages has been improved tremendously. Even more so for Internet Explorer, I guess. (But I use linux.)
Added note: the zipped version of this date has some minor format corrections, but also an error fix in \{D.22\} (which still needs more work.)
Added note: unfortunately, now the index looks like hell.
- May 4, 2012. Version 5.53 alpha. Corrections and extensions to fundamental forces, section 7.5.2. Editing of \{A.42\}.
- Apr. 25, 2012. Version 5.52 alpha. Editing of $\{A .42\}$. Corrected figures 3.3 and N.2. Very minor changes the next day.
- Feb. 15, 2012. Version 5.51 alpha. Improved discussion of field operators in \{A.15.9\}. Added a brief explanation of the Casimir force, \{A.23.4\}. Noted that pure particle and pure antiparticle states preserve norm, $\{$ D. 32$\}$ and $\{\mathrm{A} .15 .9\}$. Corrected that time reversal is antiunitary, not unitary, \{A.19.2\} Greatly expanded the discussion of the Fourier inversion theorem and Parseval, \{A.26\}. Added separate derivation of the Green's function of the Poisson equation, $\{\mathrm{D} .2\}$. Added an example of variational calculus, $\{$ A. 2$\}$. Added fields to classical Lagrangian and Hamiltonian analysis, \{A.1.5\}. Added a new addendum on forces by particle exchange, $\{\mathrm{A} .22\}$. While already big, this one will need to be expanded in a later version. Added that lone systems have definite spin and parity to chapter 7.3. Added draft explanation of the OPEP to $\{\mathrm{A} .42\}$.
- Dec. 15, 2011. Version 5.50 alpha. Further rewrites and correction of a couple of glaring errors in Quantum Field Theory in a Nanoshell \{A.15\}. I think this addendum is now much better than it was originally. Removed interpretation of the photon wave function again. Rewrites in 8.7
- Dec. 12, 2011. Version 5.49 alpha. Corrected previous history item. The Dirac $\gamma$ matrices are now defined, $\{A .36\}$. Rest mass is now just $m$, not $m_{0}$. Added note about Majorana neutrinos to $\{\mathrm{A} .44\}$. Added reference for gauge symmetries in $\{\mathrm{A} .19 .5\}$. Put in some disclaimers in \{A.42\}. Added an interpretation of the photon wave function. There is now a much needed draft rewrite of Quantum Field Theory in a Nanoshell \{A.15\}.
- Nov. 18, 2011. Version 5.48 alpha. Added a complete comparison of the mixed dipole and quadrupole gamma decays, figure 14.65. Minor corresponding rewrites. Nowadays NuDat 2 no longer tells you that you are requesting too much data and simply gives you partial data. That explained why M1 and E2 transitions stopped so quickly. It has been corrected. Added a description of neutrinos, \{A.44\}.
- Nov. 14, 2011. Version 5.47 alpha. Corrected the definition of "interval" in special relativity to be author-dependent. Due to a program error, in the comparison of gamma decay with data the program was actually selecting the nuclei to be as much the same as possible, instead of as much different as possible. It has been corrected. Not that it makes much of a visual difference. The text has been rewritten a bit too. In the "cage of Faraday" proposal, stupid me forgot about measured electromagnetic moments. That seems to kill off Meisner pretty well. It has been rewritten.
- Nov. 9, 2011. Version 5.46 alpha. Modified the "cage of Faraday" proposal a bit.
- Nov. 8, 2011. Version 5.45 alpha. Added the cage-of-Faraday proposal, chapter N.36.
- Nov. 8, 2011. Version 5.44 alpha. Added an example without charge independence to isospin to clarify the need for it. Corrected a typo in a formula and minor editing. Added examples to E0 internal conversion and edited the text a bit in chapter 14.20.6. Added a comparison of the single-particle theory of gamma decay with experimental data to chapter 14.20.5.
- Oct. 25, 2011. Version 5.43 alpha. Further editing of isospin. Seems to be OK for now. Some minor editing of quantum field theory.
- Oct. 17, 2011. Version 5.42 alpha. Rewrote the discussion for isospin. The original discussion was only defensible for a very crude model of the deuteron. The current discussion is better but needs more work.
- Oct. 12, 2011. Version 5.41 alpha. I finally got around to taking out some very dubious statements on gamma decay in 14.20 that have been bothering me for years. The relief is tremendous. I even managed to find a ballpark for the "missing" E0 transition.
- Oct. 03, 2011. Version 5.40 alpha. Some minor corrections and improvements on emission of radiation.
- Sep. 30, 2011. Version 5.39 alpha. Some minor corrections and improvements on emission of radiation. Being doing other stuff.
- Sep. 26, 2011. Version 5.38 alpha. Adds a table of hydrogen radial correction factors. Deals better with the magnetic transitions of nonrelativistic hydrogen.
- Sep. 16, 2011. Version 5.37 alpha. Minor changes and corrections in the previous items. Expanded the table with Weisskopf/Moszkowski correction factors.
- Sep. 12, 2011. Version 5.36 alpha. Minor changes in section 8.4. Added addendum \{A.25\} on multipole transitions, with corresponding derivations and notes $\{\mathrm{D} .43\},\{\mathrm{N} .13\}$, and $\{\mathrm{N} .14\}$. Took out
claim from Wikipedia that the 21 cm line is highly forbidden and replaced it with low energy.
- Aug. 10, 2011. Version 5.35 alpha. Completed addenda A. 23 and A. 24 Added section 8.4.
- Aug. 5, 2011. Version 5.34 alpha. Significant rewrite of section 7.4.3. Doing the electric transitions first really helps getting rid of all the ifs and buts. Some rewrite of addendum N.10. Improved the discussion of two-photon zero angular momentum in section 7.4.4. On second thought, bringing up the alpha particle in N. 10 was a bad idea. The worst part is that the alpha decay has an exponential dependence on angular momentum due to tunneling. That is less of an issue in beta decay, but then there is the blasted neutrino. So the particle is now a spinless nonrelativistic photon. Gee. The Lorentz gauge is now the Lorenz gauge. The Coulomb gauge is no longer misrepresented. Rewrote addenda A. 23 on second quantization and A. 24 on quantum derivation of spontaneous emission. They are incomplete; I am posting drafts since I have to go to work anyway.
- July 27, 2011. Version 5.33 alpha. The electric and magnetic fields are now $\mathcal{E}$ and $\mathcal{B}$. Hopefully. Based on [24, p. 240] and a similar message in a physics news group, took the bold step of defining a "type 2 wave function" for the photon. Some rewrite of addendum A.14. Correspondingly added notes A. 21 and D. 36 on the photon wave function and its derivation. They are incomplete; I am posting drafts since I have to go to work anyway.
- July 20, 2011. Version 5.32 alpha. Corrected statement on parity of the photon. Whatever I learn on the web does not hold up well. Added addendum A. 20 on the spin of vector particles.
- July 18, 2011. Version 5.31 alpha. Rewrote note physics of the fundamental commutators. Added an addendum with Maxwell's wave equations. Added the Klein-Gordon equation. Or at least, added a separate addendum for it, to eventually replace scattered discussions of it elsewhere.
- July 12, 2011. Version 5.30 alpha. Normalized appendices to allow question lists in them. Moved WKB to an addendum. Minor rewrites in time evolution. Added missing links to derivations in relativity.
- July 05, 2011. Version 5.29 alpha. Moved derivations from addenda to derivations. Added deuteron data from Argonne v18. Slight rewrites for relativity. Relocated some addenda. Cleaned up adiabatic theorem addendum and improved derivation. The Heisenberg formulation has been moved to an addendum. There are now direct links to the animated figures on the web in the pdf. The unsteady particle in the pipe has been animated. Made J the symbol of
generic angular momentum, with much effort. In 3D scattering, D is a private symbol of Griffiths according to his book on elementary particles, not a standard symbol as I thought. It has been removed. Rewrote intro to two-state systems. Changed action in relativistic case to be "stationary," rather than "least." Dropped claim obtained from Internet of no population inversion for semiconductor lasers. Gee. Major rewrite of the first half of time evolution.
- June 2, 2011. Version 5.28 alpha. Draft rewrite of the section on modeling the deuteron. Draft rewrite of the addendum on nuclear forces.
- May 30, 2011. Version 5.27 alpha. Inverted history list. Textual formulae make less use of images. Textual superscripts like powers and degree signs have been joined to their root with nobr tags. Made table formatting more consistent. Line length in html (at recommended browser width) has been reduced a bit. It is still longer than in the pdf version, but about the same as Lamport's LaTeX book. Maximum formulae, table, and figure lengths are now consistent in html and equal to the recommended browser width. This required a $3 \%$ reduction in displayed formulae size. Table sizes must be explicitly set due to buggy $\mathrm{AT}_{\mathrm{E}} \mathrm{X} 2 \mathrm{HTML}$ code. Center environments have been replaced by centering to eliminate redundant space, usually after the caption. Fixed formatting problems in table of contents and lists of figures, tables. Pdf links to figures and tables do now show the actual thing. Advanced angular momentum has been made a separate chapter. HTML table of contents has been cleaned up. HTML truncation of the two electron Clebsch Gordon figure has been fixed. Actually, it has NOT been fixed. :() A new attempt has been implemented. Expanded the description of fundamental forces in the section on particle exchange. Draft rewrite of the first two sections of nuclei. Made the section on nuclear forces a more limited addendum. Also eliminated a bad mistake in it.
- Apr. 25, 2011. Version 5.26 alpha. Some further minor rewrites of the section on index notation. Spell check and minor rewrites of the relativity chapter in general.
- Apr. 18, 2011. Version 5.25 alpha. Rewrote section on index notation, added an addendum about it.
- Mar. 14, 2011. Version 5.24 alpha. Bisected addenda on quantum field theory and perturbation theory. Started just a bit cleaning up the chapter on nuclei. One tiny step at a time.
- Mar. 14, 2011. Version 5.23 alpha. Brought structure into the 124 notes. Relocated the chapter "Additional Topics" in the addenda notes. Made relativity a separate Part. Minor rewrites in the intro to nuclei.
- Mar. 8, 2011. Version 5.22 alpha. Noted and fixed a blunder on cosmic redshift. Sometimes I do not seem to think at all. Everyone else seems to make the same blunder??
- Mar. 7, 2011. Version 5.21 alpha. All remaining low-resolution bitmap graphics are gone. Spherical Hankel and Bessel functions have been taken out of the note on 3D scattering and given their own note. The same for the integral Schrödinger equation. The remaining note on 3D scattering has been given a much needed clean up. Some rewrites in the note on symmetries.
- Feb. 7, 2011. Version 5.20 alpha. Some changes in the section and note on conservation laws and symmetries. A large fraction of the remaining low-resolution bitmap graphics has been replaced by higher quality vector graphics. The note on special relativity has been turned into a chapter.
- Jan. 16, 2011. Version 5.19 alpha. Very minor changes in the section on conservation laws and symmetries.
- Jan. 3, 2011. Version 5.18 alpha. Revised section on conservation laws and symmetries. Slight cosmetic improvements in some figures.
- Nov. 30, 2010. Version 5.17 alpha. Moved hydrogen and helium to the end of the periodic table; I simply got tired of saying "except hydrogen" and "except helium." Rewrote the subsection on ionic conduction.
- Nov. 16, 2010. Version 5.16 alpha. Second and for now final version of the subsection on typical metals and insulators.
- Nov. 12, 2010. Version 5.15 alpha. First rewrite of the subsection on typical metals and insulators.
- Nov. 1, 2010. Version 5.14 alpha. Various minor rewrites in the chapter on macroscopic systems.
- Oct. 11, 2010. Version 5.13 alpha. Technical modifications to allow links in the pdf. Many people seem to use the pdf for reading instead of the web pages.
- Oct. 4, 2010. Version 5.12 alpha. Various minor rewrites, including for subsection 6.22 .5 . A number of poor phrasings pointed out by Ramaswami Sastry Vedam corrected.
- Sep. 13, 2010. Version 5.11 alpha. Main change is the addition of subsection 6.22.5 giving an introduction to the band theory of three-dimensional crystals.
- Aug. 30, 2010. Version 5.10 alpha. Added spectra of actual materials to the section on crystal momentum. Fixed an erroneous statement about the presentation of spectra. Fixed an error where spins were listed, but not included in the transformation in the section on conservation laws and symmetries.
- Aug. 23, 2010. Version 5.09 alpha. Rewrites of p-n junction and transistor.
- Aug. 9, 2010. Version 5.08 alpha. Third law moved to notes. Edits in the chapter on macroscopic systems. Draft proof of the Onsager relations added and immediately removed. Gee. It will not be back.
- July 28, 2010. Version 5.07 alpha. Better description of the third law. Some rewrites and error corrections in thermoelectrics.
- July 23, 2010. Version 5.06 alpha. Some rewrites and error corrections in thermoelectrics.
- July 19, 2010. Version 5.05 alpha. Some error corrections in thermoelectrics and a discussion of the Onsager relations added.
- July 16, 2010. Version 5.04 alpha. Some rewrites and error corrections.
- July 13, 2010. Version 5.03 alpha. Various rewrites and error corrections. Also a new periodic table.
- June 6, 2010. Version 5 alpha. Lots of spelling and grammar corrections, minor rewrites, and additions of summaries during teaching a 3 hour DIS on "quantum literacy." Added a chapter on nuclei. Added sections and tables on angular momentum of shells. Alpha decay has been moved to the new chapter on nuclei. Forbidden decays are now included. Various program improvements/tuning. Corrected "effective" mass (for a two-body system) into "reduced." Added a chapter on macroscopic systems to Part II. Much of this chapter has been scavenged from Part III. It is supposed to provide some more practical knowledge in various areas. It was inspired by the DIS mentioned above, which showed you cannot do much of Part III in a single semester. The semiconductor discussion in the chapter is all new.
- March 22, 2009. Version 4.2 alpha. Spin matrices for systems greater than spin one half are now discussed. Classical Lagrangian and Hamiltonian dynamics is now covered in a note. Special relativity is now covered in a note. There is now a derivation of the hydrogen dipole selection rules and more extensive discussion of forbidden transitions. Angular momentum and parity conservation in transitions are now discussed. The Gamow theory data are now corrected for nuclear versus atomic mass. There is no perceivable difference, however. The alignment bars next to the electromagnetic tables in the web version should have been eliminated.
- Jan. 1, 2009. Version 4.0 alpha reorders the book into two parts to achieve a much better book structure. The changed thinking justifies a new version. Parts of the lengthy preface have been moved to the notes. The background sections have been combined in their own chapter to reduce distraction in part II. There is now a derivation of
effective mass in a note. A few more commutators were added to the reference. There is a note on Fourier transforms and the Parseval equality. The stupid discussion of group velocity has been replaced by a better (even more stupid?) one. Two of the gif animations were erroneous (the nondelta function tunneling and the rapid drop potential) and have been corrected. High resolution versions of the animations have been added. Time-dependent perturbation theory is now concisely covered. WKB theory is now covered. Alpha decay is now included. The adiabatic theorem is now covered. Three-dimensional scattering is now covered, in a note. Fixed a mistyped shelf number energy in the thermo chapter. The derivations of the Dirac equation and the gyromagnetic ratio of electron spin have been moved to the notes. Note D. 71 now gives the full derivation of the expectation Lorentz force. The direction of the magnetic field in the figure for Maxwell's fourth law was corrected. A section on electrostatic solutions has been added. The description on electrons in magnetic fields now includes the diamagnetic contribution. The section on Stern-Gerlach was moved to the electromagnetic section where it belongs. Electron split experiments have been removed completely. There is now a full coverage of time-independent small perturbation theory, including the hydrogen fine structure. Natural frequency is now angular frequency. Gee. The Planck formula is now the Planck-Einstein relation. The Euler identity is now the apparently more common Euler formula. Black body as noun, blackbody as compound adjective.
- Jan. 19, 2009. Version 4.1 alpha. There is now a discussion of the Heisenberg picture. The horribly written, rambling, incoherent, section on nearly-free electrons that has been bothering me for years has been rewritten into two much better sections. There is now a discussion on the quantization of the electromagnetic field, including photon spin and spontaneous emission. The Rayleigh formula is now derived. The perturbation expansion of eigenfunctions now refers to Rellich's book to show that it really works for degenerate eigenfunctions.
- July 14, 2008. Version 3 beta 4.2 expands the section on unsteady two-state systems to include a full discussion of "time-dependent perturbation theory," read emission and absorption of radiation. Earlier versions just had a highly condensed version since I greatly dislike the derivations in typical textbooks that are full of nontrivial assumptions for which no justification is, or can be, given at all.
- July 2, 2008. Version 3 beta 4.1 adds a new, "advanced," chapter on basic and quantum thermodynamics. An advanced section on the fundamental ideas underlying quantum field theory has also been
added. The discussion of the lambda transition of helium versus Bose-Einstein condensation has been rewritten to reflect the considerable uncertainty. Uniqueness has been added to the note on the hydrogen molecular ion ground state properties. Added a missing $2 \pi$ in the Rayleigh-Jeans formula.
- April 7, 2008. Version 3 beta 4 adds key points and exercises added to chapter 4 , with the usual rewrites to improve clarity. The Dirichlet completeness proof of the Fourier modes has been moved from the solution manual to the notes. The actual expressions for the hydrogen molecular ion integrals are now given in the note. The London force derivation has been moved to the notes. The subsection of ferromagnetism has been rewritten to more clearly reflect the uncertainty in the field, and a discussion of Hund's rules added.
- Dec. 20, 2007. Version 3 beta 3.4 cleans up the format of the "notes." No more need for loading an interminable web page of 64 notes all at the same time over your phone line to read 20 words. It also corrects a few errors, one important one pointed out by Johann Joss. It also also extends some further griping about correlation energy to all three web locations. You may surmise from the lack of progress that I have been installing Linux on my home PC. You are right.
- Sept. 9, 2007. Version 3 beta 3.3 mainly adds sections on solids, that have been combined with rewritten free and nearly-free electrons sections into a full chapter on solids. The rest of the old chapter on examples of multiple particle systems has been pushed back into the basic multiple particle systems chapter. A completely nonsensical discussion in a paragraph of the free-electron gas section was corrected; I cannot believe I have read over that several times. I probably was reading what I wanted to say instead of what I said. The alternative name "twilight terms" has been substituted for "exchange terms." Many minor changes.
- July 19, 2007. Version 3 beta 3.2 adds a section on Hartree-Fock. It took forever. My main regret is that most of them who wasted my time in this major way are probably no longer around to be properly blasted. Writing a book on quantum mechanics by an engineer for engineers is a minefield of having to see through countless poor definitions and dubious explanations. It takes forever. In view of the fact that many of those physicist were probably supported by tax payers much of the time, it should not be such an absolute mess!
There are some additions on Born-Oppenheimer and the variational formulation that were in the Hartree-Fock section, but that I took out, since they seemed to be too general to be shoved away inside an application. Also rewrote section 5.7 and subsection 5.9.2 to be consistent, and in particular in order to have a single consistent
notation. Zero point energy (the vacuum kind) is back. What the heck.
- May 21, 2007. An updated version 3 beta 3.1 to correct a poorly written subsection on quantum confinement for the particle in a pipe. Thanks to Swapnil Jain for pointing out the problem. I do not want people to get lost so early in the game, so I made it a priority correction. In general, I do think that the sections added later to the document are not of the same quality as the original with regard to writing style. The reason is simple. When I wrote the original, I was on a sabbatical and had plenty of time to think and rethink how it would be clearest. The later sections are written during the few spare hours I can dig up. I write them and put them in. I would need a year off to do this as it really should be done.
- May 5, 2007. There are now lists of key points and review questions for chapter 3. That makes it the 3 beta 3 version. Various other fixes, like spectral line broadening, Helium's refusal to take on electrons, and countless other less than ideal phrasings. And full solutions of the harmonic oscillator, spherical harmonics, and hydrogen wave function ODEs, Mandelshtam-Tamm energy-time uncertainty, (all in the notes.) A dice is now a die, though it sounds horrible to me. Zero point energy went out again as too speculative.
- April 2, 2007. There are now lists of key points and review questions for chapter 2. That makes it the 3 beta 2 version. So I guess the final beta version will be 3 beta 6 . Various other fixes. I also added, probably unwisely, a note about zero point energy.
- Mid Feb.,2007. There are now lists of key points and review questions for chapter 1. Answers are in the new solution manual.
- Mid Jan., 2007. Added sections on confinement and density of states, a commutator reference, a section on unsteady perturbed two state systems, and an advanced chapter on angular momentum, the Dirac equation, the electromagnetic field, and NMR. Fixed a dubious phrasing about the Dirac equation and other minor changes.
- Mid April, 2006. Various minor fixes. Also I changed the format from the "article" to the "book" style.
- Mid Feb., 2006. A new version was posted. Main differences are correction of a number of errors and improved descriptions of the free-electron and band spectra. There is also a rewrite of the many worlds interpretation to be clearer and less preachy.
- May 11 2005. I got cold feet on immediately jumping into separation of variables, so I added a section on a particle in a pipe.
- May 4, 2005. A revised version was posted. I finally read the paper by Everett, III on the many worlds interpretation, and realized that I had to take the crap out of pretty much all my discussions. I also
rewrote everything to try to make it easier to follow. I added the motion of wave packets to the discussion and expanded the one on Newtonian motion.
- Nov 27, 2004. A revised version was posted, fixing a major blunder related to a nasty problem in using classical spring potentials for more than a single particle. The fix required extensive changes. This version also added descriptions of how the wave function of larger systems is formed.
- Oct 24,2004 . The first version of this manuscript was posted

Part I is a draft.
Part II is mostly in a fairly good shape. But there are a few recent additions that probably could do with another look. Of course, fairly good is not the same as good. Chapter 7 is poor.

In Part III various parts sure could do with a few more rewrites. For example, the thermodynamics chapter is quite embarrassing. The chapter on nuclei is an incomplete absolute mess.

The shape of addenda and notes is pretty much like their root chapters
Somewhat notably missing at this time:

1. Electron split experiments. Do engineers need it?? Some mention is now in the basic ideas chapter.
2. Quantum electrodynamics. (The full relativistic theory.) Do engineers need it??
3. Density-functional theory.
4. Mössbauer effect.
5. Superfluidity (but there is not really a microscopic theory.)
6. Superconductivity.

## N. 3 Nature and real eigenvalues

The major difference between real and complex numbers is that real numbers can be ordered from smaller to larger. So you might speculate that the fact that the numbers of our world are real may favor a human tendency towards simplistic rankings where one item is "worse" or "better" than the other. What if your grade for a quantum mechanics test was $55+90$ i and someone else had a $70+65 i$ ? It would be logical in a world in which the important operators would not be Hermitian.

## N. 4 Are Hermitian operators really like that?

A mathematician might choose to phrase the problem of Hermitian operators having or not having eigenvalues and eigenfunctions in a suitable space of permissible functions and then find, with some justification, that some operators
in quantum mechanics, like the position or momentum operators do not have any permissible eigenfunctions. Let alone a complete set. The approach of this text is to simply follow the formalism anyway, and then fix the problems that arise as they arise.

More generally, what this book tells you about operators is absolutely true for systems with a finite number of variables, but gets mathematically suspect for infinite systems. The functional analysis required to do better is well beyond the scope of this book and the abstract mathematics a typical engineer would ever want to have a look at.

In any case, when problems are discretized to a finite one for numerical solution, the problem no longer exists. Or rather, it has been reduced to figuring out how the numerical solution approaches the exact solution in the limit that the problem size becomes infinite.

## N. 5 Why boundary conditions are tricky

You might well ask why you cannot have a wave function that has a change in wave function value at the ends of the pipe. In particular, you might ask what is wrong with a wave function that is a nonzero constant inside the pipe and zero outside it. Since the second derivative of a constant is zero, this (incorrectly) appears to satisfy the Hamiltonian eigenvalue problem with an energy eigenvalue equal to zero.

The problem is that this wave function has "jump discontinuities" at the ends of the pipe where the wave function jumps from the constant value to zero. (Graphically, the function is "broken" into separate pieces at the ends.) Suppose you approximate such a wave function with a smooth one whose value merely drops down steeply rather than jumps down to zero. The steep fall-off produces a first order derivative that is very large in the fall-off regions, and a second derivative that is much larger still. Therefore, including the fall-off regions, the average kinetic energy is not close to zero, as the constant part alone would suggest, but actually almost infinitely large. And in the limit of a real jump, such eigenfunctions produce infinite energy, so they are not physically acceptable.

The bottom line is that jump discontinuities in the wave function are not acceptable. However, the correct solutions will have jump discontinuities in the derivative of the wave function, where it jumps from a nonzero value to zero at the pipe walls. Such discontinuities in the derivative correspond to "kinks" in the wave function. These kinks are acceptable; they naturally form when the walls are made more and more impenetrable. Jumps are wrong, but kinks are fine. (Don't break the wave function, but crease it all you like.)

For more complicated cases, it may be less trivial to figure out what singularities are acceptable or not. In general, you want to check the "expectation
value," as defined later, of the energy of the almost singular case, using integration by parts to remove difficult-to-estimate higher derivatives, and then check that this energy remains bounded in the limit to the fully singular case. That is mathematics far beyond what this book wants to cover, but in general you want to make singularities as minor as possible.

## N. 6 Is the variational approximation best?

Clearly, "best" is a subjective term. If you are looking for the wave function within a definite set that has the most accurate expectation value of energy, then minimizing the expectation value of energy will do it. This function will also approximate the true eigenfunction shape the best, in some technical sense $\{A .7\}$. (There are many ways the best approximation of a function can be defined; you can demand that the maximum error is as small as possible, or that the average magnitude of the error is as small as possible, or that a root-mean-square error is, etcetera. In each case, the "best" answer will be different, though there may not be much of a practical difference.)

But given a set of approximate wave functions like those used in finite element methods, it may well be possible to get much better results using additional mathematical techniques like Richardson extrapolation. In effect you are then deducing what happens for wave functions that are beyond the approximate ones you are using.

## N. 7 Shielding approximation limitations

In the helium atom, if you drop the shielding approximation for the remaining electron in the ionized state, as common sense would suggest, the ionization energy would become negative! This illustrates the dangers of mixing models at random. This problem might also be why the discussion in [25] is based on the zero shielding approximation, rather than the full shielding approximation used here.

But zero shielding does make the base energy levels of the critical outer electrons of heavy atoms very large, proportional to the square of the atomic number. And that might then suggest the question: if the energy levels explode like that, why doesn't the ionization energy or the electronegativity? And it makes the explanation why helium would not want another electron more difficult. Full shielding puts you in the obviously more desirable starting position of the additional electron not being attracted, and the already present electrons being shielded from the nucleus by the new electron. And how about the size of the atoms imploding in zero shielding?

Overall, this book prefers the full shielding approach. Zero shielding would predict the helium ionization energy to be 54.4 eV , which really seems worse
than 13.6 eV when compared to the exact value of 24.6 eV . On the other hand, zero shielding does give a fair approximation of the actual total energy of the atom; 109 eV instead of an exact value of 79 . Full shielding produces a poor value of 27 eV for the total energy; the total energy is proportional to the square of the effective nucleus strength, so a lack of full shielding will increase the total energy very strongly. But also importantly, full shielding avoids the reader's distraction of having to rescale the wave functions to account for the nonunit nuclear strength.

If eventually X-ray spectra need to be covered in this book, a description of "hot" relativistic inner electrons would presumably fix any problem well.

## N. 8 Why the s states have the least energy

The probability of being found near the nucleus, i.e. the origin, is determined by the magnitude of the relevant hydrogen wave function $\left|\psi_{n l m}\right|^{2}$ near the origin. Now the power series expansion of $\psi_{n l m}$ in terms of the distance $r$ from the origin starts with power $r^{l}$, (D.8). For small enough $r$, a p, (i.e. $\psi_{n 1 m}$ ), state involving a factor $r$ will be much smaller than an $\mathrm{s},\left(\psi_{n 0 m}\right)$, state without such a factor. Similarly a d, $\left(\psi_{n 2 m}\right)$, state involving a factor $r^{2}$ will be much less still than a p state with just single factor $r$, etcetera. So states of higher angular momentum quantum number $l$ stay increasingly strongly out of the immediate vicinity of the nucleus. This reflects in increased energy since the nuclear attraction is much greater close the nucleus than elsewhere in the presence of shielding.

## N. 9 Explanation of the band gaps

Chapter 6.21 showed that the spectra of the electrons of solids have "band gaps;" energy ranges for which there are no quantum states for the electrons. These band gaps were qualitatively explained as the remnants of the discrete electron energy states of the individual atoms. These discrete energy states spread out when multiple atoms start interacting, but not necessarily enough to completely remove the gaps.

However, if you start from the free-electron gas point of view, it is much less clear why and when addition of just a bit of crystal potential would suddenly pop up band gaps out of nothing. If you are curious, this note is for you.

To understand what is going on, the Kronig \& Penney model will be used. The "crystal" is again taken to be one-dimensional. The potential consists again of a sequence of straight dips, as was shown in green in 6.22. The dips represent the attraction of the atoms on the individual atomic electrons. However, to allow an easier comparison with the free-electron gas solutions, this time the dips will taken far less deep than before. Think of it as a model for a metal, where the outer electrons are only very weakly bound to their atomic cores.

For these shallower "atomic" dips, and for a crystal consisting of very many "atoms," the energy levels are as shown to the left in figure N.1. Note that for the higher energies, this is generally speaking very similar to the energy levels for the free-electron spectrum shown to the left. That should be expected; why would the shallow potential energy dips have much of an effect when the kinetic energy of the electron considered is very large? But even for high energy levels, there are still occasional thin gaps. At these gaps, the electron velocity plunges to zero. Why are these gaps there?

weak crystal potential

free electrons

Figure N.1: Spectrum for a weak potential.
To qualitatively understand what is going on, from here on it will be assumed that the periodic "crystal" consists of just 12 "atoms," (rather than, say, a million). Mathematically, after twelve atoms, the quantum wave function becomes the same as it was initially and the solution repeats. You may think of the twelve atoms as physically being arranged in a ring shape.

To make things easier to understand, it is also desirable to switch from the complex "Bloch wave" wave functions to the equivalent real ones. These real wave functions may be found as the real and imaginary parts of the Bloch waves. That is easiest for the free-electron gas, where the Bloch waves are simply complex exponentials; the Euler identity says

$$
e^{\mathrm{i} k_{x} x}=\cos \left(k_{x} x\right)+\mathrm{i} \sin \left(k_{x} x\right)
$$

So for the free-electron gas, the real wave functions are $\cos \left(k_{x} x\right)$ and $\sin \left(k_{x} x\right)$, ignoring an unimportant normalization constant. As before, the wave number $k_{x}$ is a measure of the "crystal momentum" $p_{\mathrm{cm}, x}=\hbar k_{x}$, which is turn related to the electron velocity $v_{x}^{\mathrm{p}}$ through the energy.

band gap occurs here

Figure N.2: The 17 real wave functions of lowest energy for a small one-dimensional periodic box with only 12 atomic cells. Black curves show the square wave function, which gives the relative probability of finding the electron at that location.

For the Kronig-Penney model, the real wave functions are more complex than simple sines and cosines, but can be found the same way.

Note that normally there are two different wave functions for each value of the wave number $k_{x}$. The one exception is for the ground state of lowest energy where $k_{x}$ is zero. In terms of the free electron gas, $\sin (0 x)=0$. Zero is not a valid wave function. Remember that the square magnitude of a wave function gives the probability of finding the electron. So if a wave function would be zero, there would not be any chance of finding the electron anywhere. So there would be no electron.

For the free-electron gas, that leaves as only ground state wave function $\cos (0 x)=1$ times some constant. That is just a constant. And since the square of a constant is still a constant, that means that the probability of finding the electron is the same everywhere in the period.

For the Kronig-Penney case, the situation is a less simple. Consider first the ground state, shown in the picture at the bottom of figure N.2. (In figure N. 2 the height of a wave function picture illustrates the relative amount of energy of that wave function. So the ground state picture is at the bottom.) The square magnitude of the ground state wave function, shown as the black line, is no longer a constant. It is higher than average at the dips in the potential, at the "atoms." It is lower than average in between "atoms." So the electron is somewhat more likely to be found near an atom that attracts it than in between atoms. The electron reduces its potential energy that way. But it cannot do this without limit; if the electron is only found at the atoms, the reduced uncertainty in position increases the kinetic energy more than the potential energy is lowered. The best compromise is given by the black line at the bottom of figure N.2.

To understand the energy states above the ground state, a key concept of the general mathematical properties of real one-dimensional wave functions is needed: The more zero crossings in the wave function, the higher the energy. Qualitatively, the reason is not that hard to understand. The more zero crossings, the more wildly the wave function swings back and forward between positive and negative values, raising the kinetic energy. In figure N. 2 the number of zero crossings is listed as $z$. Note that by squaring the wave functions, the zero crossings become touching zero, not crossing it.

Note further that only even numbers of zero crossings $z$ appear. A periodic wave function must return to the same sign at the end of the period as at the start, and that is only possible if the number of zero crossings is even.

Note next that in almost all cases, there are two different wave functions of the same energy at a given number of zero crossings. That is because if you have one wave function at a given $z$, you can simply shift it over by one atomic cell, and you have another wave function of the same energy. This second wave function is almost always a different one. In particular, it can only be the same wave function if the $z$ zeros are still in the same place. But if you have 12 atomic
cells and, say, $z=8$ zeros, then some of the 12 atomic cells must have zeros and other ones not. So the shifted wave function cannot possibly have all its zeros in the same place. So the shifted wave function is a second, different, wave function of the same energy. So there are two different wave functions with the same $z$ and energy.

The only way this can possibly fail, and does, is if each atomic cell has the same number of zeros as its next neighbor. So every atomic cell must have the same number of zeros in it.

That, then, is why it is possible at all that there is only one wave function in the ground state. In the ground state there are no zeros, so every atomic cell has the same number, none. Indeed, looking closer, in the ground state the wave function is identical in every atomic cell. Mathematically, for $k_{x}=0$, the exponential part of the Bloch wave is just a trivial constant, making the complete Bloch wave the same for all atomic cells. So shifting the wave function over one atomic cell gives you back the exact same thing.

The next possibility that the shifted wave function does not give a different one occurs when every atomic cell has one zero crossing. For a "crystal" of 12 atomic cells, that requires that there are $z=12$ zero crossings. This happens when the wavenumber $k_{x}=\pi / d_{x}$ where $d_{x}$ is the atomic cell size. Then the exponential part of the Bloch wave function in any atomic cell is identical to that in the next atomic cell except for a mere minus sign. So the shifted wave function is only different by a minus sign. This means it is physically equivalent to the original one. Not a separate wave function.

But even if shifting the wave function does not give you a second one, still there must be two different eigenfunctions for each even number of zeros $z$ greater than zero. In particular, the wave functions in figure N. 2 were obtained in two ways. For the wave functions in the left-hand column, it was assumed that the derivative of the wave function is zero at the start of the period (like it is for the $\cos \left(k_{x} x\right)$ free-electron gas solutions). For the wave functions in the right-hand column, it was assumed that the wave function itself is zero at the start of the period (like it is for the $\sin \left(k_{x} x\right)$ free-electron gas solutions). These are two different solutions; they cannot be equivalent because the right-hand wave function has a zero at the start of the period, but the left-hand one does not.

For one, this explains why for the ground state where $z=0$, there is no right-hand wave function. If you start out with a zero crossing, you must have at least one of them. It also explains why a wave function in the right column is not just the wave function in the left column shifted by an atomic cell. The two wave functions were separately computed. In almost all cases, the right-hand wave function is then a combination of the shifted and unshifted left-hand wave functions, the combination that is zero at the start of the period. In about half the cases, that turns out to be the left wave function shifted by a quarter period, in the other half of the cases it is just all different. The energy of the
two solutions is still the same.
But for the special case of $z=12$ zeros for the 12 atomic cells, figure N. 2 shows that the left and right wave functions are physically fundamentally different. In the left-hand wave function, the electron is most likely to be found in the region of high potential energy between atoms. All the peaks in wave function are there. In the right-hand wave function, the electron is most likely to be found in the region of low potential energy at the atoms. The peaks are there. That means that the left hand wave function has a lot more potential energy than the right-hand one. So the two wave functions do not have the same energy in this case. We have a band gap when the number of zeros is exactly the same as the number of atoms.

Similarly there will be a band gap at $z=24$, where there are two zero crossings in each atomic cell, etcetera. The band gaps occur at whole multiples of the number of atomic cells. And there are 12 energy states in each band. For a physically realistic number of atomic cells, call it a million instead of 12 , there are a million energy states between band gaps, effectively forming a continuum band between the gaps.

One thing that may still be counter-intuitive is why the right-hand $z=$ 12 wave function has higher, rather than much lower energy than the $z=10$ ones. In particular, the peaks in the right-hand wave function at $z=12$ are all perfectly aligned with the atomic locations. That greatly reduces the potential energy. But in the $z=10$ case the peaks are not aligned with the atoms. While the $z=10$ case has some advantage in kinetic energy with less zero crossings, that advantage is small. That would not be able to explain it if the right-hand $z=12$ would really have a big advantage in potential energy over the $z=10$ states.

To see why it is possible, look more closely at the $z=10$ case in figure N. 2 . It is true that a significant fraction of the peaks in wave function are in between atoms instead of on top of atoms. However, the physics modulates the height of the peaks so that the big peaks are the ones on top of the atoms, and the small peaks the ones in between atoms. That still has the effect that the electron is most likely found at an atom, still greatly reducing the potential energy. That eliminates the apparent advantage of the right-hand $z=12$ state in potential energy.

Also note that for $z=10$, the number of zeros is still close to the number of atoms. So the distance between peaks is still almost the same as the distance between atoms, (especially for a million atoms instead of 12). So if, say, a peak is pretty much on top of an atom, the neighboring peaks are too. Therefore the modulation of peak amplitudes can be done in a way that slowly varies along the length of the crystal. So it does not add a big amount to the kinetic energy.

However, because of the modulation, the $z=10$ wave functions do give up almost all their small kinetic energy advantage compared to the right-hand $z=$ 12 case. That means that the two energies become very close together. Since
the change in energy is a measure of the electron propagation velocity $v_{x}^{\mathrm{p}}$, that velocity plunges to zero. Which is exactly what you see in figure N.1.

Similarly for the $z=14$ wave functions, the peaks are modulated so that the electron is most likely to be found in between atoms, just like for the lefthand $z=12$ wave function. So the $z=14$ wave functions have about the same potential energy as the left-hand $z=12$ one. And because the $z=12$ wave function is so effective in raising its potential energy, you would expect that the energy difference with the $z=14$ case would be relatively small, producing small electron velocity. And that is indeed what happens.

So the only finite energy gaps occur when the number of zeros is a whole multiple of the number of atoms. And the gap is between the two states with that number of zeros.

And between the states immediately above and below the gaps, the energy difference is even smaller than elsewhere in the band. That makes the electron velocity $v_{x}^{\mathrm{p}}$ zero at the edges of the bands

Since the wave functions at the edges of the bands have zero propagation velocity, electrons in these states cannot move through the crystal. Now an implicit result of the analysis above is that for these states, a whole multiple of the Bloch wave length must equal double the atomic spacing. The Bloch exponential can change sign going from one atomic cell to the next, then return to the original sign at the next cell, but nothing more. If you train a beam of electrons with a wave length like that onto the crystal, the beam cannot propagate and will be totally reflected. That is in fact a key result of the Bragg reflection theory of wave mechanics, (10.16) in chapter 10.7.2. Thus Bragg theory can provide an intuitive justification for some of the features of the band structure.

If you want to see mathematically that the propagation velocity is indeed zero at the band gaps, and you know linear algebra, you can find the derivation in $\{\mathrm{D} .84\}$. That also explains how the wave function figures in figure N. 2 were made.

## N. 10 A less fishy story

This note gives a simple model for the emission of a particle like a photon. It is assumed that the emitted particle has a typical quantum wave length $\lambda$ that is large compared to the typical size $R$ of the atom or nucleus that does the emitting. The purpose of the model is to show that in that case, the particle will very likely come out with zero orbital angular momentum but has some probability of nonzero angular momentum.

First, photon wave functions are messy and not that easy to make sense of, \{A.21.7\}. The photon would be much simpler if it did not have spin and was nonrelativistic. A reasonable wave function for a hypothetical spinless nonrela-
tivistic photon coming out of the center of the emitter with typical wave length $\lambda$ would be

$$
\psi=\frac{1}{\lambda^{3 / 2}} f\left(\frac{r^{2}}{\lambda^{2}}\right)
$$

where $r$ is the distance from the center. (The various factors $\lambda$ have been added to make the function $f$ independent of the photon wave length $\lambda$ despite the corresponding spatial scale and the normalization requirement.)

The above wave function has no preferred direction in the emission, making it spherically symmetric. It depends only on the distance $r$ from the center of the emitter. That means that the wave function has zero orbital angular momentum. Recall that zero angular momentum corresponds to the spherical harmonic $Y_{0}^{0}$, which is independent of the angular position, chapter 4.2.

There are various reasons to give why you would want the wave function of a particle coming out of the origin to have zero angular momentum. For one, since it comes out of a featureless point, there should not be a preferred direction. Or in terms of classical physics, if it had angular momentum then it would have to have infinite velocity at the origin. The similar quantum idea is that the relevant wave functions for a particle moving away from the origin, the Hankel functions of the first kind, blow up very strongly at the origin if they have angular momentum, $\{$ A. 6$\}$. But it is really better to describe the emitted particle in terms of the Bessel functions of the first kind. These have zero probability of the particle being at the origin if the angular momentum is not zero. And a particle should not be created at a point where it has zero probability of being.

Of course, a spherically symmetric quantum wave function also means that the particle is moving away from the emitter equally in all directions. Following the stated ideas of quantum mechanics, this will be true until the position of the particle is "measured." Any macroscopic surroundings cannot reasonably remain uncommitted to exactly where the outgoing particle is for very long.

Now consider the same sort of emission, but from a point in the emitter a bit away from the center. For simplicity, assume the emission point to be at $R \hat{k}$, where $R$ is the typical size of the emitter and $\hat{k}$ is the unit vector along the chosen $z$-axis. In that case the wave function is

$$
\psi=\frac{1}{\lambda^{3 / 2}} f\left(\frac{(\vec{r}-R \hat{k})^{2}}{\lambda^{2}}\right)
$$

Using Taylor series expansion, that becomes

$$
\psi=\frac{1}{\lambda^{3 / 2}} f\left(\frac{r^{2}}{\lambda^{2}}\right)-\frac{R}{\lambda} \frac{1}{\lambda^{3 / 2}} f^{\prime}\left(\frac{r^{2}}{\lambda^{2}}\right) 2 \frac{r}{\lambda} \frac{z}{r}+\ldots
$$

In the second term, $z / r$ is the spherical harmonic $Y_{1}^{0}$, table 4.3. This term has angular momentum quantum number $l=1$. So there is now uncertainty in momentum. And following the stated ideas of quantum mechanics, the probability
for $l=1$ is given by the square magnitude of the coefficient of the (normalized) eigenfunction.

That makes the probability for $l=1$ proportional to $(R / \lambda)^{2}$. If you carried out the Taylor series to the next order, you would end up with a $(z / r)^{2}$ term, which, combined with a spherically symmetric contribution, makes up the spherical harmonic $Y_{2}^{0}$. It then follows that the probability for $l=2$ is of order $(R / \lambda)^{4}$. And so on. Under the assumed condition that the emitter size $R$ is much less than the quantum wave length $\lambda$ of the emitted particle, the probabilities for nonzero angular momentum are small and decrease rapidly even further with increasing $l$.

## N. 11 Better description of two-state systems

An approximate definition of the states $\psi_{1}$ and $\psi_{2}$ would make the states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ only approximate energy eigenstates. But they can be made exact energy eigenfunctions by defining $\left(\psi_{1}+\psi_{2}\right) / \sqrt{2}$ and $\left(\psi_{1}-\psi_{2}\right) / \sqrt{2}$ to be the exact symmetric ground state and the exact antisymmetric state of second lowest energy. The precise "basic" wave function $\psi_{1}$ and $\psi_{2}$ can then be reconstructed from that.

Note that $\psi_{1}$ and $\psi_{2}$ themselves are not energy eigenstates, though they might be so by approximation. The errors in this approximation, even if small, will produce the wrong result for the time evolution. (The small differences in energy drive the nontrivial part of the unsteady evolution.)

## N. 12 Second quantization in other books

The approach to second quantization followed in this book is quite different from what you will find in other basic quantum mechanics or advanced physics books. This book simply sticks to its guns. Right at the beginning, this book said that observable properties are the eigenvalues of Hermitian operators. And that these act on particle wave functions. These same rules are then used to quantize the electromagnetic field.

What other books do is write down various classical wave solutions to Maxwell's equations. Then these books reach deep inside these messy equations, cross out certain coefficients, and scribble in new ones. The new ones have operators in them and undetermined coefficients. The undetermined coefficients are then determined by examining the energy of the wave and comparing it with a harmonic oscillator, as analyzed using quantum field theory.

This book, however, greatly dislikes writing down classical solutions. A general student may not be familiar with these solutions. Or have long forgotten them. And it seems quite doubtful that even physics students are really
familiar with the messy electric and magnetic multipole fields of classical electromagnetics. The approach in this book is to skip classical physics and give a self-contained and reasonable quantum derivation wherever possible. (Which means almost always.)

This book detests reaching into the middle of equations known to be wrong, and then crossing out things and writting in new things, all the while waving your hands a lot. The method of science is to make certain fundamental assumptions and then take them to their logical conclusion, whatever it may be. Not messing around until you get something that seems the right answer. And a book on science should showcase the methods of science.

Then there is the problem that the classical waves are inherently timedependent. The Schrödinger approach, however, is to put the time dependence in the wave function. For good reasons. That means that starting from the classical waves, you have two options, both ugly. You can suddenly switch to the Heisenberg representation, which is what everybody does. Or you can try to unextract the time dependence and put it on an explicit wave function.

And things get even uglier because the entire approach depends essentially on a deep familiarity with a different problem; the quantum-field description of the harmonic oscillator.

In fact, it may be noted that in early versions, this book did really try to give an understandable description of second quantization using the usual approach. The result was an impenetrable mess.

## N. 13 Combining angular momentum factors

Angular momenta from different sources can be combined using the ClebschGordan coefficients of chapter 12.7. For example, you can combine orbital and spin angular momenta of a particle that way, or the angular momenta of different particles.

But sometimes you need to multiply angular momentum states of the same source together. For example, you may need to figure out a product of spherical harmonics, chapter 4.2.3, like

$$
Y_{l_{1}}^{m_{1}} Y_{l_{2}}^{m_{2}}
$$

where the position coordinates refer to the same particle. If you multiply a few examples from table 4.3 together, you quickly see that the combinations are not given by the Clebsch-Gordan coefficients of figure 12.6.

One way to understand the angular momentum properties of the above product qualitatively is to consider the case that the second spherical harmonic takes the coordinates of an imagined second particle. Then you can use the normal procedures to figure out the properties of the two-particle system. And you can get the corresponding properties of the original one-particle system by re-
stricting the two-particle wave function coordinates to the subset in which the particle coordinates are equal.

Note in doing so that angular momentum properties are directly related to the effect of coordinate system rotations, $\{$ A.19\}. Coordinate system rotations maintain equality of particle coordinates; they stay within the subset. But inner products for the two-particle system will obviously be different from those for the reduced one-particle system.

And Clebsch-Gordan coefficients are in fact inner products. They are the inner product between the corresponding horizontal and vertical states in figures 12.5 and 12.6. The correct coefficients for the product above are still related to the Clebsch-Gordan ones, though you may find them in terms of the equivalent Wigner " $3 j$ " coefficients.

Wigner noticed a number of problems with the Clebsch-Gordan coefficients:

1. Clebsch and Gordan, and not Wigner, get credit for them.
2. They are far too easy to type.
3. They have an intuitive interpretation.

So Wigner changed the sign on one of the variables, took out a common factor, and reformatted the entire thing as a matrix. In short

$$
\left(\begin{array}{ccc}
j_{1} & j_{2} & j_{3}  \tag{N.1}\\
m_{1} & m_{2} & m_{3}
\end{array}\right) \equiv \frac{(-1)^{j_{1}-j_{2}-m_{3}}}{\sqrt{2 j_{3}+1}}\left\langle j_{3}-m_{3}\right|\left|j_{1} m_{1}\right\rangle\left|j_{2} m_{2}\right\rangle
$$

Behold, the spanking new "Wigner 3j symbol." Thus Wigner succeeded by his hard work in making physics a bit more impenetrable still than before. A big step for physics, a small step back for mankind.

The most important thing to note about this symbol/coefficient is that it is zero unless

$$
m_{1}+m_{2}+m_{3}=0 \quad \text { and } \quad\left|j_{1}-j_{2}\right| \leqslant j_{3} \leqslant j_{1}+j_{2}
$$

The right-hand conditions are the so-called triangle inequalities. The ordering of the $j$-values does not make a difference in these inequalities. You can swap the indices 1,2 , and 3 arbitrarily around.

If all three $m$ values are zero, then the symbol is zero if the sum of the $j$ values is odd. If the sum of the $j$ values is even, the symbol is not zero unless the triangle inequalities are violated.

If you need an occasional value for such a symbol that you cannot find in figure 12.5 and 12.6 or more extensive tables elsewhere, there are convenient calculators on the web, $\llbracket 16 \rrbracket$. There is also software available to evaluate them. Note further that $\{\mathrm{D} .65\}$ gives an explicit expression.

In literature, you may also encounter the so-called Wigner " 6 j " and " 9 j " symbols. They are typically written as

$$
\left\{\begin{array}{lll}
j_{1} & j_{2} & j_{3} \\
l_{1} & l_{2} & l_{3}
\end{array}\right\} \quad\left\{\begin{array}{lll}
j_{11} & j_{12} & j_{13} \\
j_{21} & j_{22} & j_{23} \\
j_{31} & j_{32} & j_{33}
\end{array}\right\}
$$

They appear in the combination of angular momenta. If you encounter one, there are again calculators on the web. The most useful thing to remember about 6 j symbols is that they are zero unless each of the four triads $j_{1} j_{2} j_{3}$, $j_{1} l_{2} l_{3}, l_{1} j_{2} l_{3}$, and $l_{1} l_{2} j_{3}$ satisfies the triangle inequalities.

The 9 j symbol changes by at most a sign under swapping of rows, or of columns, or transposing. It can be expressed in terms of a sum of 6 j symbols. There are also 12 j symbols, if you cannot get enough of them.

These symbols are needed to do advanced computations but these are far outside the scope of this book. And they are very abstract, definitely not something that the typical engineer would want to get involved in in the first place. All that can be done here is to mention a few key concepts. These might be enough keep you reading when you encounter them in literature. Or at least give a hint where to look for further information if necessary.

The basic idea is that it is often necessary to know how things change under rotation of the axis system. Many derivations in classical physics are much simpler if you choose your axes cleverly. However, in quantum mechanics you face problems such as the fact that angular momentum vectors are not normal vectors, but are quantized. Then the appropriate way of handling rotations is through the so-called Wigner-Eckart theorem. The above symbols then pop up in various places.

For example, they allows you to do such things as figuring out the derivatives of the harmonic polynomials $\mathcal{Y}_{l}^{m}$ of table 4.3, and to define the vector spherical harmonics $\vec{Y}_{J I M}$ that generalize the ordinary spherical harmonics to vectors. A more advanced treatment of vector bosons, $\{$ A. 20$\}$, or photon wave functions of definite angular momentum, \{A.21.7\}, would use these. And so would a more solid derivation of the Weisskopf and Moszkowski correction factors in $\{A .25 .8\}$. You may also encounter symbols such as $\mathcal{D}_{m^{\prime} m}^{(j)}$ for matrix elements of finite rotations.

All that will be done here is give the derivatives of the harmonic polynomials $r^{l} Y_{l}^{m}$, since that formula is not readily available. Define the following complex coordinates $x_{\mu}$ for $\mu=-1,0,1$ :

$$
\mu=-1: \quad x_{-1}=\frac{x-\mathrm{i} y}{\sqrt{2}} \quad \mu=0: \quad x_{0}=z \quad \mu=1: \quad x_{1}=-\frac{x+\mathrm{i} y}{\sqrt{2}}
$$

Then

$$
\begin{aligned}
\frac{\partial r^{l} Y_{l}^{m}}{\partial x_{\mu}} & =(-1)^{\mu+1} \sqrt{\frac{l(2 l+1)^{2}}{(2 l-1)}}\langle l-1 m-\mu||l m\rangle|1-\mu\rangle r^{l-1} Y_{l-1}^{m-\mu} \\
& =C_{\mu l m} r^{l-1} Y_{l-1}^{m-\mu}
\end{aligned}
$$

where the inner product of kets is a Clebsch-Gordan coefficient and

$$
C_{-1 l m}=\sqrt{\frac{(2 l+1)(l-m)(l-m-1)}{2(2 l-1)}}
$$

$$
\begin{aligned}
& C_{0 l m}=\sqrt{\frac{(2 l+1) 2(l+m)(l-m)}{2(2 l-1)}} \\
& C_{1 l m}=\sqrt{\frac{(2 l+1)(l+m)(l+m-1)}{2(2 l-1)}}
\end{aligned}
$$

or zero if the final magnetic quantum number is out of bounds.
If just having a rough idea of what the various symbols are is not enough, you will have to read up on them in a book like [13]. There are a number of such books, but this particular book has the redeeming feature that it lists some practical results in a usable form. Some highlights: general expression for the Clebsch-Gordan coefficients on p. 45; wrong definition of the 3 j coefficient on p. 46, (one of the rare mistakes; correct is above), symmetry properties of the 3 j symbol on $\mathrm{p} .47 ; 3 \mathrm{j}$ symbols with all $m$ values zero on p .50 ; list of alternate notations for the Clebsch-Gordan and 3 j coefficients on p.52, (yes, of course it is a long list); integral of the product of three spherical harmonics, like in the electric multipole matrix element, on p. 63; the correct expression for the product of two spherical harmonics with the same coordinates, as discussed above, on p. 63; effect of nuclear orientation on electric quadrupole moment on p. 78; wrong derivatives of spherical harmonics times radial functions on p. 69, 80, (another 5 rare mistakes in the second part of the expression alone, see above for the correct expression for the special case of harmonic polynomials); plane wave in spherical coordinates on p. 81. If you do try to read this book, note that $\gamma$ stands for "other quantum numbers," as well as the Euler angle. That is used well before it is defined on p. 33. If you are not psychic, it can be distracting.

## N. 14 The electric multipole problem

There is a big problem with electric multipole transitions in nuclei. Electric multipole transitions arise from a matrix element of the form

$$
H_{21}=\sum_{i}\left\langle\psi_{\mathrm{L}}\right| \vec{A}_{i}^{\mathrm{E} \ell *} \cdot \widehat{\vec{p}}_{i}\left|\psi_{\mathrm{H}}\right\rangle
$$

Here $\psi_{\mathrm{L}}$ is the final atomic or nuclear state and $\psi_{\mathrm{H}}$ the initial one. The sum is over the atomic or nuclear particles, with $i$ the particle index. Also

$$
\widehat{\vec{p}}_{i}=\frac{\hbar}{\mathrm{i}} \nabla_{i} \quad \vec{A}_{i}^{\mathrm{E} \ell}=\nabla_{i} \times \vec{r}_{i} \times \nabla_{i} j_{\ell}\left(k r_{i}\right) Y_{\ell}^{m}\left(\theta_{i}, \phi_{i}\right)
$$

where $j_{\ell}$ is a spherical Bessel function and $Y_{\ell}^{m}$ a spherical harmonic.
Under the approximation that the atomic or nuclear size is small compared to the wave length of the emitted or absorbed photon, this may be approximated.

In that approximation. the single-particle electric matrix element is commonly described as proportional to

$$
\left\langle\psi_{\mathrm{L}}\right| r_{i}^{\ell} Y_{\ell, i}^{m}\left|\psi_{\mathrm{H}}\right\rangle \quad Y_{\ell, i}^{m} \equiv Y_{\ell}^{m}\left(\theta_{i}, \phi_{i}\right)
$$

where $r_{i}^{\ell} Y_{\ell, i}^{m}$ is a harmonic polynomial. However, the correct inner product is

$$
\left\langle\psi_{\mathrm{L}}\right| r_{i}^{\ell} Y_{\ell, i}^{m}+\left[V / \hbar \omega, r_{i}^{\ell} Y_{\ell . i}^{m}\right]\left|\psi_{\mathrm{H}}\right\rangle
$$

Here $\hbar \omega$ is the energy of the photon. The additional commutator term is not mentioned in any other basic textbook on nuclei that this author knows of. A derivation is in $\{\mathrm{D} .43\}$.

If the potential depends only on position, the commutator is zero, and there is no problem. That is a valid approximation for the outer electrons in atoms. But nuclear potentials include significant momentum terms. These do not commute. One example is the spin-orbit term in the shell model. Now consider the size of the commutator term above compared to the first term. For a ballpark, note that it does not make much difference whether the orbital angular momentum in the spin-orbit term acts on the wave function $\psi_{\mathrm{H}}$ or on the harmonic polynomial. So the relative size of the commutator term ballparks to the ratio of the spin-orbit energy to the photon energy. That ratio can be big. For example, in the so-called "islands of isomerism" transitions, one state has enough spin-orbit energy to cross a major shell boundary. But the energy release $\hbar \omega$ stays within the same shell and could be quite small.

As a check on this ballpark, consider the simplest possible electric multipole transition:
$\psi_{\mathrm{L}}=R_{\mathrm{L}}\left(r_{i}\right) Y_{0, i}^{0} \uparrow \quad \psi_{\mathrm{H}}=R_{\mathrm{H}}\left(r_{i}\right) Y_{\ell, i}^{\ell} \uparrow \quad m=\ell \quad V=V_{0}-V_{\mathrm{so}} f\left(r_{i}\right) \frac{1}{\hbar^{2}} \widehat{\vec{L}}_{i} \cdot \widehat{\vec{S}}_{i}$
Here the part $V_{0}$ of the potential $V$ represents terms that only depend on position, or do not involve the position coordinates of particle $i$. This part commutes with the harmonic polynomial. Also $f$ is a function of radial position of order 1. Then the constant $V_{\text {so }}$ gives the magnitude of the spin orbit energy. In the above case, only the $z$ components of the angular momentum operators give a contribution. Then it is easily seen that the commutator term produces a contribution that is larger in magnitude than the other term by a factor of order $V_{\mathrm{so}} \ell / \hbar \omega$.

Note also that the effect is especially counter-intuitive for electric dipole transitions. It would seem logical to think that such transitions could be approximately described by a straightforward interaction of the particles with the electric field. However, the commutator need not be zero. So the electric field could be dwarfed by a larger additional field. That field is then a consequence of the fact that quantum mechanics uses the vector potential rather than the classical electric field.

Which brings up the next problem. The commutator term will not be there if you use the gauge property of the electromagnetic field to approximate the leading order electric field through an electrostatic potential. So should the commutator be there or not to get the best solution? As far as this author can see, there is no way to tell. And certainly for higher multipole orders you cannot even ignore the problem by using the electrostatic potential.
(Note that the real problem is the fact that you get different answers depending on how you select the gauge. If the nuclear Hamiltonian (A.169) respected the quantum gauge property of $\{$ A.19.5\}, the commutator would be zero. That can be seen by substituting in the gauge property: it shows that for any particle the potential must commute with $e^{-\mathrm{i} q_{i} \chi_{i} / \hbar}$, and the exponential is a completely arbitrary function of the particle coordinates. But the fact that the commutator should be zero does not take away the fact that it is not zero. Presumably, if you described the nucleus in terms of the individual quarks, you could write down a potential that respected the gauge property. But using quarks is not an option. The reality is that you must use protons and neutrons. And in those terms, a potential that does a decent job of describing the nucleus will simply not respect the gauge property. Yes, this does suggest that describing gamma decay using protons and neutrons instead of quarks is an inherently fishy procedure.)

This author knows not a single reference that gives a decent description of the above issue. Many simply do not mention the problem at all and just omit the commutator. Some simply state that the potential is assumed to depend on the particle positions only, like [33]. Surely it ought to be mentioned explicitly that the leading electric multipole operator as listed may well be no good at all? If it is listed, people will assume that is is meaningful unless stated otherwise. As [33] notes, "significant information regarding nuclear wave functions can be obtained from a comparison of experimental $\gamma$-decay transition probabilities with theoretical values calculated on basis of specific models of the nucleus." If one is not aware of the possibility of the additional commutator as a leading order effect, one might incorrectly conclude that a nuclear wave function is poor where the real problem is the ignored commutator.

At least [11, p.9-172] and [5] can be read to say that there might be a nontrivial problem. The original relativistic derivation of Stech, [44], mentions the issue, but no ballpark is given. (It is however noted that the spin-orbit term might be significant for magnetic transitions. The purely nonrelativistic analysis used here does not show such an effect. The present author suspects that the difference is that the relativistic derivation of Stech inherently assumes that the gauge property is valid. Surely there must be ways to do the relativistic analysis such that, in say the electric dipole case, both the results with and without commutator are reproduced.)

To be sure, the author no longer believes that this is a potential explanation why E1 transitions are so much slower than the Weisskopf estimate. The deviations in chapter 14.20.5 figures 14.63 and 14.64 seem much too big and
systematic to be explained by this mechanism. And it does not seem to address the concerns about mixed transitions that are mentioned there.

## N. 15 A tenth of a googol in universes

There is an oft-cited story going around that the many worlds interpretation implies the existence of $10^{99}$ worlds, and this number apparently comes from Everett, III himself. It is often used to argue that the many-worlds interpretation is just not credible. However, the truth is that the existence of infinitely many worlds, (or practically speaking infinitely many of them, maybe, if space and time would turn out to be discrete and finite), is a basic requirement of quantum mechanics itself, regardless of interpretation. Everett, III cannot be blamed for that, just for coming up with the ludicrous number of $10^{99}$ to describe infinity.

## N. 16 A single Slater determinant is not exact

The simplest example that illustrates the problem with representing a general wave function by a single Slater determinant is to try to write a general twovariable function $F(x, y)$ as a Slater determinant of two functions $f_{1}$ and $f_{2}$. You would write

$$
F(x, y)=\frac{a}{\sqrt{2}}\left(f_{1}(x) f_{2}(y)-f_{2}(x) f_{1}(y)\right)
$$

A general function $F(x, y)$ cannot be written as a combination of the same two functions $f_{1}(x)$ and $f_{2}(x)$ at every value of $y$. However well chosen the two functions are.

In fact, for a general antisymmetric function $F$, a single Slater determinant can get $F$ right at only two nontrivial values $y=y_{1}$ and $y=y_{2}$. (Nontrivial here means that functions $F\left(x, y_{1}\right)$ and $F\left(x, y_{2}\right)$ should not just be multiples of each other.) Just take $f_{1}(x)=F\left(x, y_{1}\right)$ and $f_{2}(x)=F\left(x, y_{2}\right)$. You might object that in general, you have

$$
F\left(x, y_{1}\right)=c_{11} f_{1}(x)+c_{12} f_{2}(x) \quad F\left(x, y_{2}\right)=c_{21} f_{1}(x)+c_{22} f_{2}(x)
$$

where $c_{11}, c_{12}, c_{21}$, and $c_{22}$ are some constants. (They are $f_{1}$ or $f_{2}$ values at $y_{1}$ or $y_{2}$, to be precise). But if you plug these two expressions into the Slater determinant formed with $F\left(x, y_{1}\right)$ and $F\left(x, y_{2}\right)$ and multiply out, you get the Slater determinant formed with $f_{1}$ and $f_{2}$ within a constant, so it makes no difference.

If you add a second Slater determinant, you can get $F$ right at two more $y$ values $y_{3}$ and $y_{4}$. Just take the second Slater determinant's functions to be $f_{1}^{(2)}=\Delta F\left(x, y_{3}\right)$ and $f_{2}^{(2)}=\Delta F\left(x, y_{4}\right)$, where $\Delta F$ is the deviation between the
true function and what the first Slater determinant gives. Keep adding Slater determinants to get more and more $y$-values right. Since there are infinitely many $y$-values to get right, you will in general need infinitely many determinants.

You might object that maybe the deviation $\Delta F$ from the single Slater determinant must be zero for some reason. But you can use the same ideas to explicitly construct functions $F$ that show that this is untrue. Just select two arbitrary but different functions $f_{1}$ and $f_{2}$ and form a Slater determinant. Now choose two locations $y_{1}$ and $y_{2}$ so that $f_{1}\left(y_{1}\right), f_{2}\left(y_{1}\right)$ and $f_{1}\left(y_{2}\right), f_{2}\left(y_{2}\right)$ are not in the same ratio to each other. Then add additional Slater determinants whose functions $f_{1}^{(2)}, f_{2}^{(2)}, f_{1}^{(3)}, f_{2}^{(3)}, \ldots$ you choose so that they are zero at $y_{1}$ and $y_{2}$. The so constructed function $F$ is different from just the first Slater determinant. However, if you try to describe this $F$ by a single determinant, then it could only be the first determinant since that is the only single determinant that gets $y_{1}$ and $y_{2}$ right. So a single determinant cannot get $F$ right.

## N. 17 Generalized orbitals

This note has a brief look at generalized orbitals of the form

$$
\psi_{n}^{\mathrm{p}}(\vec{r})=\psi_{n+}^{\mathrm{s}}(\vec{r}) \uparrow\left(S_{z}\right)+\psi_{n-}^{\mathrm{s}}(\vec{r}) \downarrow\left(S_{z}\right)
$$

For such orbitals, the expectation energy can be worked out in exactly the same way as in $\{D .52\}$, except without simplifying the spin terms. The energy is

$$
\begin{aligned}
\langle E\rangle= & \sum_{n=1}^{I}\left\langle\psi_{n}^{\mathrm{p}}\right| h^{\mathrm{e}}\left|\psi_{n}^{\mathrm{p}}\right\rangle \\
& +\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{\underline{n}=1 \\
\underline{n} \neq n}}^{I}\left\langle\psi_{n}^{\mathrm{p}} \psi_{\underline{n}}^{\mathrm{p}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{p}} \psi_{\underline{n}}^{\mathrm{p}}\right\rangle \\
& -\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{\underline{n}=1 \\
\underline{n} \neq n}}^{I}\left\langle\psi_{n}^{\mathrm{p}} \psi_{\underline{n}}^{\mathrm{p}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{p}} \psi_{n}^{\mathrm{p}}\right\rangle
\end{aligned}
$$

To multiply out to the individual spin terms, it is convenient to normalize the spatial functions, and write

$$
\begin{gathered}
\psi_{n}^{\mathrm{p}}=c_{n+} \psi_{n+, 0}^{\mathrm{s}} \uparrow+c_{n-} \psi_{n-, 0}^{\mathrm{s}} \downarrow, \\
\left\langle\psi_{n+, 0}^{\mathrm{s}} \mid \psi_{n+, 0}^{\mathrm{s}}\right\rangle=\left\langle\psi_{n-, 0}^{\mathrm{s}} \mid \psi_{n-, 0}^{\mathrm{s}}\right\rangle=1, \quad\left|c_{n+}\right|^{2}+\left|c_{n-}\right|^{2}=1
\end{gathered}
$$

In that case, the expectation energy multiplies out to

$$
\begin{aligned}
\langle E\rangle= & \sum_{n=1}^{I}\left\langle\psi_{n+, 0}^{\mathrm{s}}\right| h^{\mathrm{e}}\left|\psi_{n+, 0}^{\mathrm{s}}\right\rangle\left|c_{n+}\right|^{2}+\sum_{n=1}^{I}\left\langle\psi_{n-, 0}^{\mathrm{s}}\right| h^{\mathrm{e}}\left|\psi_{n-, 0}^{\mathrm{s}}\right\rangle\left|c_{n-}\right|^{2} \\
& +\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{n=1 \\
\underline{n} \neq n}}^{I}\left(\left\langle\psi_{n+, 0}^{\mathrm{s}} \psi_{\underline{n}+, 0}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n+, 0}^{\mathrm{s}} \psi_{\underline{n}+, 0}^{\mathrm{s}}\right\rangle\right. \\
& \left.\quad-\left\langle\psi_{n+, 0}^{\mathrm{s}} \psi_{\underline{n}+, 0}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}+, 0}^{\mathrm{s}} \psi_{n+, 0}^{\mathrm{s}}\right\rangle\right)\left|c_{n+}\right|^{2}\left|c_{\underline{n}+}\right|^{2} \\
& +\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{n=1 \\
\underline{n} \neq n}}^{I} 2\left\langle\psi_{n+, 0}^{\mathrm{s}} \psi_{\underline{n}-, 0}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n+, 0}^{\mathrm{s}} \psi_{\underline{n}-, 0}^{\mathrm{s}}\right\rangle\left|c_{n+}\right|^{2}\left|c_{\underline{n}-}\right|^{2} \\
& +\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{n=1 \\
\underline{n} \neq n}}^{I}\left(\left\langle\psi_{n-, 0}^{\mathrm{s}} \psi_{\underline{n-}, 0}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n-, 0}^{\mathrm{s}} \psi_{\underline{n}-, 0}^{\mathrm{s}}\right\rangle\right. \\
& \left.\quad-\left\langle\psi_{n-, 0}^{\mathrm{s}} \psi_{\underline{n}-, 0}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}-, 0}^{\mathrm{s}} \psi_{n-, 0}^{\mathrm{s}}\right\rangle\right)\left|c_{n-}\right|^{2}\left|c_{\underline{n}-}\right|^{2} \\
& -\frac{1}{2} \sum_{n=1}^{I} \sum_{\substack{\underline{n}=1 \\
\underline{n} \neq n}}^{I} 2 \Re\left(\left\langle\psi_{n+, 0}^{\mathrm{s}} \psi_{\underline{n}-, 0}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}+, 0}^{\mathrm{s}} \psi_{n-, 0}^{\mathrm{s}}\right\rangle c_{n+}^{*} c_{n-} c_{\underline{n}-}^{*} c_{\underline{n}+}\right)
\end{aligned}
$$

where $\Re$ stands for the real part of its argument.
Now assume you have a normal unrestricted Hartree-Fock solution, and you try to lower its ground-state energy by selecting, for example, a spin-up orbital $\psi_{m}^{\mathrm{s}} \uparrow \equiv \psi_{m+, 0}^{\mathrm{s}} \uparrow$ and adding some amount of spin down to it. First note then that the final sum above is zero, since at least one of $c_{n+}, c_{n-}, c_{\underline{n}-}$, and $c_{\underline{n}+}$ must be zero: all states except $m$ are still either spin-up or spin-down, and $m$ cannot be both $n$ and $\underline{n} \neq n$. With the final sum gone, the energy is a linear function of $\left|c_{m-}\right|^{2}$, with $\left|c_{m+}\right|^{2}=1-\left|c_{m-}\right|^{2}$. The minimum energy must therefore occur for either $\left|c_{m-}\right|^{2}=0$, the original purely spin up orbital, or for $\left|c_{m-}\right|^{2}=1$. (The latter case means that the unrestricted solution with the opposite spin for orbital $m$ must have less energy, so that the spin of orbital $m$ was incorrectly selected.) It follows from this argument that for correctly selected spin states, the energy cannot be lowered by replacing a single orbital with a generalized one.

Also note that for small changes, $\left|c_{m-}\right|^{2}$ is quadratically small and can be ignored. So the variational condition of zero change in energy is satisfied for all small changes in orbitals, even those that change their spin states. In other
words, the unrestricted solutions are solutions to the full variational problem $\delta\langle E\rangle=0$ for generalized orbitals as well.

Since these simple arguments do not cover finite changes in the spin state of more than one orbital, they do not seem to exclude the possibility that there might be additional solutions in which two or more orbitals are of mixed spin. But since either way the error in Hartree-Fock would be finite, there may not be much justification for dealing with the messy problem of generalized orbitals with dubious hopes of improvement. Procedures already exist that guarantee improvements on standard Hartree-Fock results.

## N. 18 "Correlation energy"

The error in Hartree-Fock is due to the single-determinant approximation only. A term like "Hartree-Fock error" or "single-determinantal error" is therefore both precise, and immediately understandable by a general audience.

However, it is called "correlation energy," and to justify that term, it would have to be both clearer and equally correct mathematically. It fails both requirements miserably. The term correlation energy is clearly confusing and distracting for nonspecialist. But in addition, there does not seem to be any theorem that proves that an independently defined correlation energy is identical to the Hartree-Fock single determinant error. That would not just make the term correlation energy disingenuous, it would make it wrong.

Instead of finding a rigorous theorem, you are lucky if standard textbooks, e.g.. $[30,34,46]$ and typical web references, offer a vague qualitative story why Hartree-Fock underestimates the repulsions if a pair of electrons gets very close. That is a symptom of the disease of having an incomplete function representation, it is not the disease itself. Low-parameter function representations have general difficulty with representing localized effects, whatever their physical source. If you make up a system where the Coulomb force vanishes both at short and at long distance, such correlations do not exist, and Hartree-Fock would still have a finite error.

The kinetic energy is not correct either; what is the correlation in that? Some sources, like [30] and web sources, seem to suggest that these are "indirect" results of having the wrong correlation energy, whatever correlation energy may be. The idea is apparently, if you would have the electron-electron repulsions exact, you would compute the correct kinetic energy too. That is just like saying, if you computed the correct kinetic energy term, you would compute the correct potential too, so let's rename the Hartree-Fock error "kinetic energy interaction."

Even if you computed the potential energy correctly, you would still have to convert the wave function to single-determinantal form before evaluating the kinetic energy, otherwise it is not Hartree-Fock, and that would produce
a finite error. Phrased differently, there is absolutely no way to get a general wave function correct with a finite number of single-electron functions, whatever corrections you make to the potential energy.

Szabo and Ostlund [46, p. 51ff,61] state that it is called correlation energy since "the motion of electrons with opposite spins is not correlated within the Hartree-Fock approximation." That is incomprehensible, for one thing since it seems to suggest that Hartree-Fock is exact for excited states with all electrons in the same spin state, which would be ludicrous. In addition, the electrons do not have motion; a stationary wave function is computed, and they do not have spin; all electrons occupy all the states, spin up and down. It is the orbitals that have spin, and the spin-up and spin-down orbitals are most definitely correlated.

However, the authors do offer a "clarification;" they take a Slater determinant of two opposite spin orbitals, compute the probability of finding the two electrons at given positions and find that it is correlated (unless the spatial orbitals are equal). They then declare that these correlated positions mean that the "motion" of the two electrons is uncorrelated.

The unrestricted Hartree-Fock solution of the dissociated hydrogen molecule is of this type. This solution was discussed in the introductory section 9.3.1. Since if one electron is around the left proton, the other is around the right one, and vice versa, normal people would call the positions of the electrons strongly correlated. And even while "motion" is not defined on quantum scales, to any engineer it would seem ludicrous to claim that strongly correlated positions would produce uncorrelated "motion" if "motion" existed.

Koch and Holthausen, [30, pp.22-23], address the same two electron example as Szabo and Ostlund, but do not have the same problem of finding the electron probabilities correlated. For example, if the spin-independent probability of finding the electrons at positions $\vec{r}_{1}$ and $\vec{r}_{2}$ in the dissociated hydrogen molecule is

$$
\frac{1}{2}\left|\psi_{1}\left(\vec{r}_{1}\right)\right|^{2}\left|\psi_{\mathrm{r}}\left(\vec{r}_{2}\right)\right|^{2}+\frac{1}{2}\left|\psi_{\mathrm{r}}\left(\vec{r}_{1}\right)\right|^{2}\left|\psi_{1}\left(\vec{r}_{2}\right)\right|^{2}
$$

then, Koch and Holthausen explain to us, the second term must be the same as the first. After all, if the two terms were different, the electrons would be distinguishable: electron 1 would be the one that selected $\psi_{1}$ in the first term that Koch and Holthausen wrote down in their book. So, the authors conclude, the second term above is the same as the first, making the probability of finding the electrons equal to twice the first term, $\left|\psi_{1}\left(\vec{r}_{1}\right)\right|^{2}\left|\psi_{r m r}\left(\vec{r}_{2}\right)\right|^{2}$. That is an uncorrelated product probability.

However, the assumption that electrons are indistinguishable with respect to mathematical formulae in books is highly controversial. Many respected references, and this book too, only see an empirical requirement that the wave function, not books, is antisymmetric with respect to exchange of any two electrons. And the wave function is antisymmetric even when the two terms above are not the same.

Wikipedia, 【21】, Hartree-Fock entry June 2007, lists electron correlation, (defined here vaguely as "effects" arising from from the mean-field approximation, i.e. using the same $v^{\mathrm{HF}}$ operator for all electrons) as an approximation made in addition to using a single Slater determinant. Sorry, but Hartree-Fock gives the best single-determinantal approximation; there is no additional approximation made. The mean "field" approximation is a consequence of the single determinant, not an additional approximation. Then this reference proceeds to declare this correlation energy the most important of the set, in other words, more important that the single-determinant approximation! And again, even if the potential energy was computed exactly, instead of using the $v^{\mathrm{HF}}$ operator, and only the kinetic energy was computed using a Slater determinant, there would still be a finite error. It would therefore appear then that the name correlation energy is sufficiently impenetrable and poorly defined that even the experts cannot necessarily figure it out.

Consider for a second the ground state of two electrons around a massive nucleus. Because of the strength of the nucleus, the Coulomb interaction between the two electrons can to first approximation be ignored. A reader of the various vague qualitative stories listed above may then be forgiven for assuming that Hartree-Fock should not have any error. But only the unrestricted Hartree-Fock solution with those nasty, "uncorrelated" (true in this case), opposite-spin "electrons" (orbitals) is the one that gets the energy right. A unrestricted solution in terms of those perfect, correlated, aligned-spin "electrons" gets the energy all wrong, since one orbital will have to be an excited one. In short the "correlation energy" (error in energy) that, we are told, is due to the "motion" of electrons of opposite spins not being "correlated" is in this case $100 \%$ due to the motion of aligned-spin orbitals being correlated. Note that both solutions get the spin wrong, but we are talking about energy.

And what happened to the word "error" in "correlation energy error?" If you did a finite difference or finite element computation of the ground state, you would not call the error in energy "truncation energy;" it would be called "truncation error" or "energy truncation error." Why does one suspect that the appropriate and informative word "error" did not sound "hot" enough to the physicists involved?

Many sources refer to a reference, (Löwdin, P.-E., 1959, Adv. Chem. Phys., $2,207)$ instead of providing a solid justification of this widely-used key term themselves. If one takes the trouble to look up the reference, does one find a rigorously defined correlation energy and a proof it is identical in magnitude to the Hartree-Fock error?

Not exactly. One finds a vague qualitative story about some perceived "holes" whose mathematically rigorous definition remains restricted to the center point of one of them. However, the lack of a defined hole size is not supposed to deter the reader from agreeing wholeheartedly with all sorts of claims about the size of their effects. Terms like "main error,", "small error," "large correla-
tion error" (qualified by "certainly"), "vanish or be very small," (your choice), are bandied around, even though there is no small parameter that would allow any rigorous mathematical definition of small or big.

Then the author, who has already noted earlier that the references cannot agree on what the heck correlation energy is supposed to mean in the first place, states "In order to get at least a formal definition of the problem, ..." and proceeds to redefine the Hartree-Fock error to be the "correlation energy." In other words, since correlation energy at this time seems to be a pseudo-scientific concept, let's just cross out the correct name Hartree-Fock error, and write in "correlation energy!"

To this author's credit, he does keep the word error in "correlation error in the wave function" instead of using "correlation wave function." But somehow, that particular term does not seem to be cited much in literature.

## N. 19 Ambiguities in electron affinity

The International Union of Pure and Applied Chemistry (IUPAC) Gold Book defines electron affinity as "Energy required to detach an electron from the singly charged negative ion [...] The equivalent more common definition is the energy released $\left(E_{\text {initial }}-E_{\text {final }}\right)$ when an additional electron is attached to a neutral atom or molecule." This is also the definition given by Wikipedia. Chemguide says "The first electron affinity is the energy released when 1 mole of gaseous atoms each acquire an electron to form 1 mole of gaseous 1- ions." HyperPhysics says "The electron affinity is a measure of the energy change when an electron is added to a neutral atom to form a negative ion." Encyclopedia Brittanica says "in chemistry, the amount of energy liberated when an electron is added to a neutral atom to form a negatively charged ion." Chemed.chem.purdue.edu says "The electron affinity of an element is the energy given off when a neutral atom in the gas phase gains an extra electron to form a negatively charged ion."

Another definition that can be found: "Electron affinity is the energy released when an electron is added to the valence shell of a gas-phase atom." Note the additional requirement here that the electron be added to the valence shell of the atom. It may make a difference.

First note that it is not self-evident that a stable negative ion exists. Atoms, even inert noble gasses, can be weakly bound together by Van der Waals/London forces. You might think that similarly, a distant electron could be weakly bound to an atom or molecule through the dipole strength it induces in the atom or molecule. The atom's or molecule's electron cloud would move a bit away from the distant electron, allowing the nucleus to exert a larger attractive force on the distant electron than the repulsive force by the electron cloud. Remember that according to the variational principle, the energy of the atom or molecule
does not change due to small changes in wave function, while the dipole strength does. So the electron would be weakly bound.

It sounds logical, but there is a catch. A theoretical electron at rest at infinity would have an infinitely large wave function blob. If it moves slightly towards the attractive side of the dipole, it would become somewhat localized. The associated kinetic energy that the uncertainty principle requires, while small at large distances, still dwarfs the attractive force by the induced dipole which is still smaller at large distances. So the electron would not be bound. Note that if the atom or molecule itself already has an inherent dipole strength, then if you ballpark the kinetic energy, you find that for small dipole strength, the kinetic energy dominates and the electron will not be bound, while for larger dipole strength, the electron will move in towards the electron cloud with increasing binding energy, presumably until it hits the electron cloud.

In the case that there is no stable negative ion, the question is, what to make of the definitions of electron affinity above. If there is a requirement that the additional electron be placed in the valence shell, there would be energy needed to do so for an unstable ion. Then the electron affinity would be negative. If there is however no requirement to place the electron in the valence shell, you could make the negative value of the electron affinity arbitrarily small by placing the electron in a sufficiently highly-excited state. Then there would be no meaningful value of the electron affinity, except maybe zero.

Various reputed sources differ greatly about what to make of the electron affinities if there is no stable negative ion. The CRC Handbook of Chemistry and Physics lists noble gasses, metals with filled s shells, and nitrogen all as "not stable" rather than giving a negative electron affinity for them. That seems to agree with the IUPAC definition above, which does not require a valence shell position. However, the Handbook does give a small negative value for ytterbium. A 2001 professional review paper on electron affinity mentioned that it would not discuss atoms with negative electron affinities, seemingly implying that they do exist.

Quite a lot of web sources list specific negative electron affinity values for atoms and molecules. For example, both Wikipedia and HyperPhysics give specific negative electron affinity values for benzene. Though one web source based on Wikipedia (!) claims the opposite.

Also note that references, like Wikipedia and HyperPhysics, differ over how the sign of electron affinity should be defined, making things even more confusing. Wikipedia however agrees with the IUPAC Gold Book on this point: if a stable ion exist, there is a positive affinity. Which makes sense; if you want to specify a negative value for a stable ion, you should not give it the name "affinity."

Wikipedia (July 2007) also claims: "All elements have a positive electron affinity, but older texts mistakenly report that some elements such as inert gases have negative [electron affinity], meaning they would repel electrons. This
is not recognized by modern chemists." However, this statement is very hard to believe in view of all the authoritative sources, like the CRC Handbook above, that explicitly claim that various elements do not form stable ions, and often give explicit negative values for the electron affinity of various elements. If the 2007 Handbook would after all these years still misstate the affinity of many elements, would not by now a lot of people have demanded their money back? It may be noted that Wikipedia lists Ytterbium as blank, and the various elements listed as not stable by the CRC handbook as stars, in other words, Wikipedia itself does not even list the positive values it claims.

## N. 20 Why Floquet theory should be called so

At about the same time as Floquet, Hill appears to have formulated similar ideas. However, he did not publish them, and the credit of publishing a publicly scrutinizable exposure fairly belongs to Floquet.

Note that there is much more to Floquet theory than what is discussed here. If you have done a course on differential equations, you can see why, since the simplest case of periodic coefficients is constant coefficients. Constant coefficient equations may have exponential solutions that do not have purely imaginary arguments, and they may include algebraic factors if the set of exponentials is not complete. The same happens to the variable coefficient case, with additional periodic factors thrown in. But these additional solutions are not relevant to the discussed periodic crystals. They can be relevant to describing simple crystal boundaries, though.

## N. 21 Superfluidity versus BEC

Many texts and most web sources suggest quite strongly, without explicitly saying so, that the so-called "lambda" phase transition at 2.17 K from normal helium I to superfluid helium II indicates Bose-Einstein condensation.

One reason given that is that the temperature at which it occurs is comparable in magnitude to the temperature for Bose-Einstein condensation in a corresponding system of noninteracting particles. However, that argument is very weak; the similarity in temperatures merely suggests that the main energy scales involved are the classical energy $k_{\mathrm{B}} T$ and the quantum energy scale formed from $\hbar^{2} / 2 m$ and the number of particles per unit volume. There are likely to be other processes that scale with those quantities besides macroscopic amounts of atoms getting dumped into the ground state.

Still, there is not much doubt that the transition is due to the fact that helium atoms are bosons. The isotope ${ }^{3} \mathrm{He}$ that is missing a neutron in its nucleus does not show a transition to a superfluid until 2.5 mK . The three orders of magnitude difference can hardly be due to the minor difference in mass;
the isotope does condense into a normal liquid at a comparable temperature as plain helium, 3.2 K versus 4.2 K . Surely, the vast difference in transition temperature to a superfluid is due to the fact that normal helium atoms are bosons, while the missing spin $1 / 2$ neutron in ${ }^{3} \mathrm{He}$ atoms makes them fermions. (The eventual superfluid transition of ${ }^{3} \mathrm{He}$ at 2.5 mK occurs because at extremely low temperatures very small effects allow the atoms to combine into pairs that act as bosons with net spin one.)

While the fact that the helium atoms are bosons is apparently essential to the lambda transition, the conclusion that the transition should therefore be Bose-Einstein condensation is simply not justified. For example, Feynman [18, p. 324] shows that the boson character has a dramatic effect on the excited states. (Distinguishable particles and spinless bosons have the same ground state; however, Feynman shows that the existence of low energy excited states that are not phonons is prohibited by the symmetrization requirement.) And this effect on the excited states is a key part of superfluidity: it requires a finite amount of energy to excite these states and thus mess up the motion of helium.

Another argument that is usually given is that the specific heat varies with temperature near the lambda point just like the one for Bose-Einstein condensation in a system of noninteracting bosons. This is certainly a good point if you pretend not to see the dramatic, glaring, differences. In particular, the Bose-Einstein specific heat is finite at the Bose-Einstein temperature, while the one at the lambda point is infinite.. How much more different can you get? In addition, the specific heat curve of helium below the lambda point has a logarithmic singularity at the lambda point. The specific heat curve of BoseEinstein condensation for a system with a unique ground state stays analytical until the condensation terminates, since at that point, out of the blue, nature starts enforcing the requirement that the number of particles in the ground state cannot be negative, $\{\mathrm{D} .57\}$.

Tilley and Tilley [47, p. 37] claim that the qualitative correspondence between the curves for the number of atoms in the ground state in Bose-Einstein condensation and the fraction of superfluid in a two-fluid description of liquid helium "are sufficient to suggest that $T_{\lambda}$ marks the onset of Bose-Einstein condensation in liquid ${ }^{4} \mathrm{He}$." Sure, if you think that a curve reaching a maximum of one exponentially has a similarity to one that reaches a maximum of one with infinite curvature. And note that this compares two completely different quantities. It does not compare curves for particles in the ground state for both systems. It is quite generally believed that the condensate fraction in liquid helium, unlike that in true Bose-Einstein condensation, does not reach one at zero temperature in the first place, but only about $10 \%$ or so, [47, pp. 62-66].

Since the specific heat curves are completely different, Occam's razor would suggest that helium has some sort of different phase transition at the lambda point. However, Tilley and Tilley [47, pp. 62-66] present data, their figure 2.17, that suggests that the number of atoms in the ground state does indeed
increase from zero at the lambda point, if various models are to be believed and one does not demand great accuracy. So, the best available knowledge seems to be that Bose-Einstein condensation, whatever that means for liquid helium, does occur at the lambda point. But the fact that many sources see "evidence" of condensation where none exists is worrisome: obviously, the desire to believe despite the evidence is strong and widespread, and might affect the objectivity of the data.

Snoke \& Baym point out (in the introduction to Bose-Einstein Condensation, Griffin, A., Snoke, D.W., \& Stringari, S., Eds, 1995, Cambridge, p. 4), that the experimental signal of a Bose-Einstein condensate is taken to be a delta function for the occupation number of the particles [particle state?] with zero momentum, associated with long-range phase coherence of the wave function. It is not likely to be unambiguously verified any time soon. The actual evidence for the occurrence of Bose-Einstein condensation is in the agreement of theoretical models and experimental data, including also models for the specific heat anomaly. However, Sokol points out in the same volume, (p. 52): "At present, however, liquid helium is the only system where the existence of an experimentally obtainable Bose condensed phase is almost universally accepted" [emphasis added].

The question whether Bose-Einstein condensation occurs at the lambda point seems to be academic anyway. The following points can be distilled from Schmets and Montfrooij [39]:

1. Bose-Einstein condensation is a property of the ground state, while superfluidity is a property of the excited states.
2. Ideal Bose-Einstein condensates are not superfluid.
3. Below 1 K , essentially $100 \%$ of the helium atoms flow without viscosity, even though only about $7 \%$ is in the ground state.
4. In fact, there is no reason why a system could not become a superfluid even if only a very small fraction of the atoms were to form a condensate.
The statement that no Bose-Einstein condensation occurs for photons applies to systems in thermal equilibrium. In fact, Snoke \& Baym, as mentioned above, use lasers as an example of a condensate that is not superfluid.

## N. 22 The mechanism of ferromagnetism

It should be noted that in solids, not just spatial antisymmetry, but also symmetry can give rise to spin alignment. In particular, in many ferrites, there is an opposite spin coupling between the iron atoms and the oxygen ones. If two iron atoms are opposite in spin to the same oxygen atom, it implies that they must have aligned spins even if their electrons do not interact directly.

It comes as somewhat a surprise to discover that in this time of hightemperature superconductors, the mechanism of plain old ferromagnetism is still not understood that well if the magnetic material is a conductor, such as a piece of iron.

For a conductor, the description of the exclusion effect should really be at least partly in terms of band theory, rather than electrons localized at atoms. More specifically, Aharoni [2, p. 48] notes "There is thus no doubt in anybody's mind that neither the itinerant electron theory nor the localized electron one can be considered to be a complete picture of the physical reality, and that they both should be combined into one theory."

Sproull notes that in solid iron, most of the 4 s electrons move to the 4 d bands. That reduces the magnetization by reducing the number of unpaired electrons.

While Sproull [42, p. 282] in 1956 describes ferromagnetism as an interaction between electrons localized at neighboring atoms, Feynman [22, p. 37-2] in 1965 notes that calculations using such a model produce the wrong sign for the interaction. According to Feynman, the interaction is thought to occur with $[4 \mathrm{~s}]$ conduction band electrons acting as intermediaries. More recently, Aharoni [2, p. 44] notes: "It used to be stated [...] that nobody has been able to compute a positive exchange integral for Fe , and a negative one for $\mathrm{Cu}[\ldots]$. More modern computations [...] already have the right sign, but the magnitude of the computed exchange still differs considerably from the experimental value. Improving the techniques [...] keeps improving the results, but not sufficiently yet."

Batista, Bonča, and Gubernatis note that "After seven decades of intense effort we still do not know what is the minimal model of itinerant ferromagnetism and, more importantly, the basic mechanism of ordering." (Phys Rev Let 88, 2002, 187203-1) and "Even though the transition metals are the most well studied itinerant ferromagnets, the ultimate reason for the stabilization of the FM phase is still unknown." (Phys Rev B 68, 2003, 214430-11)

## N. 23 Fundamental assumption of statistics

The assumption that all energy eigenstates with the same energy are equally likely is simply stated as an axiom in typical books, [4, p. 92], [18, p. 1], [25, p. 230], [52, p. 177]. Some of these sources quite explicitly suggest that the fact should be self-evident to the reader.

However, why could not an energy eigenstate, call it A, in which all particles have about the same energy, have a wildly different probability from some eigenstate B in which one particle has almost all the energy and the rest has very little? The two wave functions are wildly different. (Note that if the probabilities are only somewhat different, it would not affect various conclusions
much because of the vast numerical superiority of the most probable energy distribution.)

The fact that it does not take any energy to go from one state to the other [18, p. 1] does not imply that the system must spend equal time in each state, or that each state must be equally likely. It is not difficult at all to construct nonlinear systems of evolution equations that conserve energy and in which the system runs exponentially away towards specific states.

However, the coefficients of the energy eigenfunctions do not satisfy some arbitrary nonlinear system of evolution equations. They evolve according to the Schrödinger equation, and the interactions between the energy eigenstates are determined by a Hamiltonian matrix of coefficients. The Hamiltonian is a Hermitian matrix; it has to be to conserve energy. That means that the coupling constant that allows state A to increase or reduce the probability of state B is just as big as the coupling constant that allows $B$ to increase or reduce the probability of state A. More specifically, the rate of increase of the probability of state A due to state B and vice-versa is seen to be

$$
\left(\frac{\mathrm{d}\left|c_{A}\right|^{2}}{\mathrm{~d} t}\right)_{\text {duetoB }}=\frac{1}{\hbar} \Im\left(c_{A}^{*} H_{A B} c_{B}\right) \quad\left(\frac{\mathrm{d}\left|c_{B}\right|^{2}}{\mathrm{~d} t}\right)_{\text {duetoA }}=-\frac{1}{\hbar} \Im\left(c_{A}^{*} H_{A B} c_{B}\right)
$$

where $H_{A B}$ is the perturbation Hamiltonian coefficient between A and B. (In the absence of perturbations, the energy eigenfunctions do not interact and $H_{A B}=0$.) Assuming that the phase of the Hamiltonian coefficient is random compared to the phase difference between A and B , the transferred probability can go at random one way or the other regardless of which one state is initially more likely. Even if A is currently very improbable, it is just as likely to pick up probability from B as B is from A. Also note that eigenfunctions of the same energy are unusually effective in exchanging probability, since their coefficients evolve approximately in phase.

This note would argue that under such circumstances, it is simply no longer reasonable to think that the difference in probabilities between eigenstates of the same energy is enough to make a difference. How could energy eigenstates that readily and randomly exchange probability, in either direction, end up in a situation where some eigenstates have absolutely nothing, to incredible precision?

Feynman [18, p. 8] gives an argument based on time-dependent perturbation theory, chapter 11.10. However, time-dependent perturbations theory relies heavily on approximation, and worse, the measurement wild card. Until scientists, while maybe not agreeing exactly on what measurement is, start laying down rigorous, unambiguous, mathematical ground rules on what measurements can do and cannot do, measurement is like astrology: anything goes.

## N. 24 A problem if the energy is given

Examining all shelf number combinations with the given energy and then picking out the combination that has the most energy eigenfunctions seems straightforward enough, but it runs into a problem. The problem arises when it is required that the set of shelf numbers agrees with the given energy to mathematical precision. To see the problem, recall the simple model system of chapter 11.3 that had only three energy shelves. Now assume that the energy of the second shelf is not $\sqrt{9}=3$ as assumed there, (still arbitrary units), but slightly less at $\sqrt{8}$. The difference is small, and all figures of chapter 11.3 are essentially unchanged. However, if the average energy per particle is still assumed equal to 2.5 , so that the total system energy equals the number of particles $I$ times that amount, then $I_{2}$ must be zero: it is impossible to take a nonzero multiple of an irrational number like $\sqrt{8}$ and end up with a rational number like $2.5 I-I_{1}-4 I_{3}$. What this means graphically is that the oblique energy line in the equivalent of figure 11.5 does not hit any of the centers of the squares mathematically exactly, except for the one at $I_{2}=0$. So the conclusion would be that the system must have zero particles on the middle shelf.

Of course, physically this is absolute nonsense; the energy of a large number of perturbed particles is not going to be certain to be $2.5 I$ to mathematical precision. There will be some uncertainty in energy, and the correct shelf numbers are still those of the darkest square, even if its energy is $2.4999 \ldots I$ instead of 2.5 I exactly. Here typical textbooks will pontificate about the accuracy of your system-energy measurement device. However, this book shudders to contemplate what happens physically in your glass of ice water if you have three system-energy measurement devices, but your best one is in the shop, and you are uncertain whether to believe the unit you got for cheap at Wal-Mart or your backup unit with the sticking needle.

To avoid these conundrums, in this book it will simply be assumed that the right combination of shelf occupation numbers is still the one at the maximum in figure 11.6, i.e. the maximum when the number of energy eigenfunctions is mathematically interpolated by a continuous function. Sure, that may mean that the occupation numbers are no longer exact integers. But who is going to count $10^{20}$ particles to check that it is exactly right? (And note that those other books end up doing the same thing anyway in the end, since the mathematics of an integer-valued function defined on a strip is so much more impossible than that of a continuous function defined on a line.)

If fractional particles bothers you, even among $10^{20}$ of them, just fix things after the fact. After finding the fractional shelf numbers that have the biggest energy, select the whole shelf numbers nearest to it and then change the "given" energy to be $2.4999999 \ldots$ or whatever it turns out to be at those whole shelf numbers. Then you should have perfectly correct shelf numbers with the highest number of eigenfunctions for the new given energy.

## N. 25 The recipe of life

Religious nuts, "creationists," "intelligent designers," or whatever they are calling themselves at the time you are reading this, call them CIDOWs for short, would like to believe that the universe was created literally like it says in the bible. The bible contains two creation stories, the Genesis story and the Adam and Eve story, and they conflict. At some time in the past they were put in together for simplicity, without ironing out their contradictions. CIDOWs feel that with two conflicting creation stories, surely at least one should be right? This is the bible, you know?

Now if you want to believe desperately enough, you are willing to accept anything that seems to reasonably support your point, without looking too hard at any opposing facts. (Critically examining facts is what a scientist would do, but you can reasonably pass yourself off as a scientist in the court system and popular press without worrying about it. You do have to pass yourself off as a scientist in the United States, since it is unconstitutional to force your religious beliefs upon the public education system unless you claim they are scientific instead of religious.) Now CIDOWs had a look at life, and it seemed to be quite nonmessy to them. So they felt its entropy was obviously low. (Actually, a human being may be a highly evolved form of life, but being largely water well above absolute zero temperature, its entropy is not particularly low.) Anyway, since the earth has been around for quite some time, they reasoned that the entropy of its surface must have been increasing for a long time, and nonmessy human beings could not possibly be true. Hence the conventional scientific explanation of the evolution of life violated the second law and could not be true. It followed that the universe just had to be created by God. The Christian God of course, don't assume now that Allah or Buddha need apply.

Hello CIDOWs! The surface of the earth is hardly an adiabatic system. See that big fireball in the sky? What do you think all that plant life is doing with all those green leaves? Baierlein [4, pp. 128-130] works out some of the rough details. Since the surface of the sun is very hot, the photons of light that reach us from the sun are high energy ones. Despite the influx of solar energy, the surface of the earth does not turn into an oven because the earth emits about the same energy back into space as it receives from the sun. But since the surface of the earth is not by far as hot as that of the sun, the photons emitted by the earth are low energy ones. Baierlein estimates that the earth emits about 20 of these low energy photons for every high energy one it receives from the sun. Each photon carries one unit of entropy on average, (11.59). So the earth loses 20 units of messiness for every one it receives. So, evolution towards less messy systems is exactly what you would expect for the earth surface, based on the overall entropy picture. Talk about an argument blowing up in your face!

## N. 26 Physics of the fundamental commutators

The fundamental commutation relations look much like a mathematical axiom. Surely, there should be some other reasons for physicists to believe that they apply to nature, beyond that they seem to produce the right answers?

Addendum \{A.19\} explained that the angular momentum operators correspond to small rotations of the axis system through space. So, the commutator $\left[\widehat{J}_{x}, \widehat{J}_{y}\right]$ really corresponds to the difference between a small rotation around the $y$-axis followed by a small rotation around the $x$-axis, versus a small rotation around the $x$-axis followed by a small rotation around the $y$ axis. As shown below, in our normal world this difference is equivalent to the effect of a small rotation about the $z$-axis.

So, the fundamental commutator relations do have physical meaning; they say that this basic relationship between rotations around different axes continues to apply in the presence of spin.

This idea can be written out more precisely by using the symbols $\mathcal{R}_{x, \alpha}, \mathcal{R}_{y, \beta}$, and $\mathcal{R}_{z, \gamma}$ for, respectively, a rotation around the $x$-axis over an angle $\alpha$, around the $y$-axis over an angle $\beta$, and the $z$-axis over an angle $\gamma$. Then following $\{$ A.19\}, the angular momentum around the $z$-axis is by definition:

$$
\widehat{J}_{z} \approx \frac{\hbar \mathcal{R}_{z, \gamma}-I}{\mathrm{i}} \frac{1}{\gamma}
$$

(To get this true exactly, you have to take the limit $\gamma \rightarrow 0$. But to keep things more physical, taking the mathematical limit will be delayed to the end. The above expression can be made arbitrarily accurate by just taking $\gamma$ small enough.)

Of course, the $x$ and $y$ components of angular momentum can be written similarly. So their commutator can be written as:

$$
\left[\widehat{J}_{x}, \widehat{J}_{y}\right] \equiv \widehat{J}_{x} \widehat{J}_{y}-\widehat{J}_{y} \widehat{J}_{x} \approx \frac{\hbar^{2}}{\mathrm{i}^{2}}\left(\frac{\mathcal{R}_{x, \alpha}-I}{\alpha} \frac{\mathcal{R}_{y, \beta}-I}{\beta}-\frac{\mathcal{R}_{y, \beta}-I}{\beta} \frac{\mathcal{R}_{x, \alpha}-I}{\alpha}\right)
$$

or multiplying out

$$
\left[\widehat{J}_{x}, \widehat{J}_{y}\right] \approx \frac{\hbar^{2}}{\mathrm{i}^{2}} \frac{\mathcal{R}_{x, \alpha} \mathcal{R}_{y, \beta}-\mathcal{R}_{y, \beta} \mathcal{R}_{x, \alpha}}{\alpha \beta}
$$

The final expression is what was referred to above. Suppose you do a rotation of your axis system around the $y$-axis over a small angle $\beta$ followed by a rotation around the $x$-axis around a small angle $\alpha$. Then you will change the position coordinates of every point slightly. And so you will if you do the same two rotations in the opposite order. Now if you look at the difference between these two results, it is described by the numerator in the final ratio above.

All those small rotations are of course a complicated business. It turns out that in our normal world you can get the same differences in position in a much
simpler way: simply rotate the axis system around a small angle $\gamma=-\alpha \beta$ around the $z$-axis. The change produced by that is the numerator in the expression for the angular momentum in the $z$-direction given above. If the two numerators are the same for small $\alpha$ and $\beta$, then the fundamental commutation relation follows. At least in our normal world. So if physicists extend the fundamental commutation relations to spin, they are merely generalizing a normal property of rotations.

To show that the two numerators are the indeed the same for small angles requires a little linear algebra. You may want to take the remainder of this section for granted if you never had a course in it.

First, in linear algebra, the effects of rotations on position coordinates are described by matrices. In particular,

$$
\mathcal{R}_{x, \alpha}=\left(\begin{array}{ccc}
1 & 0 & 0 \\
0 & \cos \alpha & \sin \alpha \\
0 & -\sin \alpha & \cos \alpha
\end{array}\right) \quad \mathcal{R}_{y, \beta}=\left(\begin{array}{ccc}
\cos \beta & 0 & -\sin \beta \\
0 & 1 & 0 \\
\sin \beta & 0 & \cos \beta
\end{array}\right)
$$

By multiplying out, the commutator is found as

$$
\left[\widehat{J}_{x}, \widehat{J}_{y}\right] \approx \frac{\hbar^{2}}{\mathrm{i}^{2} \alpha \beta}\left(\begin{array}{ccc}
0 & -\sin \alpha \sin \beta & -\sin \beta(1-\cos \alpha) \\
\sin \alpha \sin \beta & 0 & -\sin \alpha(1-\cos \beta) \\
-\sin \beta(1-\cos \alpha) & -\sin \alpha(1-\cos \beta) & 0
\end{array}\right)
$$

Similarly, the angular momentum around the $z$-axis is

$$
\widehat{J}_{z} \approx \frac{\hbar}{\mathrm{i} \gamma}\left(\begin{array}{ccc}
\cos \gamma-1 & \sin \gamma & 0 \\
-\sin \gamma & \cos \gamma-1 & 0 \\
0 & 0 & 0
\end{array}\right)
$$

If you take the limit that the angles become zero in both expressions, using either l'Hôpital or Taylor series expansions, you get the fundamental commutation relationship.

And of course, it does not make a difference which of your three axes you take to be the $z$-axis. So you get a total of three of these relationships.

## N. 27 Magnitude of components of vectors

You might wonder whether the fact that the square components of angular momentum must be less than total square angular momentum still applies in the quantum case. After all, those components do not exist at the same time. But it does not make a difference: just evaluate them using expectation values. Since states $|j m\rangle$ are eigenstates, the expectation value of total square angular momentum is the actual value, and so is the square angular momentum in the $z$-direction. And while the $|j m\rangle$ states are not eigenstates of $\widehat{J}_{x}$ and $\widehat{J}_{y}$, the
expectation values of square Hermitian operators such as $\widehat{J}_{x}^{2}$ and $\widehat{J}_{y}^{2}$ is always positive anyway (as can be seen from writing it out in terms of the eigenstates of them.)

## N. 28 Adding angular momentum components

The fact that net angular momentum components can be obtained by summing the single-particle angular momentum operators is clearly following the Newtonian analogy: in classical physics each particle has its own independent angular momentum, and you just add them up,

See also addendum \{A.19\}.

## N. 29 Clebsch-Gordan tables are bidirectional

The fact that you can read the tables either by rows or by columns is due to the orthonormality of the states involved. In terms of the real vectors of physics, it is simply an expression of the fact that the component of one unit vector in the direction of another unit vector is the same as the component of the second unit vector in the direction of the first.

## N. 30 Machine language Clebsch-Gordan tables

The usual "machine language" form of the tables leaves out the $a, b$, and $a b$ identifiers, the $j_{a}=$ and $j_{b}=$ clarifications from the header, and all square root signs, the $j$ values of particles $a$ and $b$ from the kets, and all ket terminator bars and brackets, but combines the two $m$ values with missing $j$ values together in a frame to resemble an $j m$ ket as well as possible, and then puts it all in a font that is very easy to read with a magnifying glass or microscope.

## N. 31 Existence of magnetic monopoles

Actually, various advanced quantum theories really require the existence of magnetic monopoles. But having never been observed experimentally with confidence despite the big theoretical motivation for the search, they are clearly not a significant factor in real life. Classical electromagnetodynamics assumes that they do not exist at all.

## N. 32 More on Maxwell's third law

Since the voltage is minus the integral of the electric field, it might seem that there is a plus and minus mixed up in figure 13.5.

But actually, it is a bit more complex. The initial effect of the induced electric field is to drive the electrons towards the pole marked as negative. (Recall that the charge of electrons is negative, so the force on the electrons is in the direction opposite to the electric field.) The accumulation of electrons at the negative pole sets up a counter-acting electric field that stops further motion of the electrons. Since the leads to the load will be stranded together rather than laid out in a circle, they are not affected by the induced electric field, but only by the counter-acting one. If you want, just forget about voltages and consider that the induced electric field will force the electrons out of the negative terminal and through the load.

## N. 33 Setting the record straight on alignment

Some sources claim the spin is under an angle with the magnetic field; this is impossible since, as pointed out in chapter 4.2.4, the angular momentum vector does not exist. However, the angular momentum component along the magnetic field does have measurable values, and these component values, being one-dimensional, can only be aligned or anti-aligned with the magnetic field.

To intuitively grab the concept of Larmor precession, it may be useful anyway to think of the various components of angular momentum as having precise nonzero values, rather than just being uncertain. But the latter is the truth.

## N. 34 NuDat 2 data selection

The gamma decay data of figures 14.63 and 14.64 were retrieved from NuDat 2, 【12】, October-November 2011.

In the data selection, transitions were ignored if any ambiguity at all was indicated for any of the primary data. The primary data were the initial energy level, the released energy in the transition of interest, the half life, the initial and final spins and parities, the multipole type and order, the relative intensity of the gamma transition of interest, (see below for more), the mixing ratio for transitions of mixed multipole type, the conversion coefficient, (see below for more), and the decay rate in Weisskopf units. If there was a decay process other than gamma decay indicated, the gamma decay percentage had to be given without ambiguity. Indications of ambiguity included parentheses, square brackets, inequalities, tildes, question marks, multiple values, and more.

Note that the given data uncertainties were ignored. That is a weakness of the data, but presumably not really important in view of the very large
deviations from theory. Including uncertainties would make processing much more complicated.

As an overall check on the data, the computed transition rate was compared to the one provided in terms of Weisskopf units by NuDat 2 itself. If the difference was less than $5 \%$ and there were no other concerns, as discussed below, the transition was accepted automatically. Tests were also performed on whether the initial and final energy levels matched the energy release, and on spin and parity conservation. These tests were mainly to guard against typos in the data base and no violations were observed.

If there were any concerns, the data were printed out. A decision was then made manually on whether to accept the transition as a potential candidate for plotting. If the computed transition rate was substantially, (more than roughly $15 \%$ ), above the NuDat 2 value, the transition was rejected out of hand. If the computed transition rate was below the NuDat 2 one, it was examined whether the NuDat 2 value was self-evidently missing its correction for other decay types, for the other gamma intensities, the mixing ratio, or the conversion coefficient. That was observed in a relatively small number of cases, usually for a missing conversion coefficient. In all other cases, for a substantial difference in decay rates, over about $15 \%$, the transition was rejected.

Even if the computed decay rate matched the Weisskopf one, various decays were manually rejected. In doing so, if the gamma intensity was not given, it was assumed to be $100 \%$ only if there was only one gamma decay out of the energy level. If there were other gamma decays out of the same energy level, their intensities were, based on manual examination, allowed to be omitted (assumed to be zero), specified by an upper limit if small (assumed to be half the upper limit), or specified as approximate if small. If the conversion coefficient was not given, it was manually allowed to be zero if the incompressible ballpark value was below about $10^{-4}$. Some initial energy levels with multiple gamma decays were manually rejected if the transition of interest had very low intensity and only one or two digits were given. Mixed transitions were manually examined, but it was not considered cause for rejection as long as a valid mixing ratio was given. If the multipole level was higher than needed, that was also announced, but it too was not taken to be a reason for rejection.

No, in the manual selections, the author did not select the worst nuclei to make physicists look bad.

The plot range from 30 to 3000 keV (in the plots reduced to 2500 keV ) energy release was divided into 70 segments for which one symbol to plot each. Transitions to plot were selected by comparing them to the selected transitions in the other segments. The selection was designed to achieve a broad coverage of transitions. For plot segments for which there was only one available transition, that transition was immediately selected. Then the program iterated over the segments with more than one potential candidate for plotting. In each segment the best candidate to plot was selected according to the following criteria:

1. Candidates that were more distant in terms of $Z$ from the currently selected candididates in the other segments received priority. Distance was here defined as the distance from the closest selected nucleus of the other segments. The intention was to cover the entire range of atomic numbers as well as possible.
2. In case of a tie, nuclei that were different from the most other selected nuclei in terms of either proton or neutron odd/evenness received priority. The intention was to include all variations of even/oddness.
3. In case of a tie, nuclei that were stable received priority. That was in the hopes that data on stable nuclei might be better quality.
4. In case of a tie, nuclei that were more different in $A$ from the already selected nuclei received priority.
5. In case of a tie, a random choice was made between the nuclei in the tie.
Because these criteria depend on the selections in the other segments, iteration was needed. The iterations were terminated if there were no more changes in the selected candidates.

The data on the selected nuclei, including log files, are available in the web version of this document ${ }^{1}$. If you have suggestions on how the data could be improved, let me know.

## N. 35 Auger discovery

Meitner submitted the discovery of the Auger process to the Zeitschrift für Physik, a major journal, on Jan 81922 and it appeared in the Nov 1/Dec issue that year. The process is clearly described. Auger's first description appeared in the July 161923 Séance of the Comptes Rendus of the Academy of Sciences in France (in French). There is no record of Meitner having apologized to Auger for not having waited with publication even though a male physicist was clearly likely to figure it out sooner or later.

It is generally claimed that Meitner should have shared the Nobel prize with Hahn for the discovery of nuclear fission. One reason given is that it was Meitner who found the explanation of what was going on and coined the phrase "fission." Meitner also did much of the initial experimental work with Hahn that led to the discovery. Fortunately, Meitner was Jewish and had to flee Hitler's Germany in 1938. That made it much easier for Hahn to shove her out of the way and receive all the credit, rather than having to share it with some woman.

[^6]
## N. 36 Draft: Cage-of-Faraday proposal

The gigantic errors in theoretical half-life predictions in section 14.20.5 are disconcerting to say the least. They imply that the predicted gamma decay rates, (essentially the inverse of the half-lifes), are typically either much less than theory or much larger than theory.

To explain why some of the gamma decay rates, like the E2 and high energy E3 ones, are so much faster than ballpark is relatively straightforward. Decay much faster than ballpark is only possible if not just one proton, but a lot of nucleons participate in the transition. And since the effect is systematic in E2 and high energy E3 transitions, apparently it is normal for a lot of nucleons to participate in gamma decay. Or at least it is for these types of gamma decay. And since the theory assumes that only one proton participates, the miserable predictions of theory can be explained.

A much bigger problem is to explain why other transitions end up so far below ballpark in a credible way. Consider in particular the E1 transitions in figures 14.63 and 14.65. How come that they are not just occasionally, but typically slower than theory by four orders of magnitude?

Basically, you can give two reasonable types of explanation:

1. You can assume that only one proton participates in these transition, not many as in E2 and E3 transitions. Then you must assume that in addition there is a systematic very poor overlap between the initial and final states in the relevant inner product. We do not really know the initial and final states, so, why not? Problem solved. Next question?
This is essentially the explanation that basic nuclear textbooks that the author has seen give. Unfortunately, there are two big problems with it. First, how come that unlike the E2 and E3 transitions, suddenly only one proton participates in E1, low energy E3, M1 and most M2 transitions? If there is a very big systematic effect, there must be a reason. Worse, figure 14.65 seems to exclude the possibility of just one proton partipating in at the very least M1 transitions, and surely at least some very slow E1 transitions.
The second problem is to explain why the overlap is systematically extremely bad in some types of transitions, but apparently excellent in others. Again, this is a big systematic effect, as the figures show. So there must be a reason for this too.
Your hands are not enough to wave these problem away. If you want people to take you seriously, you should have a believable and comprehensive discussion.
2. Alternatively, you can assume that in the transitions that are much slower than theory, still many nucleons participate. One immediate advantage is, of course, that this would explain why the theory per-
forms miserably bad on these transitions too. And you do not have to explain why in some transitions only a single proton participates while in others many nucleons do. In particular, this removes figure 14.65 as an issue. It can also explain why for some very light nuclei, E1 and M1 transitions are at ballpark or even noticeably faster than ballpark.
But now of course, you face the apparently daunting problem of explaining why some types transitions can be so extremely slow, even now that there are many nucleons participating. In particular, you need to provide a reasonable explanation why for some types of transitions, the participation of many nucleons actually slows down the emission of electromagnetic radiation greatly, rather than increase it greatly. And apparently, this effect requires the presence of enough nucleons, as very light nuclei do not have the problem.
While standard nuclear textbooks give the first explanation above, the holes in the argument are worrisome. The magnitude of the effects pointed at by the textbooks just does not seem big enough to explain the data. And it is hard to think up reasons why not. There just is a lack of suspension of disbelieve for an engineer thinking in terms of ballparks.

Therefore, this book wants to argue that more serious consideration should be given to the second explanation. Its main liability is to explain why some transitions get slowed down greatly, rather than sped up, if a lot more nucleons participate.

Since nuclear wave functions are poorly understood, that would be difficult to explain from a quantum-mechanical viewpoint. So maybe it is again time to do what has been done before for nuclei; look for macroscopic models. And surely the macroscopic model that stands out in killing off electromagnetic effects is the cage of Faraday. (In this case the cage is assumed to shield the outside from the inside.)

Maybe then the nuclear surface acts as such a cage in some sense. In the liquid-drop idea, nucleons at the surface are in a state of increased energy. So it may not be such a crazy idea that nucleons at the surface might behave differently from nucleons in the interior.

Assume now at first, in this macroscopic model, that the nuclear surface is spherical and conducting. Then electric charge changes in the interior of the nucleus would not leak out. That would kill off the capability of transitions to emit radiation. So the model can provide a macroscopic explanation why some electromagnetic transitions can be greatly slowed down. Charges can still move around inside the nucleus, but because the surface nucleons move to compensate, that does not produce radiation outside it. So participation of many nucleons does indeed reduce, rather than increase, electromagnetic radiation greatly.

Do note that unlike normal cages of Faraday, a nucleus contains a net positive charge. And if a macroscopic cage of Faraday contains a net charge, there must
always ne a nonzero electric field outside. (That is due to Maxwell's first law.) But as long as the surface remains spherical and conducting, the outside electric field will not change if charges inside the surface are moved around. So in that case, there will be an electric field, but still no electromagnetic radiation radiated away. And the reason for that is still because many nucleons are involved, rather than a single proton.

But things change when the nuclear surface changes shape. A conducting surface makes only the electric field tangential to the surface zero. Therefore there will be variations in the electric field outside the surface if it changes shape. So now we have a situation where radiation is in fact being transmitted, and again with many nucleons involved in doing that.

That opens up the possibility of explaining why some transitions can be so far from the single proton ballpark. And why it depends on the type of transition whether the transition turns out to be much slower than ballpark or much faster than ballpark.

At least for relatively light nuclei, (but still with enough nucleons that the macroscopic picture makes sense), and small excitations, surface tension would promote a spherical surface. And "surface roughness" would not necessarily make much of a difference. That is just like small holes in a macroscopic cage do not make a difference. The field outside the nucleus is governed by the so-called Laplace equation. This equation is known to kill off short-scale perturbations quickly.

On the other hand, changes in a deformed nuclear surface shape would definitely produce nontrivial long-range electric field perturbations. Now nuclei are often modeled as spheroids or ellipsoids. Changes in such a shape would produce quadrupole and hexadecapole perturbations in the electric field outside the nuclei. So they would produce E2 radiation, but not E1 radiation. That is exactly what is needed to make some sense out of the electric transitions.

While macroscopic cages of Faraday do not block static magnetic fields, they do block changes in magnetic fields. So conceptually the model could also explain why magnetic transitions of low multipole order are often so slow. Note that there is no net magnetic "charge" inside the cage. Magnetic monopoles do not exist. So surface shape would not necessarily affect magnetic transitions much.

While this model leaves many questions unanswered, at least it suggests a reasonable way to understand how it is possible at all that the one-proton model is not just extremely miserable, but systematically miserable in the observed way. For one, it seems to make figure 14.65 far less unexplainable.

## Web Pages

Below is a list of relevant web pages.

1. chemguide.co.uk ${ }^{2}$

Jim Clarke's UK site with lots of solid info.
2. Citizendium ${ }^{3}$

The Citizen's Compendium. Had a rather good write up on the quantization of the electromagnetic field.
3. Elster's lecture notes ${ }^{4}$

Professor Elster gives a very helpful historical overview of the meson exchange potentials, (fewblect_2.pdf). She also gives the detailed potentials for scalar and vector mesons that the other references do not, (fewblect_1.pdf).
4. ENSDF data ${ }^{5}$

The Nuclear Data Sheets are an authoritative and comprehensive data source on nuclei. The corresponding
Nuclear Data Sheets policies ${ }^{6}$
have been used repeatedly in this book to decide what conventions to take as standard.
5. Richard P. Feynman: Nobel Prize lecture ${ }^{7}$

Describes the development of Feynman's path integral approach to quantum electrodynamics.
6. Hyperphysics ${ }^{8}$

Gives simple explanations of almost anything in physics. An extensive source of info on chemical bonds and the periodic table.
7. ICC program ${ }^{9}$

Program to compute internal conversion coefficients.

[^7]
## 8. J. Jäckle ${ }^{10}$

This web site includes a good description of the Peltier and Seebeck effects.
9. R.D. Klauber's pedagogical quantum field theory ${ }^{11}$

This web site gives a fully explained description of quantum field theory.
10. Mayer, M. Goeppert: Nobel Prize lecture ${ }^{12}$

An excellent introduction to the shell model of nuclear physics written for a general audience is found in the lecture.
11. NIST data ${ }^{13}$

Authoritative values of physical constants from NIST.
12. NuDat 2 database ${ }^{14}$

Extensive information about nuclei provided by the National Nuclear Data Center.
13. Purdue chemistry review ${ }^{15}$

General chemistry help.
14. Quantum Exchange ${ }^{16}$

Lots of stuff.
15. Rainwater, J.: Nobel Prize lecture ${ }^{17}$

An introduction to distorted nuclei written for a general audience is found in the lecture.
16. Anthony Stone's Wigner coefficient calculators ${ }^{18}$

The calculator on this site gives exact values for the Wigner $3 \mathrm{j}, 6 \mathrm{j}$, and 6 j symbols. The 3 j symbols are readily converted to ClebschGordan coefficients, $\{\mathrm{N} .13\}$.
17. David Tong's notes on quantum field theory ${ }^{19}$

Very helpful, especially in conjunction with Peskin \& Schroeder, [35].
18. T. $\operatorname{Tritt}^{20}$

Thermoelectric materials: principles, structure, properties, and applications. From Encyclopedia of Materials: Science and Technology. Elsevier 2002.

[^8]19. TUNL Nuclear Data Evaluation Group ${ }^{21}$

Extensive data on light nuclei from $A=3$ to 20 .
20. University of Michigan ${ }^{22}$

Invaluable source on the hydrogen molecule and chemical bonds. Have a look at the animated periodic table for actual atom energy levels.
21. Wikipedia ${ }^{23}$

Probably this book's primary source of information on about every loose end, though somewhat uneven. Some great, some confusing, some overly technical.

## Notations

The below are the simplest possible descriptions of various symbols, just to help you keep reading if you do not remember/know what they stand for. Don't cite them on a math test and then blame this book for your grade.

Watch it. There are so many ad hoc usages of symbols, some will have been overlooked here. Always use common sense first in guessing what a symbol means in a given context

The quoted values of physical constants are usually taken from NIST CODATA in 2012 or later. The final digit of the listed value is normally doubtful. (It corresponds to the first nonzero digit of the standard deviation). Numbers ending in triple dots are exact and could be written down to more digits than listed if needed.

- A dot might indicate
- A dot product between vectors, if in between them.
- A time derivative of a quantity, if on top of it.

And also many more prosaic things (punctuation signs, decimal points, ...).
$\times$ Multiplication symbol. May indicate:

- An emphatic multiplication.
- Multiplication continued on the next line or from the previous line.
- A vectorial product between vectors. In index notation, the $i$-th component of $\vec{v} \times \vec{w}$ equals

$$
(\vec{v} \times \vec{w})_{i}=v_{\bar{\imath}} w_{\overline{\bar{\imath}}}-v_{\overline{\bar{\imath}}} w_{\bar{\imath}}
$$

where $\bar{\imath}$ is the index following $i$ in the sequence 123123..., and $\overline{\bar{\imath}}$ the one preceding it (or second following). Alternatively, evaluate the determinant

$$
\vec{v} \times \vec{w}=\left|\begin{array}{ccc}
\hat{\imath} & \hat{\jmath} & \hat{k} \\
v_{x} & v_{y} & v_{z} \\
w_{x} & w_{y} & w_{z}
\end{array}\right|
$$

! Might be used to indicate a factorial. Example: 5 ! $=1 \times 2 \times 3 \times 4 \times 5=$ 120.

The function that generalizes $n$ ! to noninteger values of $n$ is called the gamma function; $n!=\Gamma(n+1)$. The gamma function generalization is due to, who else, Euler. (However, the fact that $n!=\Gamma(n+1)$ instead of $n$ ! $=\Gamma(n)$ is due to the idiocy of Legendre.) In Legendre-resistant notation,

$$
n!=\int_{0}^{\infty} t^{n} e^{-t} \mathrm{~d} t
$$

Straightforward integration shows that 0 ! is 1 as it should, and integration by parts shows that $(n+1)!=(n+1) n!$, which ensures that the integral also produces the correct value of $n$ ! for any higher integer value of $n$ than 0 . The integral, however, exists for any real value of $n$ above -1 , not just integers. The values of the integral are always positive, tending to positive infinity for both $n \downarrow-1$, (because the integral then blows up at small values of $t$ ), and for $n \uparrow \infty$, (because the integral then blows up at medium-large values of $t$ ). In particular, Stirling's formula says that for large positive $n, n$ ! can be approximated as

$$
n!\sim \sqrt{2 \pi n} n^{n} e^{-n}[1+\ldots]
$$

where the value indicated by the dots becomes negligibly small for large $n$. The function $n$ ! can be extended further to any complex value of $n$, except the negative integer values of $n$, where $n!$ is infinite, but is then no longer positive. Euler's integral can be done for $n=-\frac{1}{2}$ by making the change of variables $\sqrt{t}=u$, producing the integral $\int_{0}^{\infty} 2 e^{-u^{2}} \mathrm{~d} u$, or $\int_{-\infty}^{\infty} e^{-u^{2}} \mathrm{~d} u$, which equals $\sqrt{\int_{-\infty}^{\infty} e^{-x^{2}} \mathrm{~d} x \int_{-\infty}^{\infty} e^{-y^{2}} \mathrm{~d} y}$ and the integral under the square root can be done analytically using polar coordinates. The result is that

$$
\left(-\frac{1}{2}\right)!=\int_{-\infty}^{\infty} e^{-u^{2}} \mathrm{~d} u=\sqrt{\pi}
$$

To get $\frac{1}{2}!$, multiply by $\frac{1}{2}$, since $n!=n(n-1)$ !.
A double exclamation mark may mean every second item is skipped, e.g. $5!!=1 \times 3 \times 5$. In general, $(2 n+1)!!=(2 n+1)!/ 2^{n} n!$. Of course, $5!!$ should logically mean (5!)!. Logic would indicate that $5 \times 3 \times 1$ should be indicated by something like $5!$ '. But what is logic in physics?
| May indicate:

- The magnitude or absolute value of the number or vector, if enclosed between a pair of them.
- The determinant of a matrix, if enclosed between a pair of them.
- The norm of the function, if enclosed between two pairs of them.
- The end of a bra or start of a ket.
- A visual separator in inner products.
$|\ldots\rangle$ A "ket" is used to indicate some state. For example, $|l m\rangle$ indicates an angular momentum state with azimuthal quantum number $l$ and magnetic quantum number $m$. Similarly, $|1 / 2-1 / 2\rangle$ is the spin-down state of a particle with spin $\frac{1}{2}$. Other common ones are $|\underline{x}\rangle$ for the position eigenfunction $\underline{x}$, i.e. $\delta(x-\underline{x}),|1 \mathrm{~s}\rangle$ for the 1 s or $\psi_{100}$ hydrogen state, $\left|2 \mathrm{p}_{z}\right\rangle$ for the $2 \mathrm{p}_{z}$ or $\psi_{210}$ state, etcetera. In short, whatever can indicate some state can be pushed into a ket.
$\langle\ldots|$ A "bra" is like a ket $|\ldots\rangle$, but appears in the left side of inner products, instead of the right one.
$\uparrow$ Indicates the "spin up" state. Mathematically, equals the function $\uparrow\left(S_{z}\right)$ which is by definition equal to 1 at $S_{z}=\frac{1}{2} \hbar$ and equal to 0 at $S_{z}=-\frac{1}{2} \hbar$. A spatial wave function multiplied by $\uparrow$ is a particle in that spatial state with its spin up. For multiple particles, the spins are listed with particle 1 first.
$\downarrow$ Indicates the "spin down" state. Mathematically, equals the function $\downarrow\left(S_{z}\right)$ which is by definition equal to 0 at $S_{z}=\frac{1}{2} \hbar$ and equal to 1 at $S_{z}=-\frac{1}{2} \hbar$. A spatial wave function multiplied by $\downarrow$ is a particle in that spatial state with its spin down. For multiple particles, the spins are listed with particle 1 first.
$\sum$ Summation symbol. Example: if in three dimensional space a vector $\vec{f}$ has components $f_{1}=2, f_{2}=1, f_{3}=4$, then $\sum_{\text {all } i} f_{i}$ stands for $2+1+4=7$.
One important thing to remember: the symbol used for the summation index does not make a difference: $\sum_{\text {all } j} f_{j}$ is exactly the same as $\sum_{\text {all } i} f_{i}$. So freely rename the index, but always make sure that the new name is not already used for something else in the part that it appears in. If you use the same name for two different things, it becomes a mess.
Related to that, $\sum_{\text {all }} f_{i}$ is not something that depends on an index $i$. It is just a combined simple number. Like 7 in the example above. It is commonly said that the summation index "sums away."
$\Pi$ (Not to be confused with $\Pi$ further down.) Multiplication symbol. Example: if in three dimensional space a vector $\vec{f}$ has components $f_{1}=2, f_{2}=$ $1, f_{3}=4$, then $\prod_{\text {all } i} f_{i}$ stands for $2 \times 1 \times 4=6$.
One important thing to remember: the symbol used for the multiplications index does not make a difference: $\prod_{\text {all } j} f_{j}$ is exactly the same as $\prod_{\text {all } i} f_{i}$.

So freely rename the index, but always make sure that the new name is not already used for something else in the part that it appears in. If you use the same name for two different things, it becomes a mess.
Related to that, $\prod_{\text {all } i} f_{i}$ is not something that depends on an index $i$. It is just a combined simple number. Like 6 in the example above. It is commonly said that the multiplication index "factors away." (By who?)
$\int$ Integration symbol, the continuous version of the summation symbol. For example,

$$
\int_{\text {all } x} f(x) \mathrm{d} x
$$

is the summation of $f(x) \mathrm{d} x$ over all infinitesimally small fragments $\mathrm{d} x$ that make up the entire $x$-range. For example, $\int_{x=0}^{2}(2+x) \mathrm{d} x$ equals $3 \times$ $2=6$; the average value of $2+x$ between $x=0$ and $x=2$ is 3 , and the sum of all the infinitesimally small segments $\mathrm{d} x$ gives the total length 2 of the range in $x$ from 0 to 2 .
One important thing to remember: the symbol used for the integration variable does not make a difference: $\int_{\text {all } y} f(y) \mathrm{d} y$ is exactly the same as $\int_{\text {all } x} f(x) \mathrm{d} x$. So freely rename the integration variable, but always make sure that the new name is not already used for something else in the part it appears in. If you use the same name for two different things, it becomes a mess.
Related to that $\int_{\text {all }} f(x) \mathrm{d} x$ is not something that depends on a variable $x$. It is just a combined number. Like 6 in the example above. It is commonly said that the integration variable "integrates away."
$\rightarrow$ May indicate:

- An approaching process. $\lim _{\varepsilon \rightarrow 0}$ indicates for practical purposes the value of the expression following the $\lim$ when $\varepsilon$ is extremely small. Similarly, $\lim _{r \rightarrow \infty}$ indicates the value of the following expression when $r$ is extremely large.
- The fact that the left side leads to, or implies, the right-hand side.
$\rightarrow$ Vector symbol. An arrow above a letter indicates it is a vector. A vector is a quantity that requires more than one number to be characterized. Typical vectors in physics include position $\vec{r}$, velocity $\vec{v}$, linear momentum $\vec{p}$, acceleration $\vec{a}$, force $\vec{F}$, angular momentum $\vec{L}$, etcetera.
- A hat over a letter in this book indicates that it is the operator, turning functions into other functions.
, May indicate:
- A derivative of a function. Examples: $1^{\prime}=0, x^{\prime}=1, \sin ^{\prime}(x)=\cos (x)$, $\cos ^{\prime}(x)=-\sin (x),\left(e^{x}\right)^{\prime}=e^{x}$.
- A small or modified quantity.
- A quantity per unit length.
$\boldsymbol{\nabla}$ The spatial differentiation operator nabla. In Cartesian coordinates:

$$
\nabla \equiv\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right)=\hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

Nabla can be applied to a scalar function $f$ in which case it gives a vector of partial derivatives called the gradient of the function:

$$
\operatorname{grad} f=\nabla f=\hat{\imath} \frac{\partial f}{\partial x}+\hat{\jmath} \frac{\partial f}{\partial y}+\hat{k} \frac{\partial f}{\partial z}
$$

Nabla can be applied to a vector in a dot product multiplication, in which case it gives a scalar function called the divergence of the vector:

$$
\operatorname{div} \vec{v}=\nabla \cdot \vec{v}=\frac{\partial v_{x}}{\partial x}+\frac{\partial v_{y}}{\partial y}+\frac{\partial v_{z}}{\partial z}
$$

or in index notation

$$
\operatorname{div} \vec{v}=\nabla \cdot \vec{v}=\sum_{i=1}^{3} \frac{\partial v_{i}}{\partial x_{i}}
$$

Nabla can also be applied to a vector in a vectorial product multiplication, in which case it gives a vector function called the curl or rot of the vector. In index notation, the $i$-th component of this vector is

$$
(\operatorname{curl} \vec{v})_{i}=(\operatorname{rot} \vec{v})_{i}=(\nabla \times \vec{v})_{i}=\frac{\partial v_{\overline{\overline{\overline{ }}}}}{\partial x_{\bar{\imath}}}-\frac{\partial v_{\bar{\imath}}}{\partial x_{\overline{\bar{\imath}}}}
$$

where $\bar{\imath}$ is the index following $i$ in the sequence $123123 \ldots$, and $\overline{\bar{\imath}}$ the one preceding it (or the second following it).
The operator $\nabla^{2}$ is called the Laplacian. In Cartesian coordinates:

$$
\nabla^{2} \equiv \frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}
$$

Sometimes the Laplacian is indicated as $\Delta$. In relativistic index notation it is equal to $\partial_{i} \partial^{i}$, with maybe a minus sign depending on who you talk with.

In non Cartesian coordinates, don't guess; look these operators up in a table book, [41, pp. 124-126]: . For example, in spherical coordinates,

$$
\begin{equation*}
\nabla=\hat{\imath}_{r} \frac{\partial}{\partial r}+\hat{\imath}_{\theta} \frac{1}{r} \frac{\partial}{\partial \theta}+\hat{\imath}_{\phi} \frac{1}{r \sin \theta} \frac{\partial}{\partial \phi} \tag{N.2}
\end{equation*}
$$

That allows the gradient of a scalar function $f$, i.e. $\nabla f$, to be found immediately. But if you apply $\nabla$ on a vector, you have to be very careful because you also need to differentiate $\hat{\imath}_{r}, \hat{\imath}_{\theta}$, and $\hat{\imath}_{\phi}$. In particular, the correct divergence of a vector $\vec{v}$ is

$$
\begin{equation*}
\nabla \cdot \vec{v}=\frac{1}{r^{2}} \frac{\partial r^{2} v_{r}}{\partial r}+\frac{1}{r \sin \theta} \frac{\partial \sin \theta v_{\theta}}{\partial \theta}+\frac{1}{r \sin \theta} \frac{\partial v_{\phi}}{\partial \phi} \tag{N.3}
\end{equation*}
$$

The curl $\nabla \times \vec{v}$ of the vector is
$\frac{\hat{\imath}_{r}}{r \sin \theta}\left(\frac{\partial \sin \theta v_{\phi}}{\partial \theta}-\frac{\partial v_{\theta}}{\partial \phi}\right)+\frac{\hat{\imath}_{\theta}}{r}\left(\frac{1}{\sin \theta} \frac{\partial v_{r}}{\partial \phi}-\frac{\partial r v_{\phi}}{\partial r}\right)+\frac{\hat{\iota}_{\phi}}{r}\left(\frac{\partial r v_{\theta}}{\partial r}-\frac{\partial v_{r}}{\partial \theta}\right)$
Finally the Laplacian is:

$$
\begin{equation*}
\nabla^{2}=\frac{1}{r^{2}}\left\{\frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r}\right)+\frac{1}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)+\frac{1}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}}\right\} \tag{N.5}
\end{equation*}
$$

See also "spherical coordinates."
Cylindrical coordinates are usually indicated as $r, \theta$ and $z$. Here $z$ is the Cartesian coordinate, while $r$ is the distance from the $z$-axis and $\theta$ the angle around the $z$ axis. In two dimensions, i.e. without the $z$ terms, they are usually called polar coordinates. In cylindrical coordinates:

$$
\begin{gather*}
\nabla=\hat{\imath}_{r} \frac{\partial}{\partial r}+\hat{\imath}_{\theta} \frac{1}{r} \frac{\partial}{\partial \theta}+\hat{\imath}_{z} \frac{\partial}{\partial z}  \tag{N.6}\\
\nabla \cdot \vec{v}=\frac{1}{r} \frac{\partial r v_{r}}{\partial r}+\frac{1}{r} \frac{\partial v_{\theta}}{\partial \theta}+\frac{\partial v_{z}}{\partial z}  \tag{N.7}\\
\nabla \times \vec{v}=\hat{\imath}_{r}\left(\frac{1}{r} \frac{\partial v_{z}}{\partial \theta}-\frac{\partial v_{\theta}}{\partial z}\right)+\hat{\imath}_{\theta}\left(\frac{\partial v_{r}}{\partial z}-\frac{\partial v_{z}}{\partial r}\right)+\frac{\hat{\iota}_{z}}{r}\left(\frac{\partial r v_{\theta}}{\partial r}-\frac{\partial v_{r}}{\partial \theta}\right)  \tag{N.8}\\
\nabla^{2}=\frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial}{\partial r}\right)+\frac{1}{r^{2}} \frac{\partial^{2}}{\partial \theta^{2}}+\frac{\partial^{2}}{\partial z^{2}} \tag{N.9}
\end{gather*}
$$

- The D'Alembertian is defined as

$$
\frac{1}{c^{2}} \frac{\partial^{2}}{\partial t^{2}}-\frac{\partial^{2}}{\partial x^{2}}-\frac{\partial^{2}}{\partial y^{2}}-\frac{\partial^{2}}{\partial z^{2}}
$$

where $c$ is a constant called the wave speed. In relativistic index notation, $\square$ is equal to $-\partial_{\mu} \partial^{\mu}$.

* A superscript star normally indicates a complex conjugate. In the complex conjugate of a number, every $i$ is changed into $a-i$.
$<$ Less than.
$\leqslant \quad$ Less than or equal.
$\langle\ldots\rangle$ May indicate:
- An inner product.
- An expectation value.
$>$ Greater than.
$\geqslant$ Greater than or equal.
[...] May indicate:
- A grouping of terms in a formula.
- A commutator. For example, $[A, B]=A B-B A$.
$=$ Equals sign. The quantity to the left is the same as the one to the right.
$\equiv$ Emphatic equals sign. Typically means "by definition equal" or "everywhere equal."
$\approx$ Indicates approximately equal. Read it as "is approximately equal to."
~ Indicates approximately equal. Often used when the approximation applies only when something is small or large. Read it as "is approximately equal to" or as "is asymptotically equal to."
$\propto$ Proportional to. The two sides are equal except for some unknown constant factor.
$\boldsymbol{\alpha}$ (alpha) May indicate:
- The fine structure constant, $e^{2} / 4 \pi \epsilon_{0} \hbar c$, equal to $7.29735257010^{-3}$, or about $1 / 137$, in value.
- A Dirac equation matrix.
- A nuclear decay mode in which a helium-4 nucleus is emitted.
- Internal conversion rate as fraction of the gamma decay rate.
- Some constant.
- Some angle.
- An eigenfunction of a generic operator $A$.
- A summation index.
- Component index of a vector.
$\boldsymbol{\beta}$ (beta) May indicate:
- A nuclear decay mode in which an electron $\left(\beta^{-}\right)$or positron $\left(\beta^{+}\right)$is emitted. Sometimes $\beta^{+}$is taken to also include electron capture.
- A nuclear vibrational mode that maintains the axial symmetry of the nucleus.
- Some constant.
- Some angle.
- An eigenfunction of a generic operator $B$.
- A summation index.
$\Gamma$ (Gamma) May indicate:
- The Gamma function. Look under "!" for details.
- The "width" or uncertainty in energy of an approximate energy eigenstate.
- Origin in wave number space.
$\boldsymbol{\gamma}$ (gamma) May indicate:
- Gyromagnetic ratio.
- Standard symbol for a photon of electromagnetic radiation.
- A nuclear de-excitation mode in which a photon is emitted.
- A nuclear vibrational mode that messes up the axial symmetry of the nucleus.
- Summation index.
- Integral in the tunneling WKB approximation.
$\boldsymbol{\Delta}$ (capital delta) May indicate:
- An increment in the quantity following it.
- A delta particle.
- Often used to indicate the Laplacian $\nabla^{2}$.
$\boldsymbol{\delta}$ (delta) May indicate:
- With two subscripts, the "Kronecker delta", which by definition is equal to one if its two subscripts are equal, and zero in all other cases.
- Without two subscripts, the "Dirac delta function", which is infinite when its argument is zero, and zero if it is not. In addition the infinity is such that the integral of the delta function over its single nonzero point is unity. The delta function is not a normal function, but a distribution. It is best to think of it as the approximate function shown in the right hand side of figure 7.10 for a very, very, small positive value of $\varepsilon$.
One often important way to create a three-dimensional delta function in spherical coordinates is to take the Laplacian of the function $-1 / 4 \pi r$. Chapter 13.3 explains why. In two dimensions, take the Laplacian of $\ln (r) / 2 \pi$ to get a delta function.
- Often used to indicate a small amount of the following quantity, or of a small change in the following quantity. There are nuanced differences in the usage of $\delta, \partial$ and d that are too much to go in here.
- Often used to indicate a second small quantity in addition to $\varepsilon$.
$\boldsymbol{\partial}$ (partial) Indicates a vanishingly small change or interval of the following variable. For example, $\partial f / \partial x$ is the ratio of a vanishingly small change in function $f$ divided by the vanishingly small change in variable $x$ that causes this change in $f$. Such ratios define derivatives, in this case the partial derivative of $f$ with respect to $x$.
Also used in relativistic index notation, chapter 1.2.5.
$\boldsymbol{\epsilon}$ (epsilon) May indicate:
- $\epsilon_{0}$ is the permittivity of space. Equal to $8.854187817 \ldots 10^{-12} \mathrm{C}^{2} / \mathrm{J}$ m . The exact value is $1 / 4 \pi c^{2} 10^{7} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$, because of the exact SI definitions of ampere and speed of light.
- Scaled energy.
- Orbital energy.
- Lagrangian multiplier.
- A small quantity, if symbol $\varepsilon$ is not available.
$\varepsilon$ (variant of epsilon) May indicate:
- A very small quantity.
- The slop in energy conservation during a decay process.
$\boldsymbol{\eta} \quad$ (eta) May be used to indicate a $y$-position of a particle.
$\boldsymbol{\Theta}$ (capital theta) Used in this book to indicate some function of $\theta$ to be determined.
$\boldsymbol{\theta}$ (theta) May indicate:
- In spherical coordinates, the angle from the chosen $z$ axis, with apex at the origin.
- $z$-position of a particle.
- A generic angle, like the one between the vectors in a cross or dot product.
- Integral acting as an angle in the classical WKB approximation.
- Integral acting as an angle in the adiabatic approximation.
$\vartheta$ (variant of theta) An alternate symbol for $\theta$.
$\boldsymbol{\kappa}$ (kappa) May indicate:
- A constant that physically corresponds to some wave number.
- A summation index.
- Thermal conductivity.
$\Lambda$ (Lambda) May indicate:
- Lorentz transformation matrix.
$\boldsymbol{\lambda}$ (lambda) May indicate:
- Wave length.
- Decay constant.
- A generic eigenvalue.
- Entry of a Lorentz transformation.
- Scaled square momentum.
- Some multiple of something.
$\boldsymbol{\mu}$ (mu) May indicate:
- Magnetic dipole moment:

Alpha particle: 0 (spin is zero).
Deuteron: $0.4330734910^{-26} \mathrm{~J} / \mathrm{T}$ or $0.857438231 \mu_{\mathrm{N}}$.
Electron: - $9.284764310^{-24} \mathrm{~J} / \mathrm{T}$ or $-1.0011596521808 \mu_{\mathrm{B}}$.
Helion: - $1.0746174910^{-26} \mathrm{~J} / \mathrm{T}$ or $-2.127625306 \mu_{\mathrm{N}}$.
Neutron: - $0.966236510^{-26} \mathrm{~J} / \mathrm{T}$ or $-1.9130427 \mu_{\mathrm{N}}$.
Proton: $1.4106067410^{-26} \mathrm{~J} / \mathrm{T}$ or $2.79284736 \mu_{\mathrm{N}}$.
Triton: $1.5046094510^{-26} \mathrm{~J} / \mathrm{T}$ or $2.97896245 \mu_{\mathrm{N}}$.

- $\mu_{\mathrm{B}}=e \hbar / 2 m_{\mathrm{e}}=9.274009710^{-24} \mathrm{~J} / \mathrm{T}$ or $5.78838180710^{-5} \mathrm{eV} / \mathrm{T}$ is the Bohr magneton.
- $\mu_{\mathrm{N}}=e \hbar / 2 m_{\mathrm{p}}=5.050783510^{-27} \mathrm{~J} / \mathrm{T}$ or $3.15245126110^{-8} \mathrm{eV} / \mathrm{T}$ is the nuclear magneton.
- A summation index.
- Chemical potential/molar Gibbs free energy.
$\boldsymbol{\nu}$ (nu) May indicate:
- Electron neutrino.
- Scaled energy eigenfunction number in solids.
- A summation index.
- Strength of a delta function potential.
$\boldsymbol{\xi}$ (xi) May indicate:
- Scaled argument of the one-dimensional harmonic oscillator eigenfunctions.
- $x$-position of a particle.
- A summation or integration index.
$\boldsymbol{\Pi}$ (Oblique Pi ) (Not to be confused with $\Pi$ described higher up.) Parity operator. Replaces $\vec{r}$ by $-\vec{r}$. That is equivalent to a mirroring in a mirror through the origin, followed by a $180^{\circ}$ rotation around the axis normal to the mirror.
$\pi \quad$ (pi) May indicate:
- A constant with value $3.141592653589793238462 \ldots$. .

The area of a circle of radius $r$ is $\pi r^{2}$ and its perimeter is $2 \pi r$. The volume of a sphere of radius $r$ is $\frac{4}{3} \pi r^{3}$ and its surface is $4 \pi r^{2}$. A $180^{\circ}$ angle expressed in radians is $\pi$. Note also that $e^{ \pm \mathrm{i} \pi}=-1$ and $e^{ \pm \mathrm{i} 2 \pi}=1$.

- A chemical bond that looks from the side like a p state.
- A particle involved in the forces keeping the nuclei of atoms together ( $\pi$-meson or pion for short).
- Parity.
$\tilde{\pi}$ Canonical momentum density.
- Electric charge per unit volume.
- Scaled radial coordinate.
- Radial coordinate.
- Eigenfunction of a rotation operator $\mathcal{R}$.
- Mass-base density.
- Energy density of electromagnetic radiation.
$\boldsymbol{\sigma}$ (sigma) May indicate:
- A standard deviation of a value.
- A chemical bond that looks like an s state when seen from the side.
- Pauli spin matrix.
- Surface tension.
- Electrical conductivity.
- $\sigma_{\mathrm{B}}=5.67037 \mathrm{~W} / \mathrm{m}^{2} \mathrm{~K}^{4}$ is the Stefan-Boltzmann
$\boldsymbol{\tau}$ (tau) May indicate:
- A time or time interval.
- Life time or half life.
- Some coefficient.
$\Phi$ (capital phi) May indicate:
- Some function of $\phi$ to be determined.
- The momentum-space wave function.
- Relativistic electromagnetic potential.
$\phi \quad$ (phi) May indicate:
- In spherical coordinates, the angle around the chosen $z$ axis. Increasing $\phi$ by $2 \pi$ encircles the $z$-axis exactly once.
- A phase angle.
- Something equivalent to an angle.
- Field operator $\phi(\vec{r})$ annihilates a particle at position $\vec{r}$ while $\phi^{\dagger}(\vec{r})$ creates one at that position.
$\varphi$ (variant of phi) May indicate:
- A change in angle $\phi$.
- An alternate symbol for $\phi$.
- An electrostatic potential.
- An electrostatic quantum field.
- A hypothetical selectostatic quantum field.
$\chi$ (chi) May indicate
- Spinor component.
- Gauge function of electromagnetic field.
$\Psi \quad$ (capital psi) Upper case psi is used for the wave function.
$\boldsymbol{\psi} \quad(\mathrm{psi})$ Typically used to indicate an energy eigenfunction. Depending on the system, indices may be added to distinguish different ones. In some cases $\psi$ might be used instead of $\Psi$ to indicate a system in an energy eigenstate. Let me know and I will change it. A system in an energy eigenstate should be written as $\Psi=c \psi$, not $\psi$, with $c$ a constant of magnitude 1 .
$\boldsymbol{\Omega}$ (Omega) May indicate:
- Solid angle. See "angle" and "spherical coordinates."
$\boldsymbol{\omega}$ (omega) May indicate:
- Angular frequency of the classical harmonic oscillator. Equal to $\sqrt{c / m}$ where $c$ is the spring constant and $m$ the mass.
- Angular frequency of a system.
- Angular frequency of light waves.
- Perturbation frequency,
- Any quantity having units of frequency, $1 / \mathrm{s}$.

A May indicate:

- Repeatedly used to indicate the operator for a generic physical quantity $a$, with eigenfunctions $\alpha$.
- Electromagnetic vector potential, or four vector potential.
- Einstein $A$ coefficient.
- Some generic matrix.
- Some constant.
- Area.
$\AA$ Ångstrom. Equal to $10^{-10} \mathrm{~m}$.
a May indicate:
- The value of a generic physical quantity with operator $A$
- The amplitude of the spin-up state
- The amplitude of the first state in a two-state system.
- Acceleration.
- Start point of an integration interval.
- The first of a pair of particles.
- Some coefficient.
- Some constant.
- Absorptivity of electromagnetic radiation.
- Annihilation operator $\widehat{a}$ or creation operator $\widehat{a}^{\dagger}$.
- Bohr radius of helium ion.
$\boldsymbol{a}_{\mathbf{0}}$ May indicate:
- Bohr radius, $4 \pi \epsilon_{0} \hbar^{2} / m_{\mathrm{e}} e^{2}$ or $0.5291772109 \AA$, with $\AA=10^{-10} \mathrm{~m}$. Comparable in size to atoms, and a good size to use to simplify various formulae.
- The initial value of a coefficient $a$.
absolute May indicate:
- The absolute value of a real number $a$ is indicated by $|a|$. It equals $a$ is $a$ is positive or zero and $-a$ if $a$ is negative.
- The absolute value of a complex number $a$ is indicated by $|a|$. It equals the length of the number plotted as a vector in the complex plane. This simplifies to above definition if $a$ is real.
- An absolute temperature is a temperature measured from absolute zero. At absolute zero all systems are in their ground state. Absolute zero is $-273.15{ }^{\circ} \mathrm{C}$ in degrees Centrigrade (Celsius). The SI absolute temperature scale is degrees Kelvin, K. Absolute zero temperature is 0 K , while $0{ }^{\circ} \mathrm{C}$ is 273.15 K .
adiabatic An adiabatic process is a process in which there is no heat transfer with the surroundings. If the process is also reversible, it is called isentropic. Typically, these processes are fairly quick, in order not to give heat conduction enough time to do its stuff, but not so excessively quick that they become irreversible.
Adiabatic processes in quantum mechanics are defined quite differently to keep students on their toes. See chapter 7.1.5. These processes are very slow, to give the system all possible time to adjust to its surroundings. Of course, quantum physicist were not aware that the same term had already been used for a hundred years or so for relatively fast processes. They assumed they had just invented a great new term!
adjoint The adjoint $A^{H}$ or $A^{\dagger}$ of an operator is the one you get if you take it to the other side of an inner product. (While keeping the value of the inner product the same regardless of whatever two vectors or functions may be involved.) Hermitian operators are "self-adjoint;" they do not change if you take them to the other side of an inner product. "SkewHermitian" operators just change sign. "Unitary operators" change into their inverse when taken to the other side of an inner product. Unitary operators generalize rotations of vectors: an inner product of vectors is the same whether you rotate the first vector one way, or the second vector the opposite way. Unitary operators preserve inner products (when applied to both vectors or functions). Fourier transforms are unitary operators on account of the Parseval equality that says that inner products are preserved.
amplitude Everything in quantum mechanics is an amplitude. However, most importantly, the "quantum amplitude" gives the coefficient of a state in a wave function. For example, the usual quantum wave function gives the quantum amplitude that the particle is at the given position.
angle Consider two semi-infinite lines extending from a common intersection point. Then the angle between these lines is defined in the following way: draw a unit circle in the plane of the lines and centered at their intersection point. The angle is then the length of the circular arc that is in between the lines. More precisely, this gives the angle in radians, rad. Sometimes an angle is expressed in degrees, where $2 \pi$ rad is taken to be $360^{\circ}$. However, using degrees is usually a very bad idea in science.
In three dimensions, you may be interested in the so-called "solid angle" $\Omega$ inside a conical surface. This angle is defined in the following way: draw a sphere of unit radius centered at the apex of the conical surface. Then the solid angle is the area of the spherical surface that is inside the cone. Solid angles are in steradians. The cone does not need to be a circular
one, (i.e. have a circular cross section), for this to apply. In fact, the most common case is the solid angle corresponding to an infinitesimal element $\mathrm{d} \theta \times \mathrm{d} \phi$ of spherical coordinate system angles. In that case the surface of the unit sphere inside the conical surface is is approximately rectangular, with sides $\mathrm{d} \theta$ and $\sin (\theta) \mathrm{d} \phi$. That makes the enclosed solid angle equal to $\mathrm{d} \Omega=\sin (\theta) \mathrm{d} \theta \mathrm{d} \phi$.

B May indicate:

- Repeatedly used to indicate a generic second operator or matrix.
- Einstein $B$ coefficient.
- Some constant.
$\mathcal{B}$ May indicate:
- Magnetic field strength.
b May indicate:
- Repeatedly used to indicate the amplitude of the spin-down state
- Repeatedly used to indicate the amplitude of the second state in a two-state system.
- End point of an integration interval.
- The second of a pair of particles.
- Some coefficient.
- Some constant.
basis A basis is a minimal set of vectors or functions that you can write all other vectors or functions in terms of. For example, the unit vectors $\hat{\imath}$, $\hat{\jmath}$, and $\hat{k}$ are a basis for normal three-dimensional space. Every threedimensional vector can be written as a linear combination of the three.

C May indicate:

- A third matrix or operator.
- A variety of different constants.
${ }^{\circ} \mathbf{C}$ Degrees Centigrade. A commonly used temperature scale that has the value $-273.15^{\circ} \mathrm{C}$ instead of zero when systems are in their ground state. Recommendation: use degrees Kelvin (K) instead. However, differences in temperature are the same in Centigrade as in Kelvin.
c May indicate:
- The speed of light, $299792458 \mathrm{~m} / \mathrm{s}$ exactly (by definition of the velocity unit).
- Speed of sound.
- Spring constant.
- A variety of different constants.

Cauchy-Schwartz inequality The Cauchy-Schwartz inequality describes a limitation on the magnitude of inner products. In particular, it says that for any $f$ and $g$,

$$
|\langle f \mid g\rangle| \leq \sqrt{\langle f \mid f\rangle} \sqrt{\langle g \mid g\rangle}
$$

In words, the magnitude of an inner product $\langle f \mid g\rangle$ is at most the magnitude (i.e. the length or norm) of $f$ times the one of $g$. For example, if $f$ and $g$ are real vectors, the inner product is the dot product and you have $f \cdot g=|f||g| \cos \theta$, where $|f|$ is the length of vector $f$ and $|g|$ the one of $g$, and $\theta$ is the angle in between the two vectors. Since a cosine is less than one in magnitude, the Cauchy-Schwartz inequality is therefore true for vectors.

But it is true even if $f$ and $g$ are functions. To prove it, first recognize that $\langle f \mid g\rangle$ may in general be a complex number, which according to (2.6) must take the form $e^{i \alpha}|\langle f \mid g\rangle|$ where $\alpha$ is some real number whose value is not important, and that $\langle g \mid f\rangle$ is its complex conjugate $e^{-\mathrm{i} \alpha}|\langle f \mid g\rangle|$. Now, (yes, this is going to be some convoluted reasoning), look at

$$
\left\langle f+\lambda e^{-\mathrm{i} \alpha} g \mid f+\lambda e^{-\mathrm{i} \alpha} g\right\rangle
$$

where $\lambda$ is any real number. The above dot product gives the square magnitude of $f+\lambda e^{-\mathrm{i} \alpha} g$, so it can never be negative. But if you multiply out, you get

$$
\langle f \mid f\rangle+2|\langle f \mid g\rangle| \lambda+\langle g \mid g\rangle \lambda^{2}
$$

and if this quadratic form in $\lambda$ is never negative, its discriminant must be less or equal to zero:

$$
|\langle f \mid g\rangle|^{2} \leq\langle f \mid f\rangle\langle g \mid g\rangle
$$

and taking square roots gives the Cauchy-Schwartz inequality.
Classical Can mean any older theory. In this work, most of the time it either means "nonquantum," or "nonrelativistic."
cos The cosine function, a periodic function oscillating between 1 and -1 as shown in [41, pp. 40-]. See also "sin."
curl The curl of a vector $\vec{v}$ is defined as $\operatorname{curl} \vec{v}=\operatorname{rot} \vec{v}=\nabla \times \vec{v}$.

D May indicate:

- Difference in wave number values.
$\vec{D} \quad$ Primitive (translation) vector of a reciprocal lattice.
D Density of states.
D Often used to indicate a state with two units of orbital angular momentum.
d May indicate:
- The distance between the protons of a hydrogen molecule.
- The distance between the atoms or lattice points in a crystal.
- A constant.
$\overrightarrow{\boldsymbol{d}}$ Primitive (translation) vector of a crystal lattice.
d Indicates a vanishingly small change or interval of the following variable. For example, $\mathrm{d} x$ can be thought of as a small segment of the $x$-axis.
In three dimensions, $\mathrm{d}^{3} \vec{r} \equiv \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z$ is an infinitesimal volume element. The symbol $\int$ means that you sum over all such infinitesimal volume elements.
derivative A derivative of a function is the ratio of a vanishingly small change in a function divided by the vanishingly small change in the independent variable that causes the change in the function. The derivative of $f(x)$ with respect to $x$ is written as $\mathrm{d} f / \mathrm{d} x$, or also simply as $f^{\prime}$. Note that the derivative of function $f(x)$ is again a function of $x$ : a ratio $f^{\prime}$ can be found at every point $x$. The derivative of a function $f(x, y, z)$ with respect to $x$ is written as $\partial f / \partial x$ to indicate that there are other variables, $y$ and $z$, that do not vary.
determinant The determinant of a square matrix $A$ is a single number indicated by $|A|$. If this number is nonzero, $A \vec{v}$ can be any vector $\vec{w}$ for the right choice of $\vec{v}$. Conversely, if the determinant is zero, $A \vec{v}$ can only produce a very limited set of vectors, though if it can produce a vector $w$, it can do so for multiple vectors $\vec{v}$.

There is a recursive algorithm that allows you to compute determinants from increasingly bigger matrices in terms of determinants of smaller matrices. For a $1 \times 1$ matrix consisting of a single number, the determinant is simply that number:

$$
\left|a_{11}\right|=a_{11}
$$

(This determinant should not be confused with the absolute value of the number, which is written the same way. Since you normally do not deal with $1 \times 1$ matrices, there is normally no confusion.) For $2 \times 2$ matrices, the determinant can be written in terms of $1 \times 1$ determinants:

$$
\left|\begin{array}{ll}
a_{11} & a_{12} \\
a_{21} & a_{22}
\end{array}\right|=+a_{11}\left|\quad a_{22}\right|-a_{12}\left|a_{21}\right|
$$

so the determinant is $a_{11} a_{22}-a_{12} a_{21}$ in short. For $3 \times 3$ matrices, you have

$$
\left|\begin{array}{lll}
a_{11} & a_{12} & a_{13} \\
a_{21} & a_{22} & a_{23} \\
a_{31} & a_{32} & a_{33}
\end{array}\right|=
$$

$$
\left.+a_{11}\left|\begin{array}{ll}
a_{22} & a_{23} \\
a_{32} & a_{33}
\end{array}\right|-a_{12}\left|\begin{array}{cc}
a_{21} & a_{23} \\
a_{31} & a_{33}
\end{array}\right|+a_{13} \right\rvert\, \begin{array}{ll}
a_{21} & a_{22} \\
a_{31} & a_{32}
\end{array}
$$

and you already know how to work out those $2 \times 2$ determinants, so you now know how to do $3 \times 3$ determinants. Written out fully:

$$
a_{11}\left(a_{22} a_{33}-a_{23} a_{32}\right)-a_{12}\left(a_{21} a_{33}-a_{23} a_{31}\right)+a_{13}\left(a_{21} a_{32}-a_{22} a_{31}\right)
$$

For $4 \times 4$ determinants,

$$
\begin{aligned}
& \left|\begin{array}{llll}
a_{11} & a_{12} & a_{13} & a_{14} \\
a_{21} & a_{22} & a_{23} & a_{24} \\
a_{31} & a_{32} & a_{33} & a_{34} \\
a_{41} & a_{42} & a_{43} & a_{44}
\end{array}\right|= \\
& +a_{11}\left|\begin{array}{lll}
a_{22} & a_{23} & a_{24} \\
a_{32} & a_{33} & a_{34} \\
a_{42} & a_{43} & a_{44}
\end{array}\right|-a_{12}\left|\begin{array}{ccc} 
& \\
a_{21} & a_{23} & a_{24} \\
a_{31} & a_{33} & a_{34} \\
a_{41} & a_{43} & a_{44}
\end{array}\right| \\
& \left.+a_{13}\left|\begin{array}{lll} 
& & \\
a_{21} & a_{22} & a_{24} \\
a_{31} & a_{32} & a_{34} \\
a_{41} & a_{42} & a_{44}
\end{array}\right|-a_{14} \right\rvert\, \begin{array}{ccc}
a_{21} & a_{22} & a_{23} \\
a_{31} & a_{32} & a_{33} \\
a_{41} & a_{42} & a_{43}
\end{array}
\end{aligned}
$$

Etcetera. Note the alternating sign pattern of the terms.
As you might infer from the above, computing a good size determinant takes a large amount of work. Fortunately, it is possible to simplify the matrix to put zeros in suitable locations, and that can cut down the work of finding the determinant greatly. You are allowed to use the following manipulations without seriously affecting the computed determinant:

1. You can "transpose" the matrix, i.e. change its columns into its rows.
2. You can create zeros in a row by subtracting a suitable multiple of another row.
3. You can also swap rows, as long as you remember that each time that you swap two rows, it will flip over the sign of the computed determinant.
4. You can also multiply an entire row by a constant, but that will multiply the computed determinant by the same constant.
Applying these tricks in a systematic way, called "Gaussian elimination" or "reduction to upper triangular form", you can eliminate all matrix coefficients $a_{i j}$ for which $j$ is less than $i$, and that makes evaluating the determinant pretty much trivial.
$\operatorname{div}($ ergence $) \quad$ The divergence of a vector $\vec{v}$ is defined as $\operatorname{div} \vec{v}=\nabla \cdot \vec{v}$.
$E$ May indicate:

- The total energy. Possible values are the eigenvalues of the Hamiltonian.
- $E_{n}=E_{1} / n^{2}=-m_{\mathrm{e}} e^{4} / 32 \pi^{2} \epsilon_{0}^{2} \hbar^{2} n^{2}=-\hbar^{2} / 2 m_{\mathrm{e}} a_{0}^{2} n^{2}=\frac{1}{2} \alpha^{2} m_{\mathrm{e}} c^{2} / n^{2}$ may indicate the nonrelativistic (Bohr) energy levels of the hydrogen atom. The ground state energy $E_{1}$ equals -13.6056925 eV . This does not include relativistic and proton motion corrections.
- Internal energy of a substance.
$\mathcal{E}$ May indicate:
- Electric field strength.
e May indicate:
- The basis for the natural logarithms. Equal to $2.718281828459 \ldots$ This number produces the "exponential function" $e^{x}$, or $\exp (x)$, or in words " $e$ to the power $x$ ", whose derivative with respect to $x$ is again $e^{x}$. If $a$ is a constant, then the derivative of $e^{a x}$ is $a e^{a x}$. Also, if $a$ is an ordinary real number, then $e^{\mathrm{i} a}$ is a complex number with magnitude 1.
- The magnitude of the charge of an electron or proton, equal to $1.6021765710^{-19} \mathrm{C}$.
- Emissivity of electromagnetic radiation.
- Often used to indicate a unit vector.
- A superscript $e$ may indicate a single-electron quantity.
- Specific internal energy of a substance.
e May indicate
- Subscript e may indicate an electron.
$e^{\mathrm{i} a x}$ Assuming that $a$ is an ordinary real number, and $x$ a real variable, $e^{\mathrm{i} a x}$ is a complex function of magnitude one. The derivative of $e^{\mathrm{i} a x}$ with respect to $x$ is $\mathrm{i} a e^{\mathrm{i} a x}$
eigenvector A concept from linear algebra. A vector $\vec{v}$ is an eigenvector of a matrix $A$ if $\vec{v}$ is nonzero and $A \vec{v}=\lambda \vec{v}$ for some number $\lambda$ called the corresponding eigenvalue.
The basic quantum mechanics section of this book avoids linear algebra completely, and the advanced part almost completely. The few exceptions are almost all two-dimensional matrix eigenvalue problems. In case you did not have any linear algebra, here is the solution: the two-dimensional matrix eigenvalue problem

$$
\left(\begin{array}{ll}
a_{11} & a_{12} \\
a_{21} & a_{22}
\end{array}\right) \vec{v}=\lambda \vec{v}
$$

has eigenvalues that are the two roots of the quadratic equation

$$
\lambda^{2}-\left(a_{11}+a_{22}\right) \lambda+a_{11} a_{22}-a_{12} a_{21}=0
$$

The corresponding eigenvectors are

$$
\vec{v}_{1}=\binom{a_{12}}{\lambda_{1}-a_{11}} \quad \vec{v}_{2}=\binom{\lambda_{2}-a_{22}}{a_{21}}
$$

On occasion you may have to swap $\lambda_{1}$ and $\lambda_{2}$ to use these formulae. If $\lambda_{1}$ and $\lambda_{2}$ are equal, there might not be two eigenvectors that are not multiples of each other; then the matrix is called defective. However, Hermitian matrices are never defective.
See also "matrix" and "determinant."
$\mathbf{e V}$ The electron volt, a commonly used unit of energy. Its value is equal to $1.602176570^{-19} \mathrm{~J}$.
exponential function A function of the form $e^{\cdots}$, also written as $\exp (\ldots)$. See "function" and "e."
F May indicate:

- The force in Newtonian mechanics. Equal to the negative gradient of the potential. Quantum mechanics is formulated in terms of potentials, not forces.
- The anti-derivative of some function $f$.
- Some function.
- Helmholtz free energy.
$\mathcal{F} \quad$ Fock operator.
$f$ May indicate:
- A generic function.
- A generic vector.
- A fraction.
- The resonance factor.
- Specific Helmholtz free energy.
- Frequency.
function A mathematical object that associates values with other values. A function $f(x)$ associates every value of $x$ with a value $f$. For example, the function $f(x)=x^{2}$ associates $x=0$ with $f=0, x=\frac{1}{2}$ with $f=\frac{1}{4}, x=1$ with $f=1, x=2$ with $f=4, x=3$ with $f=9$, and more generally, any arbitrary value of $x$ with the square of that value $x^{2}$. Similarly, function $f(x)=x^{3}$ associates any arbitrary $x$ with its cube $x^{3}, f(x)=\sin (x)$ associates any arbitrary $x$ with the sine of that value, etcetera.
One way of thinking of a function is as a procedure that allows you, whenever given a number, to compute another number.
A wave function $\Psi(x, y, z)$ associates each spatial position $(x, y, z)$ with a wave function value. Going beyond mathematics, its square magnitude associates any spatial position with the relative probability of finding the particle near there.
functional A functional associates entire functions with single numbers. For example, the expectation energy is mathematically a functional: it associates any arbitrary wave function with a number: the value of the expectation energy if physics is described by that wave function.
$G$ May indicate:
- Gibbs free energy.
- Newton's constant of gravitation, $6.673810^{-11} \mathrm{~m}^{3} / \mathrm{kg} \mathrm{s}^{2}$.
g May indicate:
- A second generic function or a second generic vector.
- The strength of gravity, by definition equal to $9.80665 \mathrm{~m} / \mathrm{s}^{2}$ exactly under standard conditions on the surface of the earth.
- The g-factor, a nondimensional constant that indicates the gyromagnetic ratio relative to charge and mass. For the electron $g_{e}=$ -2.0023193043615 . For the proton $g_{p}=5.58569471$. For the neutron, based on the mass and charge of the proton, $g_{n}=-3.8260855$.
- Specific Gibbs free energy/chemical potential.

Gauss' Theorem This theorem, also called divergence theorem or GaussOstrogradsky theorem, says that for a continuously differentiable vector $\vec{v}$,

$$
\int_{V} \nabla \cdot \vec{v} \mathrm{~d} V=\int_{A} \vec{v} \cdot \vec{n} \mathrm{~d} A
$$

where the first integral is over the volume of an arbitrary region and the second integral is over all the surface area of that region; $\vec{n}$ is at each point found as the unit vector that is normal to the surface at that point.
$\operatorname{grad}($ ient $) \quad$ The gradient of a scalar $f$ is defined as $\operatorname{grad} f=\nabla f$.
$\boldsymbol{H}$ May indicate:

- The Hamiltonian, or total energy, operator. Its eigenvalues are indicated by $E$.
- $H_{n}$ stands for the $n$-th order Hermite polynomial.
- Enthalpy.
$\boldsymbol{h}$ May indicate:
- The original Planck constant $h=2 \pi \hbar$.
- $h_{n}$ is a one-dimensional harmonic oscillator eigenfunction.
- Single-electron Hamiltonian.
- Specific enthalpy.
$\hbar \quad$ The reduced Planck constant, equal to $1.0545717310^{-34} \mathrm{~J}$ s. A measure of the uncertainty of nature in quantum mechanics. Multiply by $2 \pi$ to get the original Planck constant $h$. For nuclear physics, a frequently helpful value is $\hbar c=197.326972 \mathrm{MeV} \mathrm{fm}$.
hypersphere A hypersphere is the generalization of the normal three-dimensional sphere to $n$-dimensional space. A sphere of radius $R$ in three-dimensional space consists of all points satisfying

$$
r_{1}^{2}+r_{2}^{2}+r_{3}^{2} \leqslant R^{2}
$$

where $r_{1}, r_{2}$, and $r_{3}$ are Cartesian coordinates with origin at the center of the sphere. Similarly a hypersphere in $n$-dimensional space is defined as all points satisfying

$$
r_{1}^{2}+r_{2}^{2}+\ldots+r_{n}^{2} \leqslant R^{2}
$$

So a two-dimensional "hypersphere" of radius $R$ is really just a circle of radius $R$. A one-dimensional "hypersphere" is really just the line segment $-R \leqslant x \leqslant-R$.
The "volume" $\mathcal{V}_{n}$ and surface "area" $A_{n}$ of an $n$-dimensional hypersphere is given by

$$
\begin{gathered}
\mathcal{V}_{n}=C_{n} R^{n} \quad A_{n}=n C_{n} R^{n-1} \\
C_{n}=\left\{\begin{array}{l}
(2 \pi)^{n / 2} / 2 \times 4 \times 6 \times \ldots \times n \text { if } n \text { is even } \\
(2 \pi)^{(n-1) / 2} 2 / 1 \times 3 \times 5 \times \ldots \times n \text { if } n \text { is odd }
\end{array}\right.
\end{gathered}
$$

(This is readily derived recursively. For a sphere of unit radius, note that the $n$-dimensional "volume" is an integration of $n$ - 1 -dimensional volumes with respect to $r_{1}$. Then renotate $r_{1}$ as $\sin \phi$ and look up the resulting integral in a table book. The formula for the area follows because $\mathcal{V}=\int A \mathrm{~d} r$ where $r$ is the distance from the origin.) In three dimensions, $C_{3}=4 \pi / 3$ according to the above formula. That makes the three-dimensional "volume" $4 \pi R^{3} / 3$ equal to the actual volume of the sphere, and the three-dimensional "area" $4 \pi R^{2}$ equal to the actual surface area. On the other hand in two dimensions, $C_{2}=\pi$. That makes the two-dimensional "volume" $\pi R^{2}$ really the area of the circle. Similarly the two-dimensional surface "area" $2 \pi R$ is really the perimeter of the circle. In one dimensions $C_{1}=2$ and the "volume" $2 R$ is really the length of the interval, and the "area" 2 is really its number of end points.
Often the infinitesimal $n$-dimensional "volume" element $\mathrm{d}^{n} \vec{r}$ is needed. This is the infinitesimal integration element for integration over all coordinates. It is:

$$
\mathrm{d}^{n} \vec{r}=\mathrm{d} r_{1} \mathrm{~d} r_{2} \ldots \mathrm{~d} r_{n}=\mathrm{d} A_{n} \mathrm{~d} r
$$

Specifically, in two dimensions:

$$
\mathrm{d}^{2} \vec{r}=\mathrm{d} r_{1} \mathrm{~d} r_{2}=\mathrm{d} x \mathrm{~d} y=(r \mathrm{~d} \theta) \mathrm{d} r=\mathrm{d} A_{2} \mathrm{~d} r
$$

while in three dimensions:

$$
\mathrm{d}^{3} \vec{r}=\mathrm{d} r_{1} \mathrm{~d} r_{2} \mathrm{~d} r_{3}=\mathrm{d} x \mathrm{~d} y \mathrm{~d} z=\left(r^{2} \sin \theta \mathrm{~d} \theta \mathrm{~d} \phi\right) \mathrm{d} r=\mathrm{d} A_{3} \mathrm{~d} r
$$

The expressions in parentheses are $\mathrm{d} A_{2}$ in polar coordinates, respectively $\mathrm{d} A_{3}$ in spherical coordinates.
I May indicate:

- The number of electrons or particles.
- Electrical current.
- Unit matrix or operator, which does not do anything. See "matrix."
- $I_{\mathrm{A}}$ is Avogadro's number, $6.022141310^{26}$ particles per kmol. (More standard symbols are $N_{\mathrm{A}}$ or $L$, but they are incompatible with the general notations in this book.)
$\Im$ The imaginary part of a complex number. If $c=c_{r}+\mathrm{i} c_{i}$ with $c_{r}$ and $c_{i}$ real numbers, then $\Im(c)=c_{i}$. Note that $c-c^{*}=2 \mathrm{i} \Im(c)$.

I May indicate:

- $\mathcal{I}$ is radiation energy intensity.
- $\mathcal{I}_{\mathrm{R}}$ is moment of inertia.
i May indicate:
- The number of a particle.
- A summation index.
- A generic index or counter.

Not to be confused with i.
$\hat{\imath}$ The unit vector in the $x$-direction.
i The standard square root of minus one: $\mathrm{i}=\sqrt{-1}, \mathrm{i}^{2}=-1,1 / \mathrm{i}=-\mathrm{i}, \mathrm{i}^{*}=$ -i.
index notation A more concise and powerful way of writing vector and matrix components by using a numerical index to indicate the components. For Cartesian coordinates, you might number the coordinates $x$ as $1, y$ as 2 , and $z$ as 3 . In that case, a sum like $v_{x}+v_{y}+v_{z}$ can be more concisely written as $\sum_{i} v_{i}$. And a statement like $v_{x} \neq 0, v_{y} \neq 0, v_{z} \neq 0$ can be more compactly written as $v_{i} \neq 0$. To really see how it simplifies the notations, have a look at the matrix entry. (And that one shows only 2 by 2 matrices. Just imagine 100 by 100 matrices.)
iff Emphatic "if." Should be read as "if and only if."
integer Integer numbers are the whole numbers: ..., $-2,-1,0,1,2,3,4, \ldots$.
inverse (Of matrices or operators.) If an operator $A$ converts a vector or function $f$ into a vector or function $g$, then the inverse of the operator $A^{-1}$ converts $g$ back into $f$. For example, the operator 2 converts vectors or functions into two times themselves, and its inverse operator $\frac{1}{2}$ converts these back into the originals. Some operators do not have inverses. For example, the operator 0 converts all vectors or functions into zero. But given zero, there is no way to figure out what function or vector it came from; the inverse operator does not exist.
irrotational A vector $\vec{v}$ is irrotational if its curl $\nabla \times \vec{v}$ is zero.
iso Means "equal" or "constant."

- Isenthalpic: constant enthalpy.
- Isentropic: constant entropy. This is a process that is both adiabatic and reversible.
- Isobaric: constant pressure.
- Isochoric: constant (specific) volume.
- Isospin: you don't want to know.
- Isothermal: constant temperature.
isolated An isolated system is one that does not interact with its surroundings in any way. No heat is transfered with the surroundings, no work is done on or by the surroundings.
$J$ May indicate:
- Total angular momentum.
- Number of nuclei in a quantum computation of electronic structure.
$j$ May indicate:
- The azimuthal quantum number of total angular momentum, including both orbital and spin contributions.
- $\vec{j}$ is electric current density.
- The number of a nucleus in a quantum computation.
- A summation index.
- A generic index or counter.
$\hat{\jmath}$ The unit vector in the $y$-direction.
$K$ May indicate:
- An exchange integral in Hartree-Fock.
- Maximum wave number value.
$\mathcal{K} \quad$ Thomson (Kelvin) coefficient.
K May indicate:
- The atomic states or orbitals with theoretical Bohr energy $E_{1}$
- Degrees Kelvin.
$\boldsymbol{k}$ May indicate:
- A wave number. A wave number is a measure for how fast a periodic function oscillates with variations in spatial position. In quantum mechanics, $k$ is normally defined as $\sqrt{2 m(E-V)} / \hbar$. The vector $\vec{k}$ is not to be confused with the unit vector in the $z$-direction $\hat{k}$.
- A generic summation index.
$\hat{\boldsymbol{k}} \quad$ The unit vector in the $z$-direction.
$\boldsymbol{k}_{\mathbf{B}}$ Boltzmann constant. Equal to $1.38064910^{-23} \mathrm{~J} / \mathrm{K}$. Relates absolute temperature to a typical unit of heat motion energy.
kmol A kilo mole refers to $6.022141310^{26}$ atoms or molecules. The weight of this many particles is about the number of protons and neutrons in the atom nucleus/molecule nuclei. So a kmol of hydrogen atoms has a mass of about 1 kg , and a kmol of hydrogen molecules about 2 kg . A kmol of helium atoms has a mass of about 4 kg , since helium has two protons and two neutrons in its nucleus. These numbers are not very accurate, not just because the electron masses are ignored, and the free neutron and proton masses are somewhat different, but also because of relativity effects that cause actual nuclear masses to deviate from the sum of the free proton and neutron masses.
$L$ May indicate:
- Angular momentum.
- Orbital angular momentum.
$\mathcal{L}$ Lagrangian.
L The atomic states or orbitals with theoretical Bohr energy $E_{2}$
$l$ May indicate:
- The azimuthal quantum number of angular momentum.
- The azimuthal quantum number of orbital angular momentum. Here $s$ is used for spin, and $j$ for combined angular momentum.)
- A generic summation index.
$\ell$ May indicate:
- The typical length in the harmonic oscillator problem.
- The dimensions of a solid block (with subscripts).
- A length.
- Multipole level in transitions.
$£ \quad$ Lagrangian density. This is best understood in the UK.
$\lim$ Indicates the final result of an approaching process. $\lim _{\varepsilon \rightarrow 0}$ indicates for practical purposes the value of the following expression when $\varepsilon$ is extremely small.
linear combination A very generic concept indicating sums of objects times coefficients. For example, a position vector $\vec{r}$ in basic physics is the linear combination $x \hat{\imath}+y \hat{\jmath}+z \hat{k}$ with the objects the unit vectors $\hat{\imath}, \hat{\jmath}$, and $\hat{k}$ and the coefficients the position coordinates $x, y$, and $z$. A linear combination of a set of functions $f_{1}(x), f_{2}(x), f_{3}(x), \ldots, f_{n}(x)$ would be the function

$$
c_{1} f_{1}(x)+c_{2} f_{2}(x)+c_{3} f_{3}(x)+\ldots c_{n} f_{n}(x)
$$

where $c_{1}, c_{2}, c_{3}, \ldots, c_{n}$ are constants, i.e. independent of $x$.
linear dependence A set of vectors or functions is linearly dependent if at least one of the set can be expressed in terms of the others. Consider the example of a set of functions $f_{1}(x), f_{2}(x), \ldots, f_{n}(x)$. This set is linearly dependent if

$$
c_{1} f_{1}(x)+c_{2} f_{2}(x)+c_{3} f_{3}(x)+\ldots c_{n} f_{n}(x)=0
$$

where at least one of the constants $c_{1}, c_{2}, c_{2}, \ldots, c_{n}$ is nonzero. To see why, suppose that say $c_{2}$ is nonzero. Then you can divide by $c_{2}$ and rearrange to get

$$
f_{2}(x)=-\frac{c_{1}}{c_{2}} f_{1}(x)-\frac{c_{3}}{c_{2}} f_{3}(x)-\ldots-\frac{c_{n}}{c_{2}} f_{n}(x)
$$

That expresses $f_{2}(x)$ in terms of the other functions.
linear independence A set of vectors or functions is linearly independent if none of the set can be expressed in terms of the others. Consider the example of a set of functions $f_{1}(x), f_{2}(x), \ldots, f_{n}(x)$. This set is linearly independent if

$$
c_{1} f_{1}(x)+c_{2} f_{2}(x)+c_{3} f_{3}(x)+\ldots c_{n} f_{n}(x)=0
$$

only if every one of the constants $c_{1}, c_{2}, c_{3}, \ldots, c_{n}$ is zero. To see why, assume that say $f_{2}(x)$ could be expressed in terms of the others,

$$
f_{2}(x)=C_{1} f_{1}(x)+C_{3} f_{3}(x)+\ldots+C_{n} f_{n}(x)
$$

Then taking $c_{2}=1, c_{1}=-C_{1}, c_{3}=-C_{3}, \ldots c_{n}=-C_{n}$, the condition above would be violated. So $f_{2}$ cannot be expressed in terms of the others.

M May indicate:

- Molecular mass. See "molecular mass."
- Figure of merit.
$\mathcal{M}$ Mirror operator.
M The atomic states or orbitals with theoretical Bohr energy $E_{3}$
$\boldsymbol{m}$ May indicate:
- Mass.
- $m_{\mathrm{e}}$ : electron mass. Equal to $9.109382910^{-31} \mathrm{~kg}$. The rest mass energy is 0.51099893 MeV .
- $m_{\mathrm{p}}$ : proton mass. Equal to $1.6726217810^{-27} \mathrm{~kg}$. The rest mass energy is 938.272013 MeV .
$-m_{\mathrm{n}}$ : neutron mass. Equal to $1.67492710^{-27} \mathrm{~kg}$. The rest mass energy is 939.565561 MeV .
- Alpha particle: $6.644656810^{-27} \mathrm{~kg}$ or 3727.37924 MeV .

Deuteron: $3.343583510^{-27} \mathrm{~kg}$ or 1875.61286 MeV .
Helion: $5.006412310^{-27} \mathrm{~kg}$ or 2808.391482 MeV .
$-m_{\mathrm{u}}=1.6605389210^{-27} \mathrm{~kg}$ is the atomic mass constant.

- $m$ : generic particle mass.
- The magnetic quantum number of angular momentum. The type odf angular momentum may be indicated by a subscript $l$ for orbital, $s$ for spin, or $j$ for net (orbital plus spin).
- Number of a single-electron wave function.
- Number of rows in a matrix.
- A generic summation index or generic integer.
matrix A table of numbers.
As a simple example, a two-dimensional (or $2 \times 2$ ) matrix $A$ is a table of four numbers called $a_{11}, a_{12}, a_{21}$, and $a_{22}$ :

$$
A=\left(\begin{array}{ll}
a_{11} & a_{12} \\
a_{21} & a_{22}
\end{array}\right)
$$

unlike a two-dimensional vector $\vec{v}$, which would consist of only two numbers $v_{1}$ and $v_{2}$ arranged in a column:

$$
\vec{v}=\binom{v_{1}}{v_{2}}
$$

(Such a vector can be seen as a "rectangular matrix" of size $2 \times 1$, but let's not get into that.) (Note that in quantum mechanics, if a vector is written as a column, considered the normal case, it is called a "ket" vector. If the complex conjugates of its numbers are written as a row, it is called a "bra" vector.)
In "index notation," a matrix $A$ is a set of numbers, or "coefficients," $\left\{a_{i j}\right\}$ indexed by two indices. The first index $i$ is the row number at which the coefficient $\left\{a_{i j}\right\}$ is found in matrix $A$, and the second index $j$ is the column number. In index notation, a matrix turns a vector $\vec{v}$ into another vector $\vec{w}=A \vec{v}$ according to the recipe

$$
w_{i}=\sum_{\text {all } j} a_{i j} v_{j} \quad \text { for all } i
$$

where $v_{j}$ stands for "the $j$-th component of vector $\vec{v}$," and $w_{i}$ for "the $i$-th component of vector $\vec{w}$."
As an example, the product of $A$ and $\vec{v}$ above is by definition

$$
\left(\begin{array}{ll}
a_{11} & a_{12} \\
a_{21} & a_{22}
\end{array}\right)\binom{v_{1}}{v_{2}}=\binom{a_{11} v_{1}+a_{12} v_{2}}{a_{21} v_{1}+a_{22} v_{2}}
$$

which is just another two-dimensional ket vector.
Note that in matrix multiplications, like in the example above, in geometric terms you take dot products between the rows of the first factor and the columns of the second factor.
To multiply two matrices together, just think of the columns of the second matrix as separate vectors. For example, to multiply two $2 \times 2$ matrices $A$ and $B$ together:

$$
\left(\begin{array}{ll}
a_{11} & a_{12} \\
a_{21} & a_{22}
\end{array}\right)\left(\begin{array}{ll}
b_{11} & b_{12} \\
b_{21} & b_{22}
\end{array}\right)=\left(\begin{array}{ll}
a_{11} b_{11}+a_{12} b_{21} & a_{11} b_{12}+a_{12} b_{22} \\
a_{21} b_{11}+a_{22} b_{21} & a_{21} b_{12}+a_{22} b_{22}
\end{array}\right)
$$

which is another two-dimensional matrix.
(Note that you cannot normally swap the order of matric multiplication. The matrix $B A$ is different from matrix $A B$. In the special case that $A B$ and $B A$ are the same and $A$ and $B$ have complete sets of eigenvectors, then they have a common complete set of eigenvectors, $\{\mathrm{D} .18\}$.)
In index notation, if $C=A B$, then each coefficient $c_{i j}$ of matrix $C$ is given in terms of the coefficients of $A$ and $B$ as

$$
c_{i j}=\sum_{k} a_{i k} b_{k j}
$$

Note that the index $k$ that you sum over is the second of $A$ but the first of $B$. In short, you sum over "neighboring indices." Since you sum over all $k$, the result does not depend on $k$.
The zero matrix, usually called $Z$, is like the number zero; it does not change a matrix it is added to. And it turns whatever it is multiplied with into zero. A zero matrix has every coefficient zero. For example, in two dimensions:

$$
Z=\left(\begin{array}{ll}
0 & 0 \\
0 & 0
\end{array}\right)
$$

A unit, or identity, matrix, usually called $I$, is the equivalent of the number one for matrices; it does not change the vector or matrix it is multiplied with. A unit matrix is one on its "main diagonal" $i=j$ and zero elsewhere. The 2 by 2 unit matrix is:

$$
I=\left(\begin{array}{ll}
1 & 0 \\
0 & 1
\end{array}\right)
$$

More generally the coefficients, $\left\{\delta_{i j}\right\}$, of a unit matrix are one if $i=j$ and zero otherwise.
The "transpose" of a matrix $A, A^{\mathrm{T}}$, is what you get if you swap the two indices. Graphically, it turns its rows into its columns and vice versa. The "adjoint" or "Hermitian adjoint" matrix $A^{\dagger}$ is what you get if you both swap the two indices in a matrix $A$ and then take the complex conjugate of every coefficient. If you want to take a matrix to the other side of an inner product, you will need to change it to its Hermitian adjoint. "Hermitian matrices"are equal to their Hermitian adjoint, so this does nothing for them.
The inverse of a matrix $A, A^{-1}$ is a matrix so that $A^{-1} A$ equals the identity matrix $I$. That is much like the inverse of a simple number times that number gives one. And, just like the number zero has no inverse, a matrix with zero determinant has no inverse. Otherwise, you can swap the order;
$A A^{-1}$ equals the unit matrix too. (For numbers this is trivial, for matrices you need to look a bit closer to understand why it is true.)
See also "determinant" and "eigenvector."
metric prefixes In the metric system, the prefixes $Y, Z, E, P, T, G, M$, and k stand for $10^{i}$ with $i=24,21,18,15,12,9,6$, and 3 , respectively. Similarly, $\mathrm{d}, \mathrm{c}, \mathrm{m}, \mu, \mathrm{n}, \mathrm{p}, \mathrm{f}, \mathrm{a}, \mathrm{z}, \mathrm{y}$ stand for $10^{-i}$ with $i=1,2,3,6,9,12$, $15,18,21$, and 24 respectively. For example, 1 ns is $10^{-9}$ seconds. English letter $u$ is often used as instead of greek $\mu$. Names corresponding to the mentioned prefixes $\mathrm{Y}-\mathrm{k}$ are yotta, zetta, exa, peta, tera, giga, mega, kilo, and corresponding to $\mathrm{d}-\mathrm{y}$ are deci, centi, milli, micro, nano, pico, femto, atto, zepto, and yocto.
molecular mass Typical thermodynamics books for engineers tabulate values of the "molecular mass," as a nondimensional number. The bottom line first: these numbers should have been called the "molar mass" of the substance, for the naturally occurring isotope ratio on earth. And they should have been given units of $\mathrm{kg} / \mathrm{kmol}$. That is how you use these numbers in actual computations. So just ignore the fact that what these books really tabulate is officially called the "relative molecular mass" for the natural isotope ratio.
Don't blame these textbooks too much for making a mess of things. Physicists have historically bandied about a zillion different names for what is essentially a single number. Like "molecular mass," "relative molecular mass," "molecular weight," "atomic mass," "relative atomic mass," "atomic weight," "molar mass," "relative molar mass," etcetera are basically all the same thing.
All of these have values that equal the mass of a molecule relative to a reference value for a single nucleon. So these value are about equal to the number of nucleons (protons and neutrons) in the nuclei of a single molecule. (For an isotope ratio, that becomes the average number of nucleons. Do note that nuclei are sufficiently relativistic that a proton or neutron can be noticeably heavier in one nucleus than another, and that neutrons are a bit heavier than protons even in isolation.) The official reference nucleon weight is defined based on the most common carbon isotope carbon-12. Since carbon- 12 has 6 protons plus 6 neutrons, the reference nucleon weight is taken to be one twelfth of the carbon-12 atomic weight. That is called the unified atomic mass unit (u) or Dalton (Da). The atomic mass unit (amu) is an older virtually identical unit, but physicists and chemists could never quite agree on what its value was. No kidding.
If you want to be politically correct, the deal is as follows. "Molecular mass" is just what the term says, the mass of a molecule, in mass units.
(I found zero evidence in either the IUPAC Gold Book or NIST SP811 for the claim of Wikipedia that it must always be expressed in u.) "Molar mass" is just what the words says, the mass of a mole. Official SI units are $\mathrm{kg} / \mathrm{mol}$, but you will find it in $\mathrm{g} / \mathrm{mol}$, equivalent to $\mathrm{kg} / \mathrm{kmol}$. (You cannot expect enough brains from international committees to realize that if you define the kg and not the g as unit of mass, then it would be a smart idea to also define kmol instead of mol as unit of particle count.) Simply ignore relative atomic and molecular masses, you do not care about them. (I found zero evidence in either the IUPAC Gold Book or NIST SP811 for the claims of Wikipedia that the molecular mass cannot be an average over isotopes or that the molar mass must be for a natural isotope ratio. In fact, NIST uses "molar mass of carbon-12" and specifically includes the possibility of an average in the relative molecular mass.)
See also the atomic mass constant " $m_{\mathrm{u}}$."
N May indicate:

- Number of states.
- Number of single-particle states.
- Number of neutrons in a nucleus.

N May indicate

- The atomic states or orbitals with theoretical Bohr energy $E_{4}$.
- Subscript N indicates a nucleus.
$n$ May indicate:
- The principal quantum number for hydrogen atom energy eigenfunctions.
- A quantum number for harmonic oscillator energy eigenfunctions.
- Number of a single-electron or single-particle wave function.
- Generic summation index over energy eigenfunctions.
- Generic summation index over other eigenfunctions.
- Integer factor in Fourier wave numbers.
- Probability density.
- Number of columns in a matrix.
- A generic summation index or generic integer.
- A natural number.
- $n_{s}$ is the number of spin states.
and maybe some other stuff.
n May indicate
- A subscript n may indicate a neutron.
natural Natural numbers are the numbers: $1,2,3,4, \ldots$.
normal A normal operator or matrix is one that has orthonormal eigenfunctions or eigenvectors. Since eigenvectors are not orthonormal in general, a normal operator or matrix is abnormal! Another example of a highly confusing term. Such a matrix should have been called orthodiagonalizable or something of the kind. To be fair, the author is not aware of any physicists being involved in this particular term; it may be the mathematicians that are to blame here.
For an operator or matrix $A$ to be "normal," it must commute with its Hermitian adjoint, $\left[A, A^{\dagger}\right]=0$. Hermitian matrices are normal since they are equal to their Hermitian adjoint. Skew-Hermitian matrices are normal since they are equal to the negative of their Hermitian adjoint. Unitary matrices are normal because they are the inverse of their Hermitian adjoint.
O May indicate the origin of the coordinate system.
opposite The opposite of a number $a$ is $-a$. In other words, it is the additive inverse.
$P$ May indicate:
- The linear momentum eigenfunction.
- A power series solution.
- Probability.
- Pressure
- Hermitian part of an annihilation operator.
$\mathcal{P} \quad$ Particle exchange operator. Exchanges the positions and spins of two identical particles.
$\mathcal{P}$ Peltier coefficient.
P Often used to indicate a state with one unit of orbital angular momentum.
$\boldsymbol{p}$ May indicate:
- Linear momentum.
- Linear momentum in the $x$-direction.
- Integration variable with units of linear momentum.
p May indicate
- An energy state with orbital azimuthal quantum number $l=1$.
- A superscript p may indicate a single-particle quantity.
- A subscript p may indicate a periodic function.
- A subscript p may indicate a proton.
perpendicular bisector For two given points $P$ and $Q$, the perpendicular bisector consists of all points $R$ that are equally far from $P$ as they are from $Q$. In two dimensions, the perpendicular bisector is the line that passes through the point exactly half way in between $P$ and $Q$, and that is orthogonal to the line connecting $P$ and $Q$. In three dimensions, the perpendicular bisector is the plane that passes through the point exactly half way in between $P$ and $Q$, and that is orthogonal to the line connecting $P$ and $Q$. In vector notation, the perpendicular bisector of points $P$ and $Q$ is all points $R$ whose radius vector $\vec{r}$ satisfies the equation:

$$
\left(\vec{r}-\vec{r}_{P}\right) \cdot\left(\vec{r}_{Q}-\vec{r}_{P}\right)=\frac{1}{2}\left(\vec{r}_{Q}-\vec{r}_{P}\right) \cdot\left(\vec{r}_{Q}-\vec{r}_{P}\right)
$$

(Note that the halfway point $\vec{r}-\vec{r}_{P}=\frac{1}{2}\left(\vec{r}_{Q}-\vec{r}_{P}\right)$ is included in this formula, as is the half way point plus any vector that is normal to $\left(\vec{r}_{Q}-\vec{r}_{P}\right)$.)
phase angle Any complex number can be written in "polar form" as $c=$ $|c| e^{\mathrm{i} \alpha}$ where both the magnitude $|c|$ and the phase angle $\alpha$ are real numbers. Note that when the phase angle varies from zero to $2 \pi$, the complex number $c$ varies from positive real to positive imaginary to negative real to negative imaginary and back to positive real. When the complex number is plotted in the complex plane, the phase angle is the direction of the number relative to the origin. The phase angle $\alpha$ is often called the argument, but so is about everything else in mathematics, so that is not very helpful.
In complex time-dependent waves of the form $e^{\mathrm{i}(\omega t-\phi)}$, and its real equivalent $\cos (\omega t-\phi)$, the phase angle $\phi$ gives the angular argument of the wave at time zero.
photon Unit of electromagnetic radiation (which includes light, x-rays, microwaves, etcetera). A photon has a energy $\hbar \omega$, where $\omega$ is its angular frequency, and a wave length $2 \pi c / \omega$ where $c$ is the speed of light.
potential In order to optimize confusion, pretty much everything in physics that is scalar is called potential. Potential energy is routinely concisely referred to as potential. It is the energy that a particle can pick up from a force field by changing its position. It is in Joule. But an electric potential is taken to be per unit charge, which gives it units of volts. Then there are thermodynamic potentials like the chemical potential.
$\boldsymbol{p}_{\boldsymbol{x}}$ Linear momentum in the $x$-direction. (In the one-dimensional cases at the end of the unsteady evolution chapter, the $x$ subscript is omitted.) Components in the $y$ - and $z$-directions are $p_{y}$ and $p_{z}$. Classical Newtonian physics has $p_{x}=m u$ where $m$ is the mass and $u$ the velocity in the $x$-direction. In quantum mechanics, the possible values of $p_{x}$ are the eigenvalues of the operator $\widehat{p}_{x}$ which equals $\hbar \partial / \mathrm{i} \partial x$. (But which becomes canonical momentum in a magnetic field.)

Q May indicate

- Number of energy eigenfunctions of a system of particles.
- Anti-Hermitian part of an annihilation operator divided by i.
- Heat flow or heat.
- Charge.
- Electric quadrupole moment.
- Energy release.
$\boldsymbol{q}$ May indicate:
- Charge.
- Heat flux density.
- The number of an energy eigenfunction of a system of particles.
- Generic index.
$R$ May indicate:
- Ideal gas constant.
- Transition rate.
- Nuclear radius.
- Reflection coefficient.
- Some radius or typical radius (like in the Yukawa potential).
- Some function of $r$ to be determined.
- Some function of $(x, y, z)$ to be determined.
- $R_{n l}$ is a hydrogen radial wave function
- $R_{\mathrm{u}}=8.314462 \mathrm{~kJ} / \mathrm{kmol} \mathrm{K}$ is the universal gas constant. It is the equivalent of Boltzmann's constant, but for a kmol instead of a single atom or molecule.
$\mathcal{R}$ Rotation operator.
$\Re$ The real part of a complex number. If $c=c_{r}+\mathrm{i} c_{i}$ with $c_{r}$ and $c_{i}$ real numbers, then $\Re(c)=c_{r}$. Note that $c+c^{*}=2 \Re(c)$.
$r$ May indicate:
- The radial distance from the chosen origin of the coordinate system.
- $r_{i}$ typically indicates the $i$-th Cartesian component of the radius vector $\vec{r}$.
- Some ratio.
$\vec{r}$ The position vector. In Cartesian coordinates $(x, y, z)$ or $x \hat{\imath}+y \hat{\jmath}+z \hat{k}$. In spherical coordinates $r \hat{i}_{r}$. Its three Cartesian components may be indicated by $r_{1}, r_{2}, r_{3}$ or by $x, y, z$ or by $x_{1}, x_{2}, x_{3}$.
reciprocal The reciprocal of a number $a$ is $1 / a$. In other words, it is the multiplicative inverse.
relativity The special theory of relativity accounts for the experimental observation that the speed of light $c$ is the same in all local coordinate systems. It necessarily drops the basic concepts of absolute time and length that were corner stones in Newtonian physics.
Albert Einstein should be credited with the boldness to squarely face up to the unavoidable where others wavered. However, he should also be credited for the boldness of swiping the basic ideas from Lorentz and Poincaré without giving them proper, or any, credit. The evidence is very strong he was aware of both works, and his various arguments are almost carbon copies of those of Poincaré, but in his paper it looks like it all came from Einstein, with the existence of the earlier works not mentioned. (Note that the general theory of relativity, which is of no interest to this book, is almost surely properly credited to Einstein. But he was a lot less hungry then.)
Relativity implies that a length seen by an observer moving at a speed $v$ is shorter than the one seen by a stationary observer by a factor $\sqrt{1-(v / c)^{2}}$ assuming the length is in the direction of motion. This is called LorentzFitzgerald contraction. It makes galactic travel somewhat more conceivable because the size of the galaxy will contract for an astronaut in a
rocket ship moving close to the speed of light. Relativity also implies that the time that an event takes seems to be slower by a factor $1 / \sqrt{1-(v / c)^{2}}$ if the event is seen by an observer in motion compared to the location where the event occurs. That is called time dilation. Some high-energy particles generated in space move so fast that they reach the surface of the earth though this takes much more time than the particles would last at rest in a laboratory. The decay time increases because of the motion of the particles. (Of course, as far as the particles themselves see it, the distance to travel is a lot shorter than it seems to be to earth. For them, it is a matter of length contraction.)
The following formulae give the relativistic mass, momentum, and kinetic energy of a particle in motion:

$$
m=\frac{m_{0}}{\sqrt{1-(v / c)^{2}}} \quad p=m v \quad T=m c^{2}-m_{0} c^{2}
$$

where $m_{0}$ is the rest mass of the particle, i.e. the mass as measured by an observer to whom the particle seems at rest. The formula for kinetic energy reflects the fact that even if a particle is at rest, it still has an amount of "build-in" energy equal to $m_{0} c^{2}$ left. The total energy of a particle in empty space, being kinetic and rest mass energy, is given by

$$
E=m c^{2}=\sqrt{\left(m_{0} c^{2}\right)^{2}+c^{2} p^{2}}
$$

as can be verified by substituting in the expression for the momentum, in terms of the rest mass, and then taking both terms inside the square root under a common denominator. For small linear momentum $p$, this can be approximated as $\frac{1}{2} m_{0} v^{2}$.
Relativity seemed quite a dramatic departure of Newtonian physics when it developed. Then quantum mechanics started to emerge...
rot The rot of a vector $\vec{v}$ is defined as curl $\vec{v} \equiv \operatorname{rot} \vec{v} \equiv \nabla \times \vec{v}$.
$S$ May indicate:

- Number of states per unit volume.
- Number of states at a given energy level.
- Spin angular momentum (as an alternative to using $L$ or $J$ for generic angular momentum.)
- Entropy.
- $S_{12}$ is a factor in the so-called tensor potential of nucleons.
$\mathcal{S}$ The action integral of Lagrangian mechanics, $\{$ A.1 $\}$

S Seebeck coefficient.

S Often used to indicate a state of zero orbital angular momentum.
$s$ May indicate:

- Spin value of a particle. Equals $1 / 2$ for electrons, protons, and neutrons, is also half an odd natural number for other fermions, and is a nonnegative integer for bosons. It is the azimuthal quantum number $l$ due to spin.
- Specific entropy.
- As an index, shelf number.
s May indicate:
- An energy state with orbital azimuthal quantum number $l=0$. Such a state is spherically symmetric.
scalar A quantity that is not a vector, a quantity that is just a single number.
$\sin$ The sine function, a periodic function oscillating between 1 and -1 as shown in [41, pp. 40-]. Good to remember: $\cos ^{2} \alpha+\sin ^{2} \alpha=1$ and $\sin 2 \alpha$ $=2 \sin \alpha \cos \alpha$ and $\cos 2 \alpha=\cos ^{2} \alpha-\sin ^{2} \alpha$.
solenoidal A vector $\vec{v}$ is solenoidal if its divergence $\nabla \cdot \vec{v}$ is zero.
spectrum In this book, a spectrum normally means a plot of energy levels along the vertical axis. Often, the horizontal coordinate is used to indicate a second variable, such as the density of states or the particle velocity.
For light (photons), a spectrum can be obtained experimentally by sending the light through a prism. This separates the colors in the light, and each color means a particular energy of the photons.

The word spectrum is also often used in a more general mathematical sense, but not in this book as far as I can remember.
spherical coordinates The spherical coordinates $r, \theta$, and $\phi$ of an arbitrary point P are defined as

Figure N.3: Spherical coordinates of an arbitrary point P.

In Cartesian coordinates, the unit vectors in the $x, y$, and $z$ directions are called $\hat{\imath}, \hat{\jmath}$, and $\hat{k}$. Similarly, in spherical coordinates, the unit vectors in the $r, \theta$, and $\phi$ directions are called $\hat{\imath}_{r}, \hat{\imath}_{\theta}$, and $\hat{\imath}_{\phi}$. Here, say, the $\theta$ direction is defined as the direction of the change in position if you increase $\theta$ by an infinitesimally small amount while keeping $r$ and $\varphi$ the same. Note therefore in particular that the direction of $\hat{\imath}_{r}$ is the same as that of $\vec{r}$; radially outward.
An arbitrary vector $\vec{v}$ can be decomposed in components $v_{r}, v_{\theta}$, and $v_{\phi}$ along these unit vectors. In particular

$$
\vec{v} \equiv v_{r} \hat{\imath}_{r}+v_{\theta} \hat{\imath}_{\theta}+v_{\phi} \hat{\imath}_{\phi}
$$

Recall from calculus that in spherical coordinates, a volume integral of an arbitrary function $f$ takes the form

$$
\int f \mathrm{~d}^{3} \vec{r}=\iiint f r^{2} \sin \theta \mathrm{~d} r \mathrm{~d} \theta \mathrm{~d} \phi
$$

In other words, the volume element in spherical coordinates is

$$
\mathrm{d} V=\mathrm{d}^{3} \vec{r}=r^{2} \sin \theta \mathrm{~d} r \mathrm{~d} \theta \mathrm{~d} \phi
$$

Often it is convenient of think of volume integrations as a two-step process: first perform an integration over the angular coordinates $\theta$ and $\phi$. Physically, that integrates over spherical surfaces. Then perform an integration over $r$ to integrate all the spherical surfaces together. The combined infinitesimal angular integration element

$$
\mathrm{d} \Omega=\sin \theta \mathrm{d} \theta \mathrm{~d} \phi
$$

is called the infinitesimal "solid angle" $\mathrm{d} \Omega$. In two-dimensional polar coordinates $r$ and $\theta$, the equivalent would be the infinitesimal polar angle $\mathrm{d} \theta$. Recall that $\mathrm{d} \theta$, (in proper radians of course), equals the arclength of an infinitesimal part of the circle of integration divided by the circle radius. Similarly $\mathrm{d} \Omega$ is the surface of an infinitesimal part of the sphere of integration divided by the square sphere radius.
See the " $\nabla$ " entry for the gradient operator and Laplacian in spherical coordinates.

Stokes' Theorem This theorem, first derived by Kelvin and first published by someone else I cannot recall, says that for any reasonably smoothly varying vector $\vec{v}$,

$$
\int_{A}(\nabla \times \vec{v}) \mathrm{d} A=\oint \vec{v} \cdot \mathrm{~d} \vec{r}
$$

where the first integral is over any smooth surface area $A$ and the second integral is over the edge of that surface. How did Stokes get his name on it? He tortured his students with it, that's how!
One important consequence of the Stokes theorem is for vector fields $\vec{v}$ that are "irrotational," i.e. that have $\nabla \times \vec{v}=0$. Such fields can be written as

$$
\vec{v}=\nabla f \quad f(\vec{r}) \equiv \int_{\overrightarrow{\underline{r}}=\vec{r}_{\text {ref }}}^{\vec{r}} \vec{v}(\underline{\vec{r}}) \cdot \mathrm{d} \underline{\vec{r}}
$$

Here $\vec{r}_{\text {ref }}$ is the position of an arbitrarily chosen reference point, usually the origin. The reason the field $\vec{v}$ can be written this way is the Stokes theorem. Because of the theorem, it does not make a difference along which path from $\vec{r}_{\text {ref }}$ to $\vec{r}$ you integrate. (Any two paths give the same answer, as long as $\vec{v}$ is irrotational everywhere in between the paths.) So the definition of $f$ is unambiguous. And you can verify that the partial derivatives of $f$ give the components of $\vec{v}$ by approaching the final position $\vec{r}$ in the integration from the corresponding direction.
symmetry A symmetry is an operation under which an object does not change. For example, a human face is almost, but not completely, mirror symmetric: it looks almost the same in a mirror as when seen directly. The electrical field of a single point charge is spherically symmetric; it looks the same from whatever angle you look at it, just like a sphere does. A simple smooth glass (like a glass of water) is cylindrically symmetric; it looks the same whatever way you rotate it around its vertical axis.
$T$ May indicate:

- Absolute temperature. The absolute temperature in degrees K equals the temperature in centigrade plus 273.15. When the absolute tem-
perature is zero, (i.e. at $-273.15^{\circ} \mathrm{C}$ ), nature is in the state of lowest possible energy.
- Kinetic energy. A hat indicates the associated operator. The operator is given by the Laplacian times $-\hbar^{2} / 2 m$.
- Isospin. A hat indicates the associated operator. A vector symbol or subscript distinguishes it from kinetic energy.
- Tesla. The unit of magnetic field strength, $\mathrm{kg} / \mathrm{C}-\mathrm{s}$.
$\boldsymbol{\mathcal { T }}$ Translation operator that translates a wave function through space. The amount of translation is usually indicated by a subscript.
$\boldsymbol{t}$ May indicate:
- Time.
- $t_{t}$ is the quantum number of square isospin.
temperature A measure of the heat motion of the particles making up macroscopic objects. At absolute zero temperature, the particles are in the "ground state" of lowest possible energy.
triple product A product of three vectors. There are two different versions:
- The scalar triple product $\vec{a} \cdot(\vec{b} \times \vec{c})$. In index notation,

$$
\vec{a} \cdot(\vec{b} \times \vec{c})=\sum_{i} a_{i}\left(b_{\bar{i}} c_{\overline{\bar{\imath}}}-b_{\overline{\bar{\imath}}} c_{\bar{\imath}}\right)
$$

where $\bar{\imath}$ is the index following $i$ in the sequence 123123..., and $\overline{\bar{\imath}}$ the one preceding it. This triple product equals the determinant $|\vec{a} \vec{b} \vec{c}|$ formed with the three vectors. Geometrically, it is plus or minus the volume of the parallelepiped that has vectors $\vec{a}, \vec{b}$, and $\vec{c}$ as edges. Either way, as long as the vectors are normal vectors and not operators,

$$
\vec{a} \cdot(\vec{b} \times \vec{c})=\vec{b} \cdot(\vec{c} \times \vec{a})=\vec{c} \cdot(\vec{a} \times \vec{b})
$$

and you can change the two sides of the dot product without changing the triple product, and/or you can change the sides in the vectorial product with a change of sign. If any of the vectors is an operator, use the index notation expression to work it out.

- The vectorial triple product $\vec{a} \times(\vec{b} \times \vec{c})$. In index notation, component number $i$ of this triple product is

$$
a_{\bar{\imath}}\left(b_{i} c_{\bar{\imath}}-b_{\bar{\imath}} c_{i}\right)-a_{\bar{\imath}}\left(b_{\overline{\bar{\imath}}} c_{i}-b_{i} c_{\bar{\imath}}\right)
$$

which may be rewritten as

$$
a_{i} b_{i} c_{i}+a_{\bar{\imath}} b_{i} c_{\bar{\imath}}+a_{\bar{\imath}} b_{i} c_{\bar{\imath}}-a_{i} b_{i} c_{i}-a_{\bar{\imath}} b_{\bar{\imath}} c_{i}-a_{\bar{\imath}} b_{\bar{\imath}} c_{i}
$$

In particular, as long as the vectors are normal ones,

$$
\vec{a} \times(\vec{b} \times \vec{c})=(\vec{a} \cdot \vec{c}) \vec{b}-(\vec{a} \cdot \vec{b}) \vec{c}
$$

$U$ May indicate:

- A unitary operator, in other words one that does not change the magnitude of the wave function.
- Often used for energy, though not in this book.
$\boldsymbol{U}$ The time shift operator: $\mathcal{U}(\tau, t)$ changes the wave function $\Psi(\ldots ; t)$ into $\Psi(\ldots ; t+\tau)$. If the Hamiltonian is independent of time

$$
\mathcal{U}(\tau, t)=\mathcal{U}_{\tau}=e^{-\mathrm{i} H \tau / \hbar}
$$

$\boldsymbol{u}$ May indicate:

- The first velocity component in a Cartesian coordinate system.
- A complex coordinate in the derivation of spherical harmonics.
- An integration variable.
u May indicate the atomic mass constant, equivalent to $1.6605389210^{-27} \mathrm{~kg}$ or $931.49406 \mathrm{MeV} / c^{2}$.
$V$ May indicate:
- The potential energy. $V$ is used interchangeably for the numerical values of the potential energy and for the operator that corresponds to multiplying by $V$. In other words, $\widehat{V}$ is simply written as $V$.
$\mathcal{V}$ Volume.
$\boldsymbol{v}$ May indicate:
- The second velocity component in a Cartesian coordinate system.
- Magnitude of a velocity (speed).
- $v$ is specific volume.
- A complex coordinate in the derivation of spherical harmonics.
- As $v^{\mathrm{ee}}$, a single electron pair potential.
$\vec{v}$ May indicate:
- Velocity vector.
- Generic vector.
- Summation index of a lattice potential.
vector Simply put, a list of numbers. A vector $\vec{v}$ in index notation is a set of numbers $\left\{v_{i}\right\}$ indexed by an index $i$. In normal three-dimensional Cartesian space, $i$ takes the values 1, 2, and 3, making the vector a list of three numbers, $v_{1}, v_{2}$, and $v_{3}$. These numbers are called the three components of $\vec{v}$. The list of numbers can be visualized as a column, and is then called a ket vector, or as a row, in which case it is called a bra vector. This convention indicates how multiplication should be conducted with them. A bra times a ket produces a single number, the dot product or inner product of the vectors:

$$
(1,3,5)\left(\begin{array}{c}
7 \\
11 \\
13
\end{array}\right)=17+311+513=105
$$

To turn a ket into a bra for purposes of taking inner products, write the complex conjugates of its components as a row.
Formal definitions of vectors vary, but real mathematicians will tell you that vectors are objects that can be manipulated in certain ways (addition and multiplication by a scalar). Some physicists define vectors as objects that transform in a certain way under coordinate transformation (one-dimensional tensors); that is not the same thing.
vectorial product An vectorial product, or cross product is a product of vectors that produces another vector. If

$$
\vec{c}=\vec{a} \times \vec{b}
$$

it means in index notation that the $i$-th component of vector $\vec{c}$ is

$$
c_{i}=a_{\bar{\imath}} b_{\overline{\bar{\imath}}}-a_{\bar{\imath}} b_{\bar{\imath}}
$$

where $\bar{\imath}$ is the index following $i$ in the sequence 123123..., and $\overline{\bar{\imath}}$ the one preceding it. For example, $c_{1}$ will equal $a_{2} b_{3}-a_{3} b_{2}$.

W May indicate:

- Watt, the SI unit of power.
- The $\mathrm{W}^{ \pm}$are the charged carriers of the weak force. See also " $\mathrm{Z}^{0}$."
- W.u. stands for Weisskopf unit, a simple decay ballpark for gamma decay.
$\boldsymbol{w}$ May indicate:
- The third velocity component in a Cartesian coordinate system.
- Weight factor.
$\overrightarrow{\boldsymbol{w}} \quad$ Generic vector.
$\boldsymbol{X} \quad$ Used in this book to indicate a function of $x$ to be determined.
$x$ May indicate:
- First coordinate in a Cartesian coordinate system.
- A generic argument of a function.
- An unknown value.
$Y$ Used in this book to indicate a function of $y$ to be determined.
$Y_{l}^{m} \quad$ Spherical harmonic. Eigenfunction of both angular momentum in the $z$-direction and of total square angular momentum.
$\boldsymbol{y}$ May indicate:
- Second coordinate in a Cartesian coordinate system.
- A second generic argument of a function.
- A second unknown value.
$Z$ May indicate:
- Atomic number (number of protons in the nucleus).
- Number of particles.
- Partition function.
- The $Z^{0}$ is the uncharged carrier of the weak force. See also "W"."
- Used in this book to indicate a function of $z$ to be determined.
$z \quad$ May indicate:
- Third coordinate in a Cartesian coordinate system.
- A third generic argument of a function.
- A third unknown value.

spectral line broadening, 335
spectrum, $\underline{1531}$
hydrogen, 108
spherical Bessel functions, 879
spherical coordinates, $93, \underline{1531}$
unit vectors, $\underline{1532}$
volume integral, 1532
spherical Hankel functions, 880
spherical harmonics
derivation, 1377
derivation from the ODE, 1240
derivation using ladders, 1377
generic expression, 1242
intro, 96
Laplace equation derivation, 1244
parity, 1242
spherical Neumann functions, 879
spheroid, 774
spin, 155
fundamental commutation relations
introduction, 160
nuclei
data, 755
value, 156
$x$ - and $y$-eigenstates, 601
spin down, 156
spin orbital, 446
spin states
ambiguity in sign, 1384
axis rotation, 1383
spin up, 156
spin-adapted configuration, 453
spin-orbit interaction

$$
\text { nucleons, } 707
$$

spinor, 158
spontaneous emission
multiple initial or final states, 370
quantum derivation, 1044
spontaneous fission, 751
s state, 110, 111
standard deviation, 114
definition, 116
simplified expression, 118
standard model, 332
Stark effect, 1134
stationary states, 321
statistical interpretation, 57
Stefan-Boltzmann formula, 570
Stefan-Boltzmann law, 227
steradians, 1102
Stern-Gerlach apparatus, 636
stoichiometric coefficient, 561
Stokes' theorem, 1533
string theory, 936
strong force, 647
intro, 356
superallowed beta decays, 1202
superallowed decay
beta decay, 825
superconductivity, 256
Cooper pairs, 217
superfluidity
Feynman argument, 222
superionic conductors, 266
superluminal interaction
Bell's theorem, 411
hidden variables, 412
many worlds interpretation, 425
quantum, 52
do not allow communication, 414
produce paradoxes, 414
relativistic paradoxes, 15
surface tension, 732
symmetrization requirement
fermions, see antisymmetrization
graphical depiction, 524
identical bosons, 166
indistinguishable particles, 525
using groupings, 171
using occupation numbers, 913
using permanents, 171
symmetry, 1533
$T, 1533$
$\mathcal{T}, \overline{1534}$
$t, \underline{1534}$
tantalum-180m, 832
tau, see $\tau$
temperature, 520, 1534
definition, 532
Carnot, 548
definition using entropy, 558
intro, 212
tensor particle, 1200
tensor potential
deuteron, 1160
tensors
compared to linear algebra, 870
intro, 18
thermal de Broglie wavelength, 564
thermal efficiency, 546
thermal equilibrium, 520
thermionic emission, 244
thermocouple, 309
thermodynamics
first law, 540
second law, 541
third law, 553
thermoelectric generator, 310
thermoelectrics
figure of merit, 891
macroscopic equations, 893
thermogenerator, 310
Theta, see $\Theta$
theta, see $\theta, \vartheta$
third law of thermodynamics, 553
Thomson coefficient, 31
Thomson effect, 313
Thomson relationships
thermoelectrics, 897 intro, 313
throw the dice, 59
TID, 671
time
directionality, 428
time symmetry
reservations, 963
time variation
Hamiltonian, 317
time-dependent perturbation theory, 366 time-dilation, 9
time-like
special relativity, 15
time-reversal
as a Lorentz transformation, 872
tin
white and grey, 262
tissue weighting factor, 672
$T$-multiplets, 790
total cross-section, 1103
total energy

$$
\text { operator, } 56
$$

total ionizing dose, 671
transistor, 295
transition
multipole
selection rules, 833
multipole names, 833
quadrupole, see quadrupole transition
transition elements, 191
transition metals, 191
transition probability, see decay rate

## transition rate

spontaneous, see decay rate
transitions
hydrogen atom, 107
translation operator
crystals, 396
transmission coefficient, 405, 406, 1114
transparent crystals, 300
transpose
matrices, 1523
transpose of a matrix, $\underline{1512}$
transverse gauge
classical electromagnetics, 1125
traveling waves, see linear polarization
triakontadipole transition, 833
triangle inequality, 337
triple alpha process, 674
triple product, $\underline{1534}$
triplet states, 164
derivation, 587
tritium, 658
triton, 658
tunneling, 403
field emission, 245
Stark effect, 1137
WKB approximation, 405
Zener diodes, 297
turning point, 401
turning points
WKB approximation, 1094
twilight terms, 152
exchange terms, 153
Lennard-Jones/London force, 1117
lithium hydride, 153
spontaneous emission, 1049
two state systems
ground state energy, 150
time variation, 354
two-state systems
atom-photon model, 1044
$U, \underline{1535}$
$\mathcal{U}, \underline{1535}$
$u, 1535$
u, 1535
UHF, 450
uncertainty principle
angular momentum, 99
energy, 87, 321
Heisenberg, 53
position and linear momentum, 53
uncertainty relationship
generalized, 124
Heisenberg, 125
unified atomic mass unit, 673
unit cell

## FCC, 475

intro, 475
lithium (BCC), 477
versus primitive cell, 279
zinc blende, 278
unit matrix, $1352, \underline{1523}$
unit vectors
in spherical coordinates, $\underline{1532}$ unitary

Fourier series, 1080
matrix, 1353
time advance operator, 902
unitary matrix
in coordinate rotations, 870
unitary operator, 951
unitary operators, $\underline{1507}$
universal gas constant, 558, 573
universal mass unit, 673
unperturbed shell model, 715
unrestricted Hartree-Fock, 450
$V, \underline{1535}$
$\mathcal{V}, \underline{1535}$
v, 1535
$\vec{v}, \underline{1536}$
vacancies
ionic conductivity, 265
optical effects, 301
vacuum energy, 429, 915, 1040
seething cauldron, 1041
vacuum state, 916
valence band

## intro, 258

values
observable, 57
Van der Waals forces, 469
Casimir-Polder, 470
variational calculus
worked out example, 864
variational method, 135
helium ionization energy, 1130
hydrogen molecular ion, 135
hydrogen molecule, 148
variational principle, 433
basic statement, 433
differential form, 435
Lagrangian multipliers, 436 vector, 34, 1536
vector bosons, 964
vector particle, 1176
vectorial product, $\underline{1536}$
velocity
in quantum mechanics, 325
vibrational states
seenuclei, 734
vibronic coupling terms, 1340
virial theorem, 324
virtual work, 860
viscosity, 544
Volta potential, 247
volume integral
in spherical coordinates, $\underline{1532}$
von Weizsäcker formula, 687
W, 1536
w, $\underline{1537}$
$\vec{w}, \underline{1537}$
warp factor, 15
wave function, 50
multiple particles, 140
multiple particles with spin, 161
with spin, 157
wave number, 42, 65, 392
Floquet, 484
Fourier versus Floquet, 484
one-dimensional Fourier series, 1079
one-dimensional Fourier transform, 1081
wave number vector
and linear momentum, 249
Bloch function, 491
Fourier series, 1082
Fourier transform, 1083
wave numbers, 206
wave packet
accelerated motion, 400
definition, 390
free space, 387, 399
harmonic oscillator, 401
partial reflection, 403
physical interpretation, 390
reflection, 401
wave vector
conservation, 276
weak force
intro, 356
Weisskopf estimates, 1068
comparison with data, 844
figures, 836
Weisskopf unit
derivation, 1077
Weisskopf units, 1068
well
deuteron, 1154
Weyl neutrinos, 1186
width
particle decay, 647
width of a state, 335
Wigner $3 \mathrm{j}, 6 \mathrm{j}$ and 9 j coefficients, 1456
Wigner-Eckart theorem, 1457
Wigner-Seitz cell, 489
WKB approximation
connection formulae, 1096
WKB connection formulae, 1097
WKB theory, 1092
Woods-Saxon potential, 707
work function, 245
Wronskian, 1112
W.u., 1077

YSZ, 266
yttria-stabilized zirconia, 266
Yukawa potential, 1165
loose derivation, 1162
Z, 1537
z, 1537
Zeeman effect, 1133 intermediate, 1146 weak, 1146
Zener diode, 296
zero matrix, $\underline{1523}$
zero point energy, 443
zeroth law of thermodynamics, 520
zinc blende
crystal structure, 277
ZnS, see zinc blende

[^0]:    $0-$ To first approximation, there is no attraction between the free proton and the neutral hydrogen atom, even somewhat closer together.

[^1]:    ${ }^{1}$ https://www.nist.gov/pml/periodic-table-elements
    ${ }^{2}$ http://www.eng.famu.fsu.edu/~dommelen/quansup/periodic-table.pdf

[^2]:    $0-$ Some energy slop occurs in decays.
    $0-$ Taking that into account, meaningful decay rates may be computed following Fermi's golden rule.
