Copyright © 2004, 2007, 2008, 2010, 2011, and on, Leon van Dommelen. You are allowed to copy and/or print out this work for your personal use. However, do not distribute any parts of this work to others or post it publicly without written permission of the author. Instead please link to this work. I want to be able to correct errors and improve explanations and actually have them corrected and improved. Every attempt is made to make links as permanent as possible.

Readers are advised that text, figures, and data may be inadvertently inaccurate. All responsibility for the use of any of the material in this book rests with the reader. (I took these sentences straight out of a printed commercial book. However, in this web book, I do try to correct "inaccuracies," OK, blunders, pretty quickly if pointed out to me by helpful readers, or if I happen to think twice.)

As far as search engines are concerned, conversions to html of the pdf version of this document are stupid, since there is a much better native html version already available. So try not to do it.

## Reading the PDF

## Some notes on reading the PDF version of this book:

- Without changing your Preferences/Settings, links to the web might not work on recent pdf readers. That is especially likely if you download the PDF instead of reading it in a web browser. What I had to do with Adobe Acrobat 9 on linux was to go into menu "Edit," "Preferences," "Trust Manager," "Internet Access from PDF files outside the web browser," "Change settings." There I had to enable the opening of all web pages. Specifying "Ask me" did not work; it just refused to open the link instead of asking.
- You may want to activate a [back button]. In my linux version of Adobe Acrobat reader, that is done using "Menu," "View,""Toolbars," "More Tools...," "Page Navigation Toolbar." There I had to select the "Previous View" and "Next View" buttons.
- To get/restore a separate table of contents, open "Bookmarks" from menu "View," "Navigation Panels," "Bookmarks."
- Links to some sections and figures may be hard to find. If so, search with the mouse just below the section or figure number.
- Links from the index are activated by clicking on the page number. They put you at the top of the right page; they do not put you at the right place on that page.
- A tip from Bob Sokalski: to read the book on a Nook download in PDF. Then adjust font size otherwise Nook gets absolutely confused when it is not able to fit the lines within the screen width.

## Preface

## To the Student

This is a book on the real quantum mechanics. On quantum scales it becomes clear that classical physics is simply wrong. It is quantum mechanics that describes how nature truly behaves; classical physics is just a simplistic approximation of it that can be used for some computations describing macroscopic systems. And not too many of those, either.

Here you will find the same story as physicists tell their own students. The difference is that this book is designed to be much easier to read and understand than comparable texts. Quantum mechanics is inherently mathematical, and this book explains it fully. But the mathematics is only covered to the extent that it provides insight in quantum mechanics. This is not a book for developing your skills in clever mathematical manipulations that have absolutely nothing to do with physical understanding. You can find many other texts like that already, if that is your goal.

The book was primarily written for engineering graduate students who find themselves caught up in nano technology. It is a simple fact that the typical engineering education does not provide anywhere close to the amount of physics you will need to make sense out of the literature of your field. You can start from scratch as an undergraduate in the physics department, or you can read this book.

The first part of this book provides a solid introduction to classical (i.e. nonrelativistic) quantum mechanics. It is intended to explain the ideas both rigorously and clearly. It follows a "just-in-time" learning approach. The mathematics is fully explained, but not emphasized. The intention is not to practice clever mathematics, but to understand quantum mechanics. The coverage is at the normal calculus and physics level of undergraduate engineering students. If you did well in these courses, you should be able to understand the discussion, assuming that you start reading from the beginning. In particular, you simply cannot skip the short first chapter. There are some hints in the notations section, if you forgot some calculus. If you forgot some physics, just don't worry too much about it: quantum physics is so much different that even the most basic concepts need to be covered from scratch.

Whatever you do, read all of chapters 2 and 3 . That is the very language of quantum mechanics. It will be hard to read the rest of the book if you do not know the language.

Derivations are usually "banned" to notes at the end of this book, in case you need them for one reason or the other. They correct a considerable number of mistakes that you will find in other books. No doubt they add a few new ones. Let me know and I will correct them quickly; that is the advantage of a web book.

The second part of this book discusses more advanced topics. It starts with numerical methods, since engineering graduate students are typically supported by a research grant, and the quicker you can produce some results, the better. A description of density functional theory is still missing, unfortunately.

The remaining chapters of the second part are intended to provide a crash course on many topics that nano literature would consider elementary physics, but that nobody has ever told you about. Most of it is not really part of what is normally understood to be a quantum mechanics course. Reading, rereading, and understanding it is highly recommended anyway.

The purpose is not just to provide basic literacy in those topics, although that is very important. But the purpose is also explain enough of their fundamentals, in terms that an engineer can understand, so that you can make sense of the literature in those fields if you do need to know more than can be covered here. Consider these chapters gateways into their topic areas.

There is a final chapter in part II on how to interpret quantum mechanics philosophically. Read it if you are interested; it will probably not help you do quantum mechanics any better. But as a matter of basic literacy, it is good to know how truly weird quantum mechanics really is.

The usual "Why this book?" blah-blah can be found in a note at the back of this book, $\{\mathrm{N} .1\}$ A version history is in note $\{\mathrm{N} .2\}$.

## Acknowledgments

This book is for a large part based on my reading of the excellent book by Griffiths, [25]. It now contains essentially all material in that book in one way or the other. (But you may need to look in the notes for some of it.) This book also evolved to include a lot of additional material that I thought would be appropriate for a physically-literate engineer. There are chapters on relativity, numerical methods, thermodynamics, solid mechanics, electromagnetism, and nuclei.

Somewhat to my surprise, I find that my coverage actually tends to be closer to Yariv's book, [52]. I still think Griffiths is more readable for an engineer, though Yariv has some very good items that Griffiths does not.

Matthew Leung pointed out that I had＂left＂and＂right＂mixed up in my discussion of the relativistic Doppler effect．I am dyslexic that way．

The idea of using the Lagrangian for the derivations of relativistic mechanics is from A．Kompanayets，theoretical physics，an excellent book．

I rewrote the section on functions as vectors to some extent based on com－ ments of Germano Galasso．

I thank Rob Vossen for pointing out some rather horrible typos in the section on Dirac notation．

I thank Chris Cline for pointing out a bad label on the dot product figure in the discussion of functions as vectors．I thank Richard Mertz and Mike Day for pointing out typos and poor phrasing in the same sections．

The nanomaterials lectures of colleague Anter El－Azab that I audited in－ spired me to add a bit on simple quantum confinement to the first system studied，the particle in the box．That does add a bit to a section that I wanted to keep as simple as possible，but then I figure it also adds a sense that this is really relevant stuff for future engineers．I also added a discussion of the effects of confinement on the density of states to the section on the free－electron gas．

I thank Swapnil Jain for pointing out that the initial subsection on quantum confinement in the pipe was definitely unclear and is hopefully better now．

I thank Ed Williams for pointing out a mistake in the formula for the com－ bination probabilities of the hydrogen atom electrons and Johann Joss for one in the formula for the averaged energy of two－state systems．

Thomas Pak noted some poor phrasing in the section on metals and insula－ tors．

The discussions on two－state systems are mainly based on Feynman＇s notes， ［22，chapters 8－11］．Since it is hard to determine the precise statements being made，much of that has been augmented by data from web sources，mainly those referenced．

I thank Murat Ozer for pointing out that the two highest wave functions in N． 2 were $Z=14$ instead of 16 ．

The discussion of the Onsager theorem comes from Desloge，［12］，an emeritus professor of physics at the Florida State University．

The section on conservation laws and symmetries is almost completely based on Feynman，［22］and［20］．

Harald Kirsch reported various problems in the sections on conservation laws and on position eigenfunctions．

Bob Sokalski reported an error in the section on the two－state model．
The note on the derivation of the selection rules is from［25］and lecture notes from a University of Tennessee quantum course taught by Marianne Breinig． The subsection on conservation laws and selection rules was inspired by Ellis， ［15］．

The many－worlds discussion is based on Everett＇s exposition，［17］．It is brilliant but quite impenetrable．

The section on the Born－Oppenheimer approximation comes from Wikipe－ dia，【21】，with modifications including the inclusion of spin．

The section on the Hartree－Fock method is mainly based on Szabo and Ostlund［46］，a well－written book，with some Parr and Yang［34］thrown in．

The section on solids is mainly based on Sproull，［42］，a good source for practical knowledge about application of the concepts．It is surprisingly up to date，considering it was written half a century ago．Various items，however， come from Kittel［29］．The discussion of ionic solids really comes straight from hyperphysics 【6】．I prefer hyperphysics＇example of NaCl ，instead of Sproull＇s equivalent discussion of KCl．My colleague Steve Van Sciver helped me get some handle on what to say about helium and Bose－Einstein condensation．

The thermodynamics section started from Griffiths＇discussion，［25］，which follows Yariv＇s，［52］．However，it expanded greatly during writing．It now comes mostly from Baierlein［4］，with some help from Feynman，［18］，and some of the books I use in undergraduate thermo．

Mark Troll noted that the discussion of the specific heat of gases was pretty poorly written．I have rewritten it pretty much along the lines he suggested．

The derivation of the classical energy of a spinning particle in a magnetic field is from Yariv，［52］．

The initial inspiration for the chapter on nuclear physics was the Nobel Prize acceptance lecture of Goeppert Mayer 【10】．This is an excellent introduction to nuclear physics for a nonspecialist audience．It is freely available on the web．As the chapter expanded，the main reference became the popular book by Krane ［31］．That book is particularly recommended if you want an understandable description of how the experimental evidence led physicists to formulate the theoretical models for nuclei．Other primary references were［36］and［40］．The Handbook of Physics，Hyperphysics，and various other web sources were also helpful．Much of the experimental data are from NUBASE 2003，an official database of nuclei，［3］．Updates after 2003 are not included．Data on magnetic moments derive mostly from a 2001 preprint by Stone；see［45］．Nu－Dat $2 \llbracket 12 \rrbracket$ provided the the excited energy levels and additional reference data to validate various data in［45］．

Lynn Bowen corrected a bad number on the life time of helium with another proton or neutron added，because I stupidly misread ys（yoctosecond）in a reference as y（year）．Very embarrassing，especially as I was amazed by the number．

The discussion of the Born series follows［25］．
The brief description of quantum field theory and the quantization of the electromagnetic field is mostly from Wikipedia，$\llbracket 21 \rrbracket$ ，with a bit of fill－in from Yariv［52］，Feynman［18］，Kittel［29］，and citizendium 【2］．The example on field operators is an exercise from Srednicki［43］，whose solution was posted online by a TA of Joe Polchinski from UCSB．

Acknowledgments for specific items are not listed here if a citation is given in the text, or if, as far as I know, the argument is standard theory. This is a text book, not a research paper or historical note. But if a reference is appropriate somewhere, let me know.

Grammatical and spelling errors have been pointed out by Ernesto Bosque, Eric Eros, Tag Jong Lee, Alastair McDonald, Samuel Rustan, Dan Schmidt, Mark Vanderlaan, Ramaswami Sastry Vedamm, Mikas Vengris, Rob Vossen, and Ed Williams. I will try to keep changing "therefor" into "therefore," and "send" into "sent", but they do keep sneaking in.

Thank you all.

## Comments and Feedback

If you find an error, please let me know. There seems to be an unending supply of them. As one author described it brilliantly, "the hand is still writing though the brain has long since disengaged."

Also let me know if you find points that are unclear to the intended readership, mechanical engineering graduate students with a typical exposure to mathematics and physics, or equivalent. Every section, except a few explicitly marked as requiring advanced linear algebra, should be understandable by anyone with a good knowledge of calculus and undergraduate physics.

The same for sections that cannot be understood without delving back into earlier material. All within reason of course. If you pick a random starting word somewhere in the book and start reading from there, you most likely will be completely lost. But sections are intended to be fairly self-contained, and you should be able read one without backing up through all of the text.

General editorial comments are also welcome. I'll skip the philosophical discussions. I am an engineer.

Feedback can be e-mailed to me at quantum@dommelen.net.
This is a living document. I am still adding things here and there, and fixing various mistakes and doubtful phrasing. Even before every comma is perfect, I think the document can be of value to people looking for an easy-to-read introduction to quantum mechanics at a calculus level. So I am treating it as software, with version numbers indicating the level of confidence I have in it all.

## Part I

Special Relativity

## Chapter 1

## Special Relativity [Draft]

#### Abstract

This first chapter reviews the theory of special relativity. It can be skipped if desired. Special relativity is not needed to understand the discussion of quantum mechanics in the remainder of this book. However, some parts of this chapter might provide a deeper understanding and justification for some of the issues that will come up in quantum mechanics. The main reason for this chapter is that the book can be used as a review and expansion of typical courses on "Modern Physics." Such classes always cover relativity. While relativity is nowhere as important as basic quantum mechanics, it does have that "Einstein mystique" that is great at parties. The chapter starts with an overview of the key ideas of relativity. This is material that is typically covered in modern physics classes. Subsequent sections provide more advanced explanations of the various ideas of special relativity.

### 1.1 Overview of Relativity

### 1.1.1 A note on the history of the theory

Special relativity is commonly attributed to Albert Einstein's 1905 papers. That is certainly justifiable. However, Einstein swiped the big ideas of relativity from Henri Poincaré, (who developed and named the principle of relativity in 1895 and a mass-energy relation in 1900), without giving him any credit or even mentioning his name.

He may also have swiped the underlying mathematics he used from Lorentz, (who is mentioned, but not in connection with the Lorentz transformation.)

However, in case of Lorentz, it is possible to believe that Einstein was unaware of his earlier work, if you are so trusting. Before you do, it must be pointed out that a review of Lorentz' 1904 work appeared in the second half of February 1905 in Beiblätter zu den Annalen der Physik. Einstein was well aware of that journal, since he wrote 21 reviews for it himself in 1905. Several of these were in the very next issue after the one with the Lorentz review, in the first half of March. Einstein's first paper on relativity was received June 301905 and published September 26 in Annalen der Physik. Einstein had been regularly writing papers for Annalen der Physik since 1901. You do the math.

In case of Poincaré, it is known that Einstein and a friend pored over Poincaré's 1902 book "Science and Hypothesis." In fact the friend noted that it kept them "breathless for weeks on end." So Einstein cannot possibly have been unaware of Poincaré's work.

However, Einstein should not just be blamed for his boldness in swiping most of the ideas in his paper from then more famous authors, but also be commended for his boldness in completely abandoning the basic premises of Newtonian mechanics, where earlier authors wavered.

It should also be noted that general relativity can surely be credited to Einstein fair and square. But he was a lot less hungry then. And had a lot more false starts. (There is a possibility that the mathematician Hilbert may have some partial claim on completing general relativity, but it is clearly Einstein who developed it. In fact, Hilbert wrote in one paper that his differential equations seemed to agree with the "magnificent theory of general relativity established by Einstein in his later papers." Clearly then, Hilbert himself agreed that Einstein established general relativity.)

### 1.1.2 The mass-energy relation

The most important result of relativity for the rest of this book is without doubt Einstein's famous relation $E=m c^{2}$. Here $E$ is energy, $m$ mass, and $c$ the speed of light. (A very limited version of this relation was given before Einstein by Poincaré.)

The relation implies that the kinetic energy of a particle is not $\frac{1}{2} m v^{2}$, with $m$ the mass and $v$ the velocity, as Newtonian physics would have it. Instead the kinetic energy is the difference between the energy $m_{v} c^{2}$ based on the mass $m_{v}$ of the particle in motion and the energy $m c^{2}$ based on the mass $m$ of the same particle at rest. According to special relativity the mass in motion is related to the mass at rest as

$$
\begin{equation*}
m_{v}=\frac{m}{\sqrt{1-(v / c)^{2}}} \tag{1.1}
\end{equation*}
$$

Therefore the true kinetic energy can be written as

$$
T=\frac{m}{\sqrt{1-(v / c)^{2}}} c^{2}-m c^{2}
$$

For velocities small compared to the tremendous speed of light, this is equivalent to the classical $\frac{1}{2} m v^{2}$. That can be seen from Taylor series expansion of the square root. But when the particle speed approaches the speed of light, the above expression implies that the kinetic energy approaches infinity. Since there is no infinite supply of energy, the velocity of a material object must always remain less than the speed of light.

The photons of electromagnetic radiation, (which includes radio waves, microwaves, light, x-rays, gamma rays, etcetera), do travel at the speed of light through a vacuum. However, the only reason that they can do so is because they have zero rest mass $m$. There is no way that photons in vacuum can be brought to a halt, or even slowed down, because there would be nothing left.

If the kinetic energy is the difference between $m_{v} c^{2}$ and $m c^{2}$, then both of these terms must have units of energy. That does of course not prove that each term is a physically meaningful energy by itself. But it does look plausible. It suggests that a particle at rest still has a "rest mass energy" $m c^{2}$ left. And so it turns out to be. For example, an electron and a positron can completely annihilate each other, releasing their rest mass energies as two photons that fly apart in opposite directions. Similarly, a photon of electromagnetic radiation with enough energy can create an electron-positron pair out of nothing. (This does require that a heavy nucleus is around to absorb the photon's linear momentum without absorbing too much of its energy; otherwise it would violate momentum conservation.) Perhaps more importantly for engineering applications, the energy released in nuclear reactions is produced by a reduction in the rest masses of the nuclei involved.

Quantum mechanics does not use the speed $v$ of a particle, but its momentum $p=m_{v} v$. In those terms the total energy, kinetic plus rest mass energy, can be rewritten as

$$
\begin{equation*}
E=T+m c^{2}=\sqrt{\left(m c^{2}\right)^{2}+p^{2} c^{2}} \tag{1.2}
\end{equation*}
$$

This expression is readily checked by substituting in for $p$, then for $m_{v}$, and cleaning up.

### 1.1.3 The universal speed of light

The key discovery of relativity is that the observed speed of light through vacuum is the same regardless of how fast you are traveling. One historical step that led to this discovery was a famous experiment by Michelson \& Morley. In simplified terms, Michelson \& Morley tried to determine the absolute speed of the earth through space by "horse-racing" it against light. If a passenger jet airplane flies at three quarters of the speed of sound, then sound waves going in the same direction as the plane only have a speed advantage of one quarter of the speed of sound over the plane. Seen from inside the plane, that sound seems to move away from it at only a quarter of the normal speed of sound.

Essentially, Michelson \& Morley reasoned that the speed of the earth could similarly be observed by measuring how much it reduces the apparent speed of light moving in the same direction through a vacuum. But it proved that the motion of the earth produced no reduction in the apparent speed of light whatsoever. It is as if you are racing a fast horse, but regardless of how fast you are going, you do not reduce the velocity difference any more than if you would just stop your horse and have a drink.

The simplest explanation would be that earth is at rest compared to the universe. But that cannot possibly be true. Earth is a minor planet in an outer arm of the galaxy. And earth moves around the sun once a year. Obviously, the entire universe could not possibly follow that noninertial motion.

So how come that earth still seems to be at rest compared to light waves moving through vacuum? You can think up a hundred excuses. In particular, the sound inside a plane does not seem to move any slower in the direction of motion. But of course, sound is transmitted by real air molecules that can be trapped inside a plane by well established mechanisms. It is not transmitted through empty space like light.

But then, at the time of the Michelson \& Morley experiment the prevailing theory was that light did move through some hypothetical medium. This madeup medium was called the "ether." It was supposedly maybe dragged along by the earth, or maybe dragged along a bit, or maybe not after all. In fact, Michelson \& Morley were really trying to decide how much it was being dragged along. Looking back, it seems self-evident that this ether was an unsubstantiated theory full of holes. But at the time most scientists took it very seriously.

The results of the Michelson \& Morley experiment and others upped the ante. To what could reasonably be taken to be experimental error, the earth did not seem to move relative to light waves in vacuum. So in 1895 Poincaré reasoned that experiments like the one of Michelson \& Morley suggested that it is impossible to detect absolute motion. In 1900 he proposed the "Principle of Relative Motion." It proposed that the laws of movement would be the same in all coordinate systems regardless of their velocity, as long as they are not accelerating. In 1902, in the book read by Einstein, he discussed philosophical assessments on the relativity of space, time, and simultaneity, and the idea that a violation of the relativity principle can never be detected. In 1904 he called it
"The principle of relativity, according to which the laws of physical phenomena must be the same for a stationary observer as for one carried along in a uniform motion of translation, so that we have no means, and can have none, of determining whether or not we are being carried along in such a motion."

In short, if two observers are moving at different, but constant speeds, it is impossible to say which one, if any, is at rest. The laws of physics observed by the two observers are exactly the same. In particular, the
moving observers see the same speed of light regardless of their different physical motion.
(Do note however that if an observer is accelerating or spinning around, that can be determined through the generated inertia forces. Not all motion is relative. Just an important subset of it.)

A couple of additional historical notes may be appropriate. Quite a number of historians of science argue that Poincaré did not "really" propose relativity, because he continued to use the ether in various computations afterwards. This argument is unjustified. To this very day, the overwhelming majority of physicists and engineers still use Newtonian physics in their computations. That does not mean that these physicists and engineers do not believe in special relativity. It means that they find doing the Newtonian computation a lot easier, and it gives the right answer for their applications. Similarly, Poincaré himself clearly stated that he still considered the ether a "convenient hypothesis." There were well established procedures for computing such things as the propagation of light in moving media using an assumed ether that had been well verified by experiment.

A more interesting hypothesis advanced by historians is that Einstein may have been more inclined to do away with the ether from the start than other physicists. The concept of the ether was without doubt significantly motivated by the propagation of other types of waves like sound waves and water waves. In such waves, there is some material substance that performs a wave motion. Unlike waves, however, particles of all kinds readily propagate through empty space; they do not depend on a separate medium that waves. That did not seem relevant to light, because its wave-like nature had been well established. But in quantum mechanics, the complementary nature of light as particles called photons was emerging. And Einstein may have been more comfortable with the quantum mechanical concept of light than most at the time. He was a major developer of it.

### 1.1.4 Disagreements about space and time

At first, it may not seem such a big deal that the speed of light is the same regardless of the motion of the observer. But when this notion is examined in some more detail, it leads to some very counter-intuitive conclusions.

It turns out that if observers are in motion compared to each other, they will unavoidably disagree about such things as spatial distances and the time that things take. Often, different observers cannot even agree on which of two physical events takes place earlier than the other. Assuming that they determine the times correctly in their own coordinate system, they will come up with different answers.

Self-evidently, if observers cannot even agree on which of two events happened first, then an absolute time scale that everyone can agree on is not possible
either. And neither is a system of absolute spatial coordinates that everybody can agree upon.

Figure 1.1: Different views of the same experiment. Left is the view of observers on the planets. Right is the view of an alien space ship.

Consider a basic thought experiment. A thought experiment is an experiment that should in principle be possible, but you do not want to be in charge of actually doing it. Suppose that the planets Venus and Mars happen to be at opposite sides of earth, and at roughly the same distance from it. The left side of figure 1.1 shows the basic idea. Experimenters on earth flash simultaneous light waves at each planet. Since Venus happens to be a bit closer than Mars, the light hits Venus first. All very straightforward. Observers on Venus and Mars would agree completely with observers on earth that Venus got hit first. They also agree with earth about how many minutes it took for the light to hit Venus and Mars.

To be sure, the planets move with speeds of the order of $100,000 \mathrm{mph}$ relative to one another. But that speed, while very large in human terms, is so small compared to the tremendous speed of light that it can be ignored. For the purposes of this discussion, it can be assumed that the planets are at rest relative to earth.

Next assume that a space ship with aliens was just passing by and watched the whole thing, like in the right half of figure 1.1. As seen by observers on earth, the aliens are moving to the right with half the speed of light. However, the aliens can argue that it is they that are at rest, and that the three planets are moving towards the left with half the speed of light. According to the principle of relativity, both points of view are equally valid. There is nothing that can show whether the space ship or the planets are at rest, or neither one.

In particular, the speed of the light waves that the aliens observe is identical to the speed that earth sees. But now note that as far as the aliens are concerned, Venus moves with half the speed of light away from its incoming light wave. Of course, that significantly increases the time that the light needs to reach Venus. On the other hand, the aliens see Mars moving at half the speed of light towards its incoming light wave. That roughly halves the time needed for the light wave to hit Mars. In short, unlike earth, the aliens observe that the light hits Mars a lot earlier than it hits Venus.

That example demonstrates that observers in relative motion disagree about the time difference between events occurring at different locations. Worse, even if two events happen right in the hands of one of the observers, the observers
will disagree about how long the entire thing takes. In that case, the observer compared to which the location of the events is in motion will think that it takes longer. This is called "time-dilation." The time difference between two events slows down according to

$$
\begin{equation*}
\Delta t_{v}=\frac{\Delta t_{0}}{\sqrt{1-(v / c)^{2}}} \tag{1.3}
\end{equation*}
$$

Here $\Delta t_{0}$ is shorthand for the time difference between the two events as seen by an observer compared to whom the two events occur at the same location. Similarly $\Delta t_{v}$ is the time difference between the two events as perceived by an observer compared to whom the location of the events is moving at speed $v$.

An "event" can be anything with an unambiguous physical meaning, like when the hands of a clock reach a certain position. So clocks are found to run slow when they are in motion compared to the observer. The best current clocks are accurate enough to directly measure this effect at human-scale speeds, as low as 20 mph . But relativity has already been verified in myriad other ways. The time is long gone that serious scientists still doubted the conclusions of relativity.

As a more practical example, cosmic rays can create radioactive particles in the upper atmosphere that survive long enough to reach the surface of the earth. The surprising thing is that at rest in a laboratory these same particles would not survive that long by far. The particles created by cosmic rays have extremely high speed when seen by observers standing on earth. That slows down the decay process due to time dilation.

Which of course raises the question: should then not an observer moving along with one such particle observe that the particle does not reach the earth? The answer is no; relativity maintains a single reality; a particle either reaches the earth or not, regardless of who is doing the observing. It is quantum mechanics, not relativity, that does away with a single reality. The observer moving with the particle observes that the particle reaches the earth, not because the particle seems to last longer than usual, but because the distance to travel to the surface of the earth has become much shorter! This is called "Lorentz-Fitzgerald contraction."

For the observer moving with the particle, it seems that the entire earth system, including the atmosphere, is in motion with almost the speed of light. The size of objects in motion seems to contract in the direction of the motion according to

$$
\begin{equation*}
\Delta x_{v}=\Delta x_{0} \sqrt{1-(v / c)^{2}} \tag{1.4}
\end{equation*}
$$

Here the $x$-axis is taken to be in the direction of motion. Also $\Delta x_{0}$ is the distance in the x -direction between any two points as seen by an observer compared to whom the points are at rest. Similarly, $\Delta x_{v}$ is the distance as seen by an observer compared to whom the points are moving with speed $v$ in the $x$-direction.

In short, for the observer standing on earth, the particle reaches earth because its motion slows down the decay process by a factor $1 / \sqrt{1-(v / c)^{2}}$. For the observer moving along with the particle, the particle reaches earth because the distance to travel to the surface of the earth has become shorter by exactly that same factor. The reciprocal square root is called the "Lorentz factor."

Lorentz-Fitzgerald contraction is also evident in how the aliens see the planets in figure 1.1. But note that the difference in the wave lengths of the light waves is not a simple matter of Lorentz-Fitzgerald contraction. The light waves are in motion compared to both observers, so Lorentz-Fitzgerald contraction simply does not apply.

The correct equation that governs the difference in observed wave length $\lambda$ of the light, and the corresponding difference in observed frequency $\omega$, is

$$
\begin{equation*}
\lambda_{v}=\lambda_{0} \sqrt{\frac{1+(v / c)}{1-(v / c)}} \quad \omega_{v}=\omega_{0} \sqrt{\frac{1-(v / c)}{1+(v / c)}} \tag{1.5}
\end{equation*}
$$

Here the subscript 0 stands for the emitter of the light, and subscript $v$ for an observer moving with speed $v$ away from the emitter. If the observer moves towards the emitter, $v$ is negative. (To be true, the formulae above apply whether the observer 0 is emitting the light or not. But in most practical applications, observer 0 is indeed the emitter.)

In terms of the example figure 1.1, 0 indicates the emitter earth, and $v$ indicates the aliens observing the radiation. If the aliens are still to the left of earth, they are still closing in on it and $v$ is negative. Then the formulae above say that the wave length seen by the aliens is shorter than the one seen by earth. Also, the frequency seen by the aliens is higher than the one seen by earth, and so is the energy of the light. When the aliens get to the right of earth, they are moving away from it. That makes $v$ positive, and the light from earth that is reaching them now seems to be of longer wave length, of lower frequency, and less energetic. These changes are referred to as "Doppler shifts."

One related effect is cosmic redshift. The entire universe is expanding. As a result, far away galaxies move away from us at extremely high speeds. That causes wave length shifts; the radiation emitted or absorbed by various excited atoms in these galaxies appears to us to have wave lengths that are too long. The received wave lengths are longer than those that these same atoms would emit or absorb on earth. In particular, the colors of visible light are shifted towards the red side of the spectrum. To observers in the galaxies themselves, however, the colors would look perfectly fine.

Note that the cosmic redshift can only qualitatively be understood from the formulae above. It is more accurate to say that the photons traveling to us from remote galaxies get stretched due to the expansion of the universe. The cosmic redshift is not due to the motion of the galaxies through space, but due to the motion of space itself. If the expansion of space is rephrased in terms of
a relative velocity of the galaxies compared to us, that velocity can exceed the speed of light. That would produce nonsense in the formulae above. Objects cannot move faster than the speed of light through space, but the velocity of different regions of space compared to each other can exceed the speed of light.

Returning to the normal Doppler shift, the changes in wave length are not directly due to Lorentz-Fitzgerald contraction. Instead, they can in part be attributed to time dilation. In figure 1.1 both the aliens and earth can deduce the wave length from how frequently the peaks of the wave leave the emitter earth. But in doing so, one source of disagreement is time dilation. Since earth is in motion compared to the aliens, the aliens think that the peaks leave earth less frequently than earth does. In addition, the aliens and earth disagree about the relative velocity between the light waves and earth. Earth thinks that the light waves leave with the speed of light relative to earth. The aliens also think that the light waves travel with the speed of light, but in addition they see earth moving towards the left with half the speed of light. Combine the two effects, for arbitrary velocity of the aliens, and the relation between the wave lengths is as given above. Further, since the speed of light is the same for both earth and aliens, the observed frequency of the light is inversely proportional to the observed wave length.

### 1.2 The Lorentz Transformation

The "Lorentz transformation" describes how measurements of the position and time of events change from one observer to the next. It includes LorentzFitzgerald contraction and time dilation as special cases.

### 1.2.1 The transformation formulae

This subsection explains how the position and time coordinates of events differ from one observer to the next.

Figure 1.2: Coordinate systems for the Lorentz transformation.

Consider two observers A and B that are in motion compared to each other with a relative speed $V$. To make things as simple as possible, it will be assumed that the relative motion is along the line through the two observers,

As the left side of figure 1.2 shows, observer A can believe herself to be at rest and see observer B moving away from her at speed $V$; similarly, observer B can believe himself to be at rest and see observer A moving away from him at speed $V$, as in the right side of the figure. The principle of relativity says that both views are equally valid; there is no physical measurement that can find a fundamental difference between the two observers. That implies that both observers must agree on the same magnitude of the relative velocity $V$ between them. And it implies that they need to agree on the speed $c$ that light moves.

It will further be assumed that both observers use coordinate systems with themselves at the origin to describe the locations and times of events. In addition, they both take their $x$ axes along the line of their relative motion. They also align their $y$ and $z$ axes. And they both define time to be zero at the instant that they meet.

In that case the Lorentz transformation says that the relation between positions and times of events as perceived by the two observers is, $\{\mathrm{D} .4\}$ :

$$
\begin{equation*}
c t_{\mathrm{B}}=\frac{c t_{\mathrm{A}}-(V / c) x_{\mathrm{A}}}{\sqrt{1-(V / c)^{2}}} \quad x_{\mathrm{B}}=\frac{x_{\mathrm{A}}-(V / c) c t_{\mathrm{A}}}{\sqrt{1-(V / c)^{2}}} \quad y_{\mathrm{B}}=y_{\mathrm{A}} \quad z_{\mathrm{B}}=z_{\mathrm{A}} \tag{1.6}
\end{equation*}
$$

To get the transformation of the coordinates of B into those of A, just swap A and B and replace $V$ by $-V$. Indeed, if observer B is moving in the positive $x$ direction with speed $V$ compared to observer A, then observer A is moving in the negative $x$-direction with speed $V$ compared to observer B, as in figure 1.2. In the limit that the speed of light $c$ becomes infinite, the Lorentz transformation becomes the nonrelativistic "Galilean transformation" in which $t_{\mathrm{B}}$ is simply $t_{\mathrm{A}}$ and $x_{\mathrm{B}}=x_{\mathrm{A}}-V t$, i.e. $x_{\mathrm{B}}$ equals $x_{\mathrm{A}}$ except for a shift of magnitude $V t$.

The made assumptions are that A and B are at the origin of their coordinate system. And that their spatial coordinate systems are aligned. And that their relative motion is along the $x$ axes. And that they take the zero of time to be the instant that they meet. These simplifying assumptions may look very restrictive. But they are not. A different observer A' at rest relative to A can still use any coordinate system he wants, with any arbitrary orientation, origin, and zero of time. Since A' is at rest relative to A, the two fundamentally agree about space and time. So whatever coordinates and times A' uses for events are easily converted to those that A uses in the classical way, $\{\mathrm{A} .3\}$. Similarly an observer B' at rest compared to B can still use any arbitrary coordinate system that she wants. The coordinates and times of events observed by the arbitrary observers A' and B' can then be related to each other in stages. First relate the coordinates of $\mathrm{A}^{\prime}$ to those of A in the classical way. Next use the Lorentz transformation as given above to relate those to the coordinates of B.

Then relate those in the classical way to the coordinates of B'. In this way, the coordinates and times of any two observers in relative motion to each other, using arbitrary coordinate systems and zeros of time, can be related. The simple Lorentz transformation above describes the nontrivial part of how the observations of different observers relate.

Time dilation is one special case of the Lorentz transformation. Assume that two events 1 and 2 happen at the same location $x_{\mathrm{A}}, y_{\mathrm{A}}, z_{\mathrm{A}}$ in system A . Then the first Lorentz transformation formula (1.6) gives

$$
t_{2, \mathrm{~B}}-t_{1, \mathrm{~B}}=\frac{t_{2, \mathrm{~A}}-t_{1, \mathrm{~A}}}{\sqrt{1-(V / c)^{2}}}
$$

So observer B finds that the time difference between the events is larger. The same is of course true vice-versa, just use the inverse formulae.

Lorentz-Fitzgerald contraction is another special case of the Lorentz transformation. Assume that two stationary locations in system B are apart by a distance $x_{2, B}-x_{1, B}$ in the direction of relative motion. The second Lorentz transformation formula (1.6) then says how far these points are apart in system A at any given time $t_{\mathrm{A}}$ :

$$
x_{2, \mathrm{~B}}-x_{1, \mathrm{~B}}=\frac{x_{2, \mathrm{~A}}-x_{1, \mathrm{~A}}}{\sqrt{1-(V / c)^{2}}}
$$

Taking the square root to the other side gives the contraction.
As a result of the Lorentz transformation, measured velocities are related as

$$
\begin{equation*}
v_{x, B}=\frac{v_{x, A}-V}{1-\left(V / c^{2}\right) v_{x, A}} \quad v_{y, B}=\frac{v_{y, A} \sqrt{1-(V / c)^{2}}}{1-\left(V / c^{2}\right) v_{x, A}} \quad v_{z, B}=\frac{v_{z, A} \sqrt{1-(V / c)^{2}}}{1-\left(V / c^{2}\right) v_{x, A}} \tag{1.7}
\end{equation*}
$$

Note that $v_{x}, v_{y}, v_{z}$ refer here to the perceived velocity components of some moving object; they are not components of the velocity difference $V$ between the coordinate systems.

### 1.2.2 Proper time and distance

In classical Newtonian mechanics, time is absolute. All observers agree about the difference in time $\Delta t$ between any two events:
nonrelativistic: $\Delta t$ is independent of the observer
The time difference is an "invariant;" it is the same for all observers.
All observers, regardless of how their spatial coordinate systems are oriented, also agree over the distance $|\Delta \vec{r}|$ between two events that occur at the same time: nonrelativistic: $|\Delta \vec{r}|$ is independent of the observer if $\Delta t=0$

Here the distance between any two points 1 and 2 is found as

$$
|\Delta \vec{r}| \equiv \sqrt{(\Delta \vec{r}) \cdot(\Delta \vec{r})}=\sqrt{(\Delta x)^{2}+(\Delta y)^{2}+(\Delta z)^{2}} \quad \Delta \vec{r} \equiv \vec{r}_{2}-\vec{r}_{1}
$$

The fact that the distance may be expressed as a square root of the sum of the square components is known as the "Pythagorean theorem."

Relativity messes all these things up big time. As time dilation shows, the time between events now depends on who is doing the observing. And as Lorentz-Fitzgerald contraction shows, distances now depend on who is doing the observing. For example, consider a moving ticking clock. Not only do different observers disagree over the distance $|\Delta \vec{r}|$ traveled between ticks, (as they would do nonrelativistically), but they also disagree about the time difference $\Delta t$ between ticks, (which they would not do nonrelativistically).

However, there is one thing that all observers can agree on. They do agree on how much time between ticks an observer moving along with the clock would measure. That time difference is called the "proper time" difference. (The word proper is a wrongly translated French "propre," which here means "own." So proper time really means the clock's own time.) The time difference $\Delta t$ that an observer actually perceives is longer than the proper time difference $\Delta t_{0}$ due to the time dilation:

$$
\Delta t=\frac{\Delta t_{0}}{\sqrt{1-(v / c)^{2}}}
$$

Here $v$ is the velocity of the clock as perceived by the observer.
To clean this up, take the square root to the other side and write $v$ as the distance $|\Delta \vec{r}|$ traveled by the clock divided by $\Delta t$. That gives the proper time difference $\Delta t_{0}$ between two events, like the ticks of a clock here, as

$$
\begin{equation*}
\Delta t_{0}=\Delta t \sqrt{1-\frac{(\Delta x)^{2}+(\Delta y)^{2}+(\Delta z)^{2}}{(c \Delta t)^{2}}} \tag{1.8}
\end{equation*}
$$

The numerator in the ratio is the square of the distance between the events.
Note however that the proper time difference is imaginary if the quantity under the square root is negative. For example, if an observer perceives two events as happening simultaneously at two different locations, then the proper time difference between those two events is imaginary. To avoid dealing with complex numbers, it is then more convenient to define the "proper distance" $\Delta s$ between the two events as

$$
\begin{equation*}
\Delta s=\sqrt{(\Delta x)^{2}+(\Delta y)^{2}+(\Delta z)^{2}-(c \Delta t)^{2}} \tag{1.9}
\end{equation*}
$$

Note that this is the ordinary distance between the two events if they are at the same time, i.e. $\Delta t=0$. The proper distance is different from the proper time difference by a factor $\sqrt{-c^{2}}$. Because of the minus sign under the square
root, this factor is imaginary. As a result, $\Delta s$ is imaginary if $\Delta t_{0}$ is real and vice-versa.

All observers agree about the values of the proper time difference $\Delta t_{0}$ and the proper distance $\Delta s$ for any two given events.

Physicists define the square of the proper distance to be the "space-time interval" $I$. The term is obviously confusing, as a dictionary defines an interval as a difference in time or space, not as the square of such a difference. To add more confusion, some physicists change sign in the definition, and others divide by the square speed of light. And some rightly define the interval to be $\Delta s$ without the square, unfortunately causing still more confusion.

If the interval, defined as $(\Delta s)^{2}$, is positive, then the proper distance $\Delta s$ between the two events is real. Such an interval is called "space-like." On the other hand, if the interval is negative, then the proper distance is imaginary. In that case it is the proper time difference between the events that is real. Such an interval is called "time-like."

If the proper time difference is real, the earlier event can affect, or even cause, the later event. If the proper time difference is imaginary however, then the effects of either event cannot reach the other event even if traveling at the speed of light. It follows that the sign of the interval is directly related to "causality," to what can cause what. Since all observers agree about the value of the proper time difference, they all agree about what can cause what.

For small differences in time and location, all differences $\Delta$ above become differentials d.

### 1.2.3 Subluminal and superluminal effects

Suppose you stepped off the curb at the wrong moment and are now in the hospital. The pain is agonizing, so you contact one of the telecommunications microchips buzzing in the sky overhead. These chips are capable of sending out a "superluminal" beam; a beam that propagates with a speed greater than the speed of light. The factor with which the speed of the beam exceeds the speed of light is called the "warp factor" $w$. A beam with a high warp factor is great for rapid communication with space ships at distant locations in the solar system and beyond. A beam with a warp factor of 10 allows ten times quicker communication than those old-fashioned radio waves that propagate at the speed of light. And these chips have other very helpful uses, like for your predicament.

You select a microchip that is moving at high speed away from the location where the accident occurred. The microchip sends out its superluminal beam. In its coordinate system, the beam reaches the location of the accident at a time $t_{m}$, at which time the beam has traveled a distance $x_{m}$ equal to $w c t_{m}$. According to the Lorentz transformation (1.6), in the coordinate system fixed to the earth, the beam reaches the location of the accident at a position and
time equal to

$$
t=\frac{1-(w V / c)}{\sqrt{1-(V / c)^{2}}} t_{m} \quad x=\frac{w c-V}{\sqrt{1-(V / c)^{2}}} t_{m}
$$

Because of the high speed $V$ of the microchip and the additional warp factor, the time that the beam reaches the location of the accident is negative; the beam has entered into the past. Not far enough in the past however, so another microchip picks up the message and beams it back, achieving another reduction in time. After a few more bounces, the message is beamed to your cell phone. It reaches you just when you are about to step off the curb. The message will warn you of the approaching car, but it is not really needed. The mere distraction of your buzzing cell phone causes you to pause for just a second, and the car rushes past safely. So the accident never happens; you are no longer in agony in the hospital, but on your Bermuda vacation as planned. And these microchips are great for investing in the stock market too.

Sounds good, does it not? Unfortunately, there is a hitch. Physicists refuse to work on the underlying physics to enable this technology. They claim it will not be workable, since it will force them to think up answers to tough questions like: "if you did not end up in the hospital after all, then why did you still send the message?" Until they change their mind, our reality will be that observable matter or radiation cannot propagate faster than the speed of light.

Therefore, manipulating the past is not possible. An event can only affect later events. Even more specifically, an event can only affect a later event if the location of that later event is sufficiently close that it can be reached with a speed of no more than the speed of light. A look at the definition of the proper time interval then shows that this means that the proper time interval between the events must be real, or "time-like." And while different observers may disagree about the location and time of the events, they all agree about the proper time interval. So all observers, regardless of their velocity, agree on whether an event can affect another event. And they also all agree on which event is the earlier one, because before the time interval $\Delta t$ could change sign for some observer speeds, it would have to pass through zero. It cannot, because it must be the same for all observers. Relativity maintains a single reality, even though observers may disagree about precise times and locations.

A more visual interpretation of those concepts can also be given. Imagine a hypothetical spherical wave front spreading out from the earlier event with the speed of light. Then a later event can be affected by the earlier event only if that later event is within or on that spherical wave front. If you restrict attention to events in the $x, y$ plane, you can use the $z$-coordinate to plot the values of time. In such a plot, the expanding circular wave front becomes a cone, called the "light-cone." Only events within this light cone can be affected. Similarly in three dimensions and time, an event can only be affected if it is within the light
cone in four-dimensional space-time. But of course, a cone in four dimensions is hard to visualize geometrically.

### 1.2.4 Four-vectors

The Lorentz transformation mixes up the space and time coordinates badly. In relativity, it is therefore best to think of the spatial coordinates and time as coordinates in a four-dimensional "space-time."

Since you would surely like all components in a vector to have the same units, you probably want to multiply time by the speed of light, because ct has units of length. So the four-dimensional "position vector" can logically be defined to be (ct, x,y,z); ct is the "zeroth" component of the vector where $x$, $y$, and $z$ are components number 1,2 , and 3 as usual. This four-dimensional position vector will be indicated by

$$
\stackrel{\rightharpoonup}{r} \equiv\left(\begin{array}{c}
c t  \tag{1.10}\\
x \\
y \\
z
\end{array}\right) \equiv\left(\begin{array}{c}
r_{0} \\
r_{1} \\
r_{2} \\
r_{3}
\end{array}\right)
$$

The hook on the arrow indicates that time has been hooked into it.
How about the important dot product between vectors? In three dimensional space this produces such important quantities as the length of vectors and the angle between vectors. Moreover, the dot product between two vectors is the same regardless of the orientation of the coordinate system in which it is viewed.

It turns out that the proper way to define the dot product for four-vectors reverses the sign of the contribution of the time components:

$$
\begin{equation*}
\stackrel{\rightharpoonup}{r}_{1} \cdot \stackrel{\rightharpoonup}{r}_{2} \equiv-c^{2} t_{1} t_{2}+x_{1} x_{2}+y_{1} y_{2}+z_{1} z_{2} \tag{1.11}
\end{equation*}
$$

It can be checked by simple substitution that the Lorentz transformation (1.6) preserves this dot product. In more expensive words, this "inner product" is "invariant under the Lorentz transformation." Different observers may disagree about the individual components of four-vectors, but not about their dot products.

The difference between the four-vector positions of two events has a "proper length" equal to the proper distance between the events

$$
\begin{equation*}
\Delta s=\sqrt{(\Delta \stackrel{\rightharpoonup}{r}) \cdot(\Delta \stackrel{\rightharpoonup}{r})} \tag{1.12}
\end{equation*}
$$

So, the fact that all observers agree about proper distance can be seen as a consequence of the fact that they all agree about dot products.

It should be pointed out that many physicist reverse the sign of the spatial components instead of the time in their inner product. Obviously, this is completely inconsistent with the nonrelativistic analysis, which is often still a valid
approximation. And this inconsistent sign convention seems to be becoming the dominant one too. Count on physicists to argue for more than a century about a sign convention and end up getting it all wrong in the end. One very notable exception is [49]; you can see why he would end up with a Nobel Prize in physics.

Some physicists also like to point out that if time is replaced by it, then the above dot product becomes the normal one. The Lorentz transformation can then be considered as a mere rotation of the coordinate system in this four-dimensional space-time. Gee, thanks physicists! This will be very helpful when examining what happens in universes in which time is imaginary, unlike our own universe, in which it is real. The good thing you can say about these physicists is that they define the dot product the right way: the $\mathrm{i}^{2}$ takes care of the minus sign on the zeroth component.

Returning to our own universe, the proper length of a four-vector can be imaginary, and a zero proper length does not imply that the four-vector is zero as it does in normal three-dimensional space. In fact, a zero proper length merely indicates that it requires motion at the speed of light to go from the start point of the four-vector to its end point.

### 1.2.5 Index notation

The notations used in the previous subsection are not standard. In literature, you will almost invariably find the four-vectors and the Lorentz transform written out in index notation. Fortunately, it does not require courses in linear algebra and tensor algebra to make some basic sense out of it.

First of all, in the nonrelativistic case position vectors are normally indicated by $\vec{r}$. The three components of this vector are commonly indicated by $x, y$, and $z$, or using indices, by $r_{1}, r_{2}$, and $r_{3}$. To handle space-time, physicists do not simply add a zeroth component $r_{0}$ equal to $c t$. That would make the meaning too easy to guess. Instead physicists like to indicate the components of four-vectors by $x^{0}, x^{1}, x^{2}, x^{3}$. It is harder to guess correctly what that means, especially since the letter $x$ is already greatly over-used as it is. A generic component may be denoted as $x^{\mu}$. An entire four-vector can then be indicated by $\left\{x^{\mu}\right\}$ where the brackets indicate the set of all four components. Needless to say, most physicists forget about the brackets, because using a component where a vector is required can have hilarious consequences.

In short,

$$
\left(\begin{array}{c}
c t \\
x \\
y \\
z
\end{array}\right) \equiv \vec{r} \equiv\left(\begin{array}{c}
r_{0} \\
r_{1} \\
r_{2} \\
r_{3}
\end{array}\right) \quad\left(\begin{array}{c}
c t \\
x \\
y \\
z
\end{array}\right) \equiv\left\{x^{\mu}\right\} \equiv\left(\begin{array}{c}
x^{0} \\
x^{1} \\
x^{2} \\
x^{3}
\end{array}\right)
$$

shows this book's common sense notation to the left and the index notation commonly used in physics to the right.

Recall now the Lorentz transformation (1.6). It described the relationship between the positions and times of events as observed by two different observers A and B. These observers were in motion compared to each other with a relative speed $V$. Physicists like to put the coefficients of such a Lorentz transformation into a table, as follows:

$$
\Lambda \equiv\left(\begin{array}{cccc}
\lambda^{0}{ }_{0} & \lambda^{0}{ }_{1} & \lambda^{0}{ }_{2} & \lambda^{0}{ }_{3}  \tag{1.13}\\
\lambda^{1}{ }_{0} & \lambda^{1}{ }_{1} & \lambda^{1}{ }_{2} & \lambda^{1}{ }_{3} \\
\lambda^{2}{ }_{0} & \lambda^{2}{ }_{1} & \lambda^{2}{ }_{2} & \lambda^{2}{ }_{3} \\
\lambda^{3}{ }_{0} & \lambda^{3}{ }_{1} & \lambda^{3}{ }_{2} & \lambda^{3}{ }_{3}
\end{array}\right) \equiv\left(\begin{array}{cccc}
\gamma & -\beta \gamma & 0 & 0 \\
-\beta \gamma & \gamma & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{array}\right)
$$

where

$$
\gamma \equiv \frac{1}{\sqrt{1-(V / c)^{2}}} \quad \beta \equiv \frac{V}{c} \quad \gamma^{2}-\beta^{2} \gamma^{2}=1
$$

A table like $\Lambda$ is called a "matrix" or "second-order tensor." The individual entries in the matrix are indicated by $\lambda^{\mu}{ }_{\nu}$ where $\mu$ is the number of the row and $\nu$ the number of the column. Note also the convention of showing the first index as a superscript. That is a tensor algebra convention. In linear algebra, you normally make all indices subscripts.
(Different sources use different letters for the Lorentz matrix and its entries. Some common examples are $\Lambda^{\mu}{ }_{\nu}$ and $a^{\mu}{ }_{\nu}$. The name "Lorentz" starts with L and the Greek letter for L is $\Lambda$. And Lorentz was Dutch, which makes him a European just like the Greek. Therefore $\Lambda$ is a good choice for the name of the Lorentz matrix, and $\Lambda$ or lower case $\lambda$ for the entries of the matrix. An $L$ for the matrix and $l$ for its entries would be just too easy to guess. Also, $\lambda$ is the standard name for the eigenvalues of matrices and $\Lambda$ for the matrix of those eigenvalues. So there is some potential for hilarious confusion there. An "a" for the Lorentz matrix is good too: the name "Lorentz" consists of roman letters and a is the first letter of the roman alphabet.)

The values of the entries $\lambda^{\mu}{ }_{\nu}$ may vary. The ones shown in the final matrix in (1.13) above apply only in the simplest nontrivial case. In particular, they require that the relative motion of the observers is aligned with the $x$ axes as in figure 1.2. If that is not the case, the values become a lot more messy.

In terms of the above notations, the Lorentz transformation (1.6) can be written as

$$
x_{\mathrm{B}}^{\mu}=\sum_{\nu=0}^{3} \lambda^{\mu}{ }_{\nu} x_{\mathrm{A}}^{\nu} \quad \text { for all four values } \mu=0,1,2,3
$$

That is obviously a lot more concise than (1.6). Some further shorthand notation is now used. In particular, the "Einstein summation convention" is to leave away
the summation symbol $\sum$. So, you will likely find the Lorentz transformation written more concisely as

$$
x_{\mathrm{B}}^{\mu}=\lambda^{\mu}{ }_{\nu} x_{\mathrm{A}}^{\nu}
$$

Whenever an index like $\nu$ appears twice in an expression, summation over that index is to be understood. In other words, you yourself are supposed to mentally add back the missing summation over all four values of $\nu$ to the expression above. Also, if an index appears only once, like $\mu$ above, it is to be understood that the equation is valid for all four values of that index.

It should be noted that mathematicians call the matrix $\Lambda$ the transformation matrix from B to A, even though it produces the coordinates of B from those of A. However, after you have read some more in this book, insane notation will no longer surprise you. Just that in this case it comes from mathematicians.

In understanding tensor algebra, it is essential to recognize one thing. It is that a quantity like a position differential transforms different from a quantity like a gradient:

$$
\mathrm{d} x_{\mathrm{B}}^{\mu}=\frac{\partial x_{\mathrm{B}}^{\mu}}{\partial x_{\mathrm{A}}^{\nu}} \mathrm{d} x_{\mathrm{A}}^{\nu} \quad \frac{\partial f}{\partial x_{\mathrm{B}}^{\mu}}=\frac{\partial f}{\partial x_{\mathrm{A}}^{\nu}} \frac{\partial x_{\mathrm{A}}^{\nu}}{\partial x_{\mathrm{B}}^{\mu}}
$$

In the first expression, the partial derivatives are by definition the entries of the Lorentz matrix $\Lambda$,

$$
\frac{\partial x_{\mathrm{B}}^{\mu}}{\partial x_{\mathrm{A}}^{\nu}} \equiv \lambda^{\mu}{ }_{\nu}
$$

In the second expression, the corresponding partial derivatives will be indicated by

$$
\frac{\partial x_{\mathrm{A}}^{\mu}}{\partial x_{\mathrm{B}}^{\nu}} \equiv\left(\lambda^{-1}\right)^{\mu}{ }_{\nu}
$$

The entries $\left(\lambda^{-1}\right)^{\mu}{ }_{\nu}$ form the so-called "inverse" Lorentz matrix $\Lambda^{-1}$. If the Lorentz transformation describes a transformation from an observer A to an observer B, then the inverse transformation describes the transformation from B to A.

Assuming that the Lorentz transformation matrix is the simple one to the right in (1.13), the inverse matrix $\Lambda^{-1}$ looks exactly the same as $\Lambda$ except that $-\beta$ gets replaced by $+\beta$. The reason is fairly simple. The quantity $\beta$ is the velocity between the observers scaled with the speed of light. And the relative velocity of $B$ seen by $A$ is the opposite of the one of $A$ seen by $B$, if their coordinate systems are aligned.

Consider now the reason why tensor analysis raises some indices. Physicists use a superscript index on a vector if it transforms using the normal Lorentz transformation matrix $\Lambda$. Such a vector is called a "contravariant" vector for reasons not worth describing. As an example, a position differential is a contravariant vector. So the components of a position differential are indicated by $\mathrm{d} x^{\mu}$ with a superscript index.

If a vector transforms using the inverse matrix $\Lambda^{-1}$, it is called a "covariant" vector. In that case subscript indices are used. For example, the gradient of a function $f$ is a covariant vector. So a component $\partial f / \partial x^{\mu}$ is commonly indicated by $\partial_{\mu} f$.

Now suppose that you flip over the sign of the zeroth, time, component of a four-vector like a position or a position differential. It turns out that the resulting four-vector then transforms using the inverse Lorentz transformation matrix. That means that it has become a covariant vector. (You can easily verify this in case of the simple Lorentz transform above.) Therefore lower indices are used for the flipped-over vector:

$$
\left\{x_{\mu}\right\} \equiv(-c t, x, y, z) \equiv\left(x_{0}, x_{1}, x_{2}, x_{3}\right)
$$

The convention of showing covariant vectors as rows instead of columns comes from linear algebra. Tensor notation by itself does not have such a graphical interpretation.

Keep one important thing in mind though. If you flip the sign of a component of a vector, you get a fundamentally different vector. The vector $\left\{x_{\mu}\right\}$ is not just a somewhat different way to write the position four-vector $\left\{x^{\mu}\right\}$ of the spacetime point that you are interested in. Now normally if you define some new vector that is different from a vector that you are already using, you change the name. For example, you might change the name from $x$ to $y$ or to $x^{\mathrm{L}}$ say. Tensor algebra does not do that. Therefore the golden rule is:

The names of tensors are only correct if the indices are at the right height.

If you remember that, tensor algebra becomes a lot less confusing. The expression $\left\{x^{\mu}\right\}$ is only your space-time location named $x$ if the index is a superscript as shown. The four-vector $\left\{x_{\mu}\right\}$ is simply a different animal. How do you know what is the right height? You just have to remember, you know.

Now consider two different contravariant four-vectors, call them $\left\{x^{\mu}\right\}$ and $\left\{y^{\mu}\right\}$. The dot product between these two four-vectors can be written as

$$
x_{\mu} y^{\mu}
$$

To see why, recall that since the index $\mu$ appears twice, summation over that index is understood. Also, the lowered index of $x_{\mu}$ indicates that the sign of the zeroth component is flipped over. That produces the required minus sign on the product of the time components in the dot product.

Note also from the above examples that summation indices appear once as a subscript and once as a superscript. That is characteristic of tensor algebra.

Addendum \{A.4\} gives a more extensive description of the most important tensor algebra formulae for those with a good knowledge of linear algebra.

### 1.2.6 Group property

The derivation of the Lorentz transformation as given earlier examined two observers A and B. But now assume that a third observer C is in motion compared to observer B. The coordinates of an event as perceived by observer C may then be computed from those of B using the corresponding Lorentz transformation, and the coordinates of B may in turn be computed from those of A using that Lorentz transformation. Schematically,

$$
\vec{r}_{\mathrm{C}}=\Lambda_{C \leftarrow B} \vec{r}_{\mathrm{B}}=\Lambda_{C \leftarrow B} \Lambda_{B \leftarrow A} \vec{r}_{\mathrm{A}}
$$

But if everything is OK, that means that the Lorentz transformations from A to B followed by the Lorentz transformation from B to C must be the same as the Lorentz transformation from A directly to C. In other words, the combination of two Lorentz transformations must be another Lorentz transformation.

Mathematicians say that Lorentz transformations must form a "group." It is much like rotations of a coordinate system in three spatial dimensions: a rotation followed by another one is equivalent to a single rotation over some combined angle. In fact, such spatial rotations are Lorentz transformations; just between coordinate systems that do not move compared to each other.

Using a lot of linear algebra, it may be verified that indeed the Lorentz transformations form a group, $\{\mathrm{D} .5\}$.

### 1.3 Relativistic Mechanics

### 1.3.1 Intro to relativistic mechanics

Nonrelativistic mechanics is often based on the use of a potential energy to describe the forces. For example, in a typical molecular dynamics computation, the forces between the molecules are derived from a potential that depends on the differences in position between the atoms. Unfortunately, this sort of description fails badly in the truly relativistic case.

The basic problem is not difficult to understand. If a potential depends only on the spatial configuration of the atoms involved, then the motion of an atom instantaneously affects all the other ones. Relativity simply cannot handle instantaneous effects; they must be limited by the speed of light or major problems appear. It makes relativistic mechanics more difficult.

The simplest way to deal with the problem is to look at collisions between particles. Direct collisions inherently avoid erroneous action at a distance. They allow simple dynamics to be done without the use of a potential between particles that is relativistically suspect.

As a first example, consider two particles of equal mass and opposite speeds that collide as shown in the center of figure 1.3. You might think of the particles as two helium atoms. It will be assumed that while the speed of the atoms may

Figure 1.3: Example elastic collision seen by different observers.
be quite high, the collision is at a shallow enough angle that it does not excite the atoms. In other words, it is assumed that the collision is elastic.

As seen by observer C, the collision is perfectly symmetric. Regardless of the mechanics of the actual collision, observer C sees nothing wrong with it. The energy of the helium atoms is the same after the collision as before. Also, the net linear momentum was zero before the collision and still zero afterwards. And whatever little angular momentum there is, it too is still the same after the collision.

But now consider an observer A that moves horizontally along with the top helium atom. For this observer, the top helium atom comes down vertically and bounces back vertically. Observer B moves along with the bottom helium atom in the horizontal direction and sees that atom moving vertically. Now consider the Lorentz transformation (1.7) of the vertical velocity $v_{y, 2}$ of the top atom as seen by observer A into the vertical velocity $v_{y}$ of that atom as seen by observer B:

$$
v_{y}=\sqrt{1-\left(v_{x} / c\right)^{2}} v_{y, 2}
$$

They are different! In particular, $v_{y}$ is smaller than $v_{y, 2}$. Therefore, if the masses of the helium atoms that the observers perceive would be their rest mass, linear momentum would not be conserved. For example, observer A would perceive a net downwards linear momentum before the collision and a net upwards linear momentum after it.

Clearly, linear momentum conservation is too fundamental a concept to be summarily thrown out. Instead, observer A perceives the mass of the rapidly moving lower atom to be the moving mass $m_{v}$, which is larger than the rest mass $m$ by the Lorentz factor:

$$
m_{v}=\frac{m}{\sqrt{1-(v / c)^{2}}}
$$

and that exactly compensates for the lower vertical velocity in the expression for the momentum. (Remember that it was assumed that the collision is under a shallow angle, so the vertical velocity components are too small to have an effect on the masses.)

It is not difficult to understand why things are like this. The nonrelativistic definition of momentum allows two plausible generalizations to the relativistic
case:

$$
\vec{p}=m \frac{\mathrm{~d} \vec{r}}{\mathrm{~d} t} \quad \Longrightarrow\left\{\begin{array}{l}
\stackrel{\rightharpoonup}{p}=m \frac{\mathrm{~d} \stackrel{\rightharpoonup}{r}}{\mathrm{~d} t} ? \\
\stackrel{\mathrm{p}}{\mathrm{p}}=m \frac{\mathrm{~d}}{\mathrm{~d} t_{0}}
\end{array}\right.
$$

Indeed, nonrelativistically, all observers agree about time intervals. However, relativistically the question arises whether the right time differential in momentum is $\mathrm{d} t$ as perceived by the observer, or the proper time difference $\mathrm{d} t_{0}$ as perceived by a hypothetical second observer moving along with the particle.

A little thought shows that the right time differential has to be $\mathrm{d} t_{0}$. For, after collisions the sum of the momenta should be the same as before them. However, the Lorentz velocity transformation (1.7) shows that perceived velocities transform nonlinearly from one observer to the next. For a nonlinear transformation, there is no reason to assume that if the momenta after a collision are the same as before for one observer, they are also so for another observer. On the other hand, since all observers agree about the proper time intervals, momentum based on the proper time interval $\mathrm{d} t_{0}$ transforms like $\mathrm{d} \stackrel{\rightharpoonup}{r}$, like position, and that is linear. A linear transformation does assure that if an observer A perceives that the sum of the momenta of a collection of particles $j=1,2, \ldots$ is the same before and after,

$$
\sum_{j} \overleftrightarrow{p}_{j A, \text { after }}=\sum_{j} \overleftrightarrow{p}_{j A, \text { before }}
$$

then so does any other observer B:

$$
\sum_{j} \Lambda_{B \leftarrow A} \overleftrightarrow{p}_{j A, \text { after }}=\sum_{j} \Lambda_{B \leftarrow A} \stackrel{p}{p}_{j A, \text { before }} \quad \Rightarrow \quad \sum_{j} \overleftrightarrow{p}_{j B, \text { after }}=\sum_{j} \overleftrightarrow{p}_{j B, \text { before }}
$$

Using the chain rule of differentiation, the components of the momentum four-vector $\vec{p}$ can be written out as

$$
\begin{equation*}
p_{0}=m c \frac{\mathrm{~d} t}{\mathrm{~d} t_{0}} \quad p_{1}=m \frac{\mathrm{~d} t}{\mathrm{~d} t_{0}} \frac{\mathrm{~d} x}{\mathrm{~d} t} \quad p_{2}=m \frac{\mathrm{~d} t}{\mathrm{~d} t_{0}} \frac{\mathrm{~d} y}{\mathrm{~d} t} \quad p_{3}=m \frac{\mathrm{~d} t}{\mathrm{~d} t_{0}} \frac{\mathrm{~d} z}{\mathrm{~d} t} \tag{1.14}
\end{equation*}
$$

The components $p_{1}, p_{2}, p_{3}$ can be written in the same form as in the nonrelativistic case by defining a moving mass

$$
\begin{equation*}
m_{v}=m \frac{\mathrm{~d} t}{\mathrm{~d} t_{0}}=\frac{m}{\sqrt{1-(v / c)^{2}}} \tag{1.15}
\end{equation*}
$$

How about the zeroth component? Since it too is part of the conservation law, reasonably speaking it can only be the relativistic equivalent of the nonrelativistic kinetic energy. Indeed, it equals $m_{v} c^{2}$ except for a trivial scaling factor $1 / c$ to give it units of momentum.

Seen by observer A: Seen by observer B:
Before:
After:

Figure 1.4: A completely inelastic collision.

Note that so far, this only indicates that the difference between $m_{v} c^{2}$ and $m c^{2}$ gives the kinetic energy. It does not imply that $m c^{2}$ by itself also corresponds to a meaningful energy. However, there is a beautifully simple argument to show that indeed kinetic energy can be converted into rest mass, [21]. Consider two identical rest masses $m$ that are accelerated to high speed and then made to crash into each other head-on, as in the left part of figure 1.4. In this case, think of the masses as macroscopic objects, so that thermal energy is a meaningful concept for them. Assume that the collision has so much energy that the masses melt and merge without any rebound. By symmetry, the combined mass $M$ has zero velocity. Momentum is conserved: the net momentum was zero before the collision because the masses had opposite velocity, and it is still zero after the collision. All very straightforward.

But now consider the same collision from the point of view of a second observer who is moving upwards slowly compared to the first observer with a small speed $v_{\mathrm{B}}$. No relativity involved here at all; going up so slowly, the second observer sees almost the same thing as the first one, with one difference. According to the second observer, the entire collision process seems to have a small downward velocity $v_{\mathrm{B}}$. The two masses have a slight downward velocity $v_{\mathrm{B}}$ before the collision and so has the mass $M$ after the collision. But then vertical momentum conservation inevitably implies

$$
2 m_{v} v_{\mathrm{B}}=M v_{\mathrm{B}}
$$

So $M$ must be twice the moving mass $m_{v}$. The combined rest mass $M$ is not the sum of the rest masses $m$, but of the moving masses $m_{v}$. All the kinetic energy given to the two masses has ended up as additional rest mass in $M$.

### 1.3.2 Lagrangian mechanics

Lagrangian mechanics can simplify many complicated dynamics problems. As an example, in this section it is used to derive the relativistic motion of a particle in an electromagnetic field.

Consider first the nonrelativistic motion of a particle in an electrostatic field. That is an important case for this book, because it is a good approximation for the electron in the hydrogen atom. To describe such purely nonrelativistic
motion, physicists like to define a Lagrangian as

$$
\begin{equation*}
\mathcal{L}=\frac{1}{2} m|\vec{v}|^{2}-q \varphi \tag{1.16}
\end{equation*}
$$

where $m$ is the mass of the particle, $\vec{v}$ its velocity, and $q$ its charge, while $q \varphi$ is the potential energy due to the electrostatic field, which depends on the position of the particle. (It is important to remember that the Lagrangian should mathematically be treated as a function of velocity and position of the particle. While for a given motion, the position and velocity are in turn functions of time, time derivatives must be implemented through the chain rule, i.e. by means of total derivatives of the Lagrangian.)

Physicists next define canonical, or generalized, momentum as the partial derivative of the Lagrangian with respect to velocity. An arbitrary component $p_{i}^{c}$ of the canonical momentum is found as

$$
\begin{equation*}
p_{i}^{\mathrm{c}}=\frac{\partial \mathcal{L}}{\partial v_{i}} \tag{1.17}
\end{equation*}
$$

This works out to be simply component $p_{i}=m v_{i}$ of the normal momentum. The equations of motion are taken to be

$$
\begin{equation*}
\frac{\mathrm{d} p_{i}^{\mathrm{c}}}{\mathrm{~d} t}=\frac{\partial \mathcal{L}}{\partial r_{i}} \tag{1.18}
\end{equation*}
$$

which is found to be

$$
\frac{\mathrm{d} p_{i}}{\mathrm{~d} t}=-q \frac{\partial \varphi}{\partial r_{i}}
$$

That is simply Newton's second law; the left hand side is just mass times acceleration while in the right hand side minus the spatial derivative of the potential energy gives the force. It can also be seen that the sum of kinetic and potential energy of the particle remains constant, by multiplying Newton's equation by $v_{i}$ and summing over $i$.

Since the Lagrangian is a just a scalar, it is relatively simple to guess its form in the relativistic case. To get the momentum right, simply replace the kinetic energy by an reciprocal Lorentz factor,

$$
-m c^{2} \sqrt{1-(|\vec{v}| / c)^{2}}
$$

For velocities small compared to the speed of light, a two term Taylor series shows this is equivalent to $m c^{2}$ plus the kinetic energy. The constant $m c^{2}$ is of no importance since only derivatives of the Lagrangian are used. For any velocity, big or small, the canonical momentum as defined above produces the relativistic momentum based on the moving mass as it should.

The potential energy part of the Lagrangian is a bit trickier. The previous section showed that momentum is a four-vector including energy. Therefore,
going from one observer to another mixes up energy and momentum nontrivially, just like it mixes up space and time. That has consequences for energy conservation. In the classical solution, kinetic energy of the particle can temporarily be stored away as electrostatic potential energy and recovered later intact. But relativistically, the kinetic energy seen by one observer becomes momentum seen by another one. If that momentum is to be recovered intact later, there should be something like potential momentum. Since momentum is a vector, obviously so should potential momentum be: there must be something like a vector potential $\vec{A}$.

Based on those arguments, you might guess that the Lagrangian should be something like

$$
\begin{equation*}
\mathcal{L}=-m c^{2} \sqrt{1-(|\vec{v}| / c)^{2}}+q \overleftrightarrow{A} \cdot \frac{\mathrm{~d} \stackrel{\rightharpoonup}{r}}{\mathrm{~d} t} \quad \stackrel{\rightharpoonup}{A}=\left(\frac{1}{c} \varphi, A_{x}, A_{y}, A_{z}\right) \tag{1.19}
\end{equation*}
$$

And that is in fact right. Component zero of the potential four-vector is the classical electrostatic potential. The spatial vector $\vec{A}=\left(A_{x}, A_{y}, A_{z}\right)$ is called the "magnetic vector potential."

The canonical momentum is now

$$
\begin{equation*}
p_{i}^{\mathrm{c}}=\frac{\partial \mathcal{L}}{\partial v_{i}}=m_{v} v_{i}+q A_{i} \tag{1.20}
\end{equation*}
$$

and that is no longer just the normal momentum, $p_{i}=m_{v} v_{i}$, but includes the magnetic vector potential.

The Lagrangian equations of motion become, the same way as before, but after clean up and in vector notation, $\{$ D. 6$\}$ :

$$
\begin{equation*}
\frac{\mathrm{d} \vec{p}}{\mathrm{~d} t}=q \overrightarrow{\mathcal{E}}+q \vec{v} \times \overrightarrow{\mathcal{B}} \tag{1.21}
\end{equation*}
$$

The right-hand side in this equation of motion is called the Lorentz force. In it, $\overrightarrow{\mathcal{E}}$ is called the electric field and $\overrightarrow{\mathcal{B}}$ the magnetic field. These fields are related to the four-vector potential as

$$
\overrightarrow{\mathcal{E}}=-\nabla \varphi-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A}
$$

where by definition

$$
\nabla=\hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

is the vector operator called nabla or del.
Of course, if the Lagrangian above is right, it should apply to all observers, regardless of their relative motion. In particular, all observers should agree that the so-called "action" integral $\int \mathcal{L} \mathrm{d} t$ is stationary for the way that the
particle moves, $\{$ A.1.3\}, $\{$ D.3.1\} That requires that $\overleftrightarrow{A}$ transforms according to the Lorentz transformation.
(To see why, recall that dot products are the same for all observers, and that the square root in the Lagrangian (1.19) equals $\mathrm{d} t_{0} / \mathrm{d} t$ where the proper time interval $\mathrm{d} t_{0}$ is the same for all observers. So the action is the same for all observers.)

From the Lorentz transformation of $\overleftrightarrow{A}$, that of the electric and magnetic fields may be found; that is not a Lorentz transformation. Note that this suggests that $\vec{A}$ might be more fundamental physically than the more intuitive electric and magnetic fields. And that is in fact exactly what more advanced quantum mechanics shows, chapter 13.1.

It may be noted that the field strengths are unchanged in a "gauge transformation" that modifies $\varphi$ and $\vec{A}$ into

$$
\begin{equation*}
\varphi^{\prime}=\varphi-\frac{\partial \chi}{\partial t} \quad \vec{A}^{\prime}=\vec{A}+\nabla \chi \tag{1.22}
\end{equation*}
$$

where $\chi$ is any arbitrary function of position and time. This might at first seem no more than a neat mathematical trick. But actually, in advanced quantum mechanics it is of decisive importance, chapter 7.3, \{A.19.5\}.

The energy can be found following addendum $\{$ A. 1$\}$ as

$$
E=\vec{v} \cdot \vec{p}^{\mathrm{c}}-\mathcal{L}=m_{v} c^{2}+q \varphi
$$

The Hamiltonian is the energy expressed in terms of the canonical momentum $\vec{p}^{\mathrm{c}}$ instead of $\vec{v}$; that works out to

$$
H=\sqrt{\left(m c^{2}\right)^{2}+\left(\vec{p}^{c}-q \vec{A}\right)^{2} c^{2}}+q \varphi
$$

using the formula given in the overview subsection. The Hamiltonian is of great importance in quantum mechanics.

#### Abstract

\section*{Abstract}

Quantum mechanics is based on a number of advanced mathematical ideas that are described in this chapter.

First the normal real numbers will be generalized to complex numbers. A number such as $\mathrm{i}=\sqrt{-1}$ is an invalid real number, but it is considered to be a valid complex one. The mathematics of quantum mechanics is most easily described in terms of complex numbers.

Classical physics tends to deal with numbers such as the position, velocity, and acceleration of particles. However, quantum mechanics deals primarily with functions rather than with numbers. To facilitate manipulating functions, they will be modeled as vectors in infinitely many dimensions. Dot products, lengths, and orthogonality can then all be used to manipulate functions. Dot products will however be renamed to be "inner products" and lengths to be "norms." "Operators" will be defined that turn functions into other functions. Particularly important for quantum mechanics are "eigenvalue" cases, in which an operator turns a function into a simple multiple of itself. A special class of operators, "Hermitian" operators will be defined. These will eventually turn out to be very important, because quantum mechanics associates physical quantities like position, momentum, and energy with corresponding Hermitian operators and their eigenvalues.

### 2.1 Complex Numbers

Quantum mechanics is full of complex numbers, numbers involving

$$
\mathrm{i}=\sqrt{-1}
$$

Note that $\sqrt{-1}$ is not an ordinary, "real", number, since there is no real number whose square is -1 ; the square of a real number is always positive. This section summarizes the most important properties of complex numbers.

First, any complex number, call it $c$, can by definition always be written in the form

$$
\begin{equation*}
c=c_{r}+\mathrm{i} c_{i} \tag{2.1}
\end{equation*}
$$

where both $c_{r}$ and $c_{i}$ are ordinary real numbers, not involving $\sqrt{-1}$. The number $c_{r}$ is called the real part of $c$ and $c_{i}$ the imaginary part.

You can think of the real and imaginary parts of a complex number as the components of a two-dimensional vector:

The length of that vector is called the "magnitude," or "absolute value" $|c|$ of the complex number. It equals

$$
|c|=\sqrt{c_{r}^{2}+c_{i}^{2}}
$$

Complex numbers can be manipulated pretty much in the same way as ordinary numbers can. A relation to remember is:

$$
\begin{equation*}
\frac{1}{\mathrm{i}}=-\mathrm{i} \tag{2.2}
\end{equation*}
$$

which can be verified by multiplying the top and bottom of the fraction by i and noting that by definition $\mathrm{i}^{2}=-1$ in the bottom.

The complex conjugate of a complex number $c$, denoted by $c^{*}$, is found by replacing i everywhere by -i . In particular, if $c=c_{r}+\mathrm{i} c_{i}$, where $c_{r}$ and $c_{i}$ are real numbers, the complex conjugate is

$$
\begin{equation*}
c^{*}=c_{r}-\mathrm{i} c_{i} \tag{2.3}
\end{equation*}
$$

The following picture shows that graphically, you get the complex conjugate of a complex number by flipping it over around the horizontal axis:

You can get the magnitude of a complex number $c$ by multiplying $c$ with its complex conjugate $c^{*}$ and taking a square root:

$$
\begin{equation*}
|c|=\sqrt{c^{*} c} \tag{2.4}
\end{equation*}
$$

If $c=c_{r}+\mathrm{i} c_{i}$, where $c_{r}$ and $c_{i}$ are real numbers, multiplying out $c^{*} c$ shows the magnitude of $c$ to be

$$
|c|=\sqrt{c_{r}^{2}+c_{i}^{2}}
$$

which is indeed the same as before.
From the above graph of the vector representing a complex number $c$, the real part is $c_{r}=|c| \cos \alpha$ where $\alpha$ is the angle that the vector makes with the horizontal axis, and the imaginary part is $c_{i}=|c| \sin \alpha$. So you can write any complex number in the form

$$
c=|c|(\cos \alpha+\mathrm{i} \sin \alpha)
$$

The critically important Euler formula says that:

$$
\begin{equation*}
\cos \alpha+\mathrm{i} \sin \alpha=e^{\mathrm{i} \alpha} \tag{2.5}
\end{equation*}
$$

So, any complex number can be written in "polar form" as

$$
\begin{equation*}
c=|c| e^{\mathrm{i} \alpha} \tag{2.6}
\end{equation*}
$$

where both the magnitude $|c|$ and the phase angle (or argument) $\alpha$ are real numbers.

Any complex number of magnitude one can therefore be written as $e^{\mathrm{i} \alpha}$. Note that the only two real numbers of magnitude one, 1 and -1 , are included for $\alpha$ $=0$, respectively $\alpha=\pi$. The number i is obtained for $\alpha=\pi / 2$ and -i for $\alpha=$ $-\pi / 2$.
(See derivation $\{\mathrm{D} .7\}$ if you want to know where the Euler formula comes from.)

## Key Points

$0-$ Complex numbers include the square root of minus one, $i$, as a valid number.
0- All complex numbers can be written as a real part plus i times an imaginary part, where both parts are normal real numbers.
$0-$ The complex conjugate of a complex number is obtained by replacing i everywhere by -i .
$0-$ The magnitude of a complex number is obtained by multiplying the number by its complex conjugate and then taking a square root.

0 - The Euler formula relates exponentials to sines and cosines.

1. Multiply out $(2+3 \mathrm{i})^{2}$ and then find its real and imaginary part. Solution mathcplx-a
2. Show more directly that $1 / \mathrm{i}=-\mathrm{i}$.

Solution mathcplx-b
3. Multiply out $(2+3 \mathrm{i})(2-3 \mathrm{i})$ and then find its real and imaginary part. Solution mathcplx-c
4. Find the magnitude or absolute value of $2+3 \mathrm{i}$. Solution mathcplx-d
5. Verify that $(2-3 \mathrm{i})^{2}$ is still the complex conjugate of $(2+3 \mathrm{i})^{2}$ if both are multiplied out.

Solution mathcplx-e
6. Verify that $e^{-2 \mathrm{i}}$ is still the complex conjugate of $e^{2 \mathrm{i}}$ after both are rewritten using the Euler formula.
Solution mathcplx-f
7. Verify that $\left(e^{\mathrm{i} \alpha}+e^{-\mathrm{i} \alpha}\right) / 2=\cos \alpha$.

Solution mathcplx-g
8. Verify that $\left(e^{\mathrm{i} \alpha}-e^{-\mathrm{i} \alpha}\right) / 2 \mathrm{i}=\sin \alpha$. Solution mathcplx-h

### 2.2 Functions as Vectors

The second mathematical idea that is crucial for quantum mechanics is that functions can be treated in a way that is fundamentally not that much different from vectors.

A vector $\vec{f}$ (which might be velocity $\vec{v}$, linear momentum $\vec{p}=m \vec{v}$, force $\vec{F}$, or whatever) is usually shown in physics in the form of an arrow:

Figure 2.1: The classical picture of a vector.

However, the same vector may instead be represented as a spike diagram, by plotting the value of the components versus the component index:

Figure 2.2: Spike diagram of a vector.
(The symbol $i$ for the component index is not to be confused with $\mathrm{i}=\sqrt{-1}$.) In the same way as in two dimensions, a vector in three dimensions, or, for that matter, in thirty dimensions, can be represented by a spike diagram:

Figure 2.3: More dimensions.
And just like vectors can be interpreted as spike diagrams, spike diagrams can be interpreted as vectors. So a spike diagram with very many spikes can be considered to be a single vector in a space with a very high number of dimensions.

In the limit of infinitely many spikes, the large values of $i$ can be rescaled into a continuous coordinate, call it $x$. For example, $x$ might be defined as $i$ divided by the number of dimensions. In any case, the spike diagram becomes a function $f$ of a continuous coordinate $x$ :

Figure 2.4: Infinite dimensions.
For functions, the spikes are usually not shown:

Figure 2.5: The classical picture of a function.

In this way, a function is just a single vector in an infinite dimensional space.
Note that the $(x)$ in $f(x)$ does not mean "multiply by $x$." Here the $(x)$ is only a way of reminding you that $f$ is not a simple number but a function. Just like the arrow in $\vec{f}$ is only a way of reminding you that that $f$ is not a simple number but a vector.
(It should be noted that to make the transition to infinite dimensions mathematically meaningful, you need to impose some smoothness constraints on the function. Typically, it is required that the function is continuous, or at least integrable in some sense. These details are not important for this book.)

## Key Points

$0-\mathrm{A}$ function can be thought of as a vector with infinitely many components.
0- This allows quantum mechanics do the same things with functions as you can do with vectors.

### 2.2 Review Questions

1. Graphically compare the spike diagram of the 10 -dimensional vector $\vec{v}$ with components ( $0.5,1,1.5,2,2.5,3,3.5,4,4.5,5$ ) with the plot of the function $f(x)=0.5 x$.
Solution funcvec-a
2. Graphically compare the spike diagram of the 10 -dimensional unit vector $\hat{\imath}_{3}$, with components ( $0,0,1,0,0,0,0,0,0,0$ ), with the plot of the function $f(x)=1$. (No, they do not look alike.)

Solution funcvec-b

### 2.3 The Dot, oops, INNER Product

The dot product of vectors is an important tool. It makes it possible to find the length of a vector, by multiplying the vector by itself and taking the square root. It is also used to check if two vectors are orthogonal: if their dot product is zero, they are. In this subsection, the dot product is defined for complex vectors and functions.

The usual dot product of two vectors $\vec{f}$ and $\vec{g}$ can be found by multiplying components with the same index $i$ together and summing that:

$$
\vec{f} \cdot \vec{g} \equiv f_{1} g_{1}+f_{2} g_{2}+f_{3} g_{3}
$$

(The emphatic equal, $\equiv$, is commonly used to indicate "is by definition equal" or "is always equal.") Figure 2.6 shows multiplied components using equal colors.

Figure 2.6: Forming the dot product of two vectors.
Note the use of numeric subscripts, $f_{1}, f_{2}$, and $f_{3}$ rather than $f_{x}, f_{y}$, and $f_{z}$; it means the same thing. Numeric subscripts allow the three term sum above to be written more compactly as:

$$
\vec{f} \cdot \vec{g} \equiv \sum_{\text {all } i} f_{i} g_{i}
$$

The $\Sigma$ is called the "summation symbol."
The length of a vector $\vec{f}$, indicated by $|\vec{f}|$ or simply by $f$, is normally computed as

$$
|\vec{f}|=\sqrt{\vec{f} \cdot \vec{f}}=\sqrt{\sum_{\text {all } i} f_{i}^{2}}
$$

However, this does not work correctly for complex vectors. The difficulty is that terms of the form $f_{i}^{2}$ are no longer necessarily positive numbers. For example, $\mathrm{i}^{2}=-1$.

Therefore, it is necessary to use a generalized "inner product" for complex vectors, which puts a complex conjugate on the first vector:

$$
\begin{equation*}
\langle\vec{f} \mid \vec{g}\rangle \equiv \sum_{\text {all } i} f_{i}^{*} g_{i} \tag{2.7}
\end{equation*}
$$

If the vector $\vec{f}$ is real, the complex conjugate does nothing, and the inner product $\langle\vec{f} \mid \vec{g}\rangle$ is the same as the dot product $\vec{f} \cdot \vec{g}$. Otherwise, in the inner product $\vec{f}$ and $\vec{g}$ are no longer interchangeable; the conjugates are only on the first factor, $\vec{f}$. Interchanging $\vec{f}$ and $\vec{g}$ changes the inner product's value into its complex conjugate.

The length of a nonzero vector is now always a positive number:

$$
\begin{equation*}
|\vec{f}|=\sqrt{\langle\vec{f} \mid \vec{f}\rangle}=\sqrt{\sum_{\text {all } i}\left|f_{i}\right|^{2}} \tag{2.8}
\end{equation*}
$$

Physicists take the inner product "bracket" verbally apart as

| $\langle\vec{f}\|$ |  | $\|\vec{g}\rangle$ |
| :---: | :---: | :---: |
| bra | $\&$ | ket |

and refer to vectors as bras and kets.
The inner product of functions is defined in exactly the same way as for vectors, by multiplying values at the same $x$-position together and summing. But since there are infinitely many $x$ values, the sum becomes an integral:

$$
\begin{equation*}
\langle f \mid g\rangle=\int_{\operatorname{all} x} f^{*}(x) g(x) \mathrm{d} x \tag{2.9}
\end{equation*}
$$

Figure 2.7 shows multiplied function values using equal colors:

Figure 2.7: Forming the inner product of two functions.
The equivalent of the length of a vector is in the case of a function called its "norm:"

$$
\begin{equation*}
\|f\| \equiv \sqrt{\langle f \mid f\rangle}=\sqrt{\int_{\text {all } x}|f(x)|^{2} \mathrm{~d} x} \tag{2.10}
\end{equation*}
$$

The double bars are used to avoid confusion with the absolute value of the function.

A vector or function is called "normalized" if its length or norm is one:

$$
\begin{equation*}
\langle f \mid f\rangle=1 \text { iff } f \text { is normalized. } \tag{2.11}
\end{equation*}
$$

("iff" should really be read as "if and only if.")
Two vectors, or two functions, $f$ and $g$, are by definition orthogonal if their inner product is zero:

$$
\begin{equation*}
\langle f \mid g\rangle=0 \text { iff } f \text { and } g \text { are orthogonal. } \tag{2.12}
\end{equation*}
$$

Sets of vectors or functions that are all

- mutually orthogonal, and
- normalized
occur a lot in quantum mechanics. Such sets should be called "orthonormal", though the less precise term "orthogonal" is often used instead. This document will refer to them correctly as being orthonormal.

So, a set of functions or vectors $f_{1}, f_{2}, f_{3}, \ldots$ is orthonormal if

$$
0=\left\langle f_{1} \mid f_{2}\right\rangle=\left\langle f_{2} \mid f_{1}\right\rangle=\left\langle f_{1} \mid f_{3}\right\rangle=\left\langle f_{3} \mid f_{1}\right\rangle=\left\langle f_{2} \mid f_{3}\right\rangle=\left\langle f_{3} \mid f_{2}\right\rangle=\ldots
$$

and

$$
1=\left\langle f_{1} \mid f_{1}\right\rangle=\left\langle f_{2} \mid f_{2}\right\rangle=\left\langle f_{3} \mid f_{3}\right\rangle=\ldots
$$

## Key Points

0 - For complex vectors and functions, the normal dot product becomes the inner product.
$0-$ To take an inner product of vectors,

- take complex conjugates of the components of the first vector;
- multiply corresponding components of the two vectors together;
- sum these products.
$0-$ To take an inner product of functions,
- take the complex conjugate of the first function;
- multiply the two functions;
- integrate the product function.
$0-$ To find the length of a vector, take the inner product of the vector with itself, and then a square root.
$0-$ To find the norm of a function, take the inner product of the function with itself, and then a square root.
$0-$ A pair of vectors, or a pair of functions, is orthogonal if their inner product is zero.
$0-A$ set of vectors forms an orthonormal set if every one is orthogonal to all the rest, and every one is of unit length.
$0-A$ set of functions forms an orthonormal set if every one is orthogonal to all the rest, and every one is of unit norm.

### 2.3 Review Questions

1. Find the following inner product of the two vectors:

$$
\left\langle\left.\binom{ 1+\mathrm{i}}{2-\mathrm{i}} \right\rvert\,\binom{ 2 \mathrm{i}}{3}\right\rangle
$$

Solution dot-a
2. Find the length of the vector

$$
\binom{1+\mathrm{i}}{3}
$$

Solution dot-b
3. Find the inner product of the functions $\sin (x)$ and $\cos (x)$ on the interval $0 \leqslant x \leqslant 1$.

Solution dot-c
4. Show that the functions $\sin (x)$ and $\cos (x)$ are orthogonal on the interval $0 \leqslant x \leqslant 2 \pi$.

Solution dot-d
5. Verify that $\sin (x)$ is not a normalized function on the interval $0 \leqslant x \leqslant$ $2 \pi$, and normalize it by dividing by its norm.

Solution dot-e
6. Verify that the most general multiple of $\sin (x)$ that is normalized on the interval $0 \leqslant x \leqslant 2 \pi$ is $e^{\mathrm{i} \alpha} \sin (x) / \sqrt{\pi}$ where $\alpha$ is any arbitrary real number. So, using the Euler formula, the following multiples of $\sin (x)$ are all normalized: $\sin (x) / \sqrt{\pi}$, (for $\alpha=0$ ), $-\sin (x) / \sqrt{\pi}$, (for $\alpha=\pi$ ), and $\mathrm{i} \sin (x) / \sqrt{\pi}$, (for $\alpha=\pi / 2$ ).
Solution dot-f
7. Show that the functions $e^{4 \mathrm{i} \pi x}$ and $e^{6 \mathrm{i} \pi x}$ are an orthonormal set on the interval $0 \leqslant x \leqslant 1$.

Solution dot-g

### 2.4 Operators

This section defines operators, which are a generalization of matrices. Operators are the principal components of quantum mechanics.

In a finite number of dimensions, a matrix A can transform any arbitrary vector $v$ into a different vector $A \vec{v}$ :

$$
\vec{v} \xrightarrow{\text { matrix } A} \vec{w}=A \vec{v}
$$

Similarly, an operator transforms a function into another function:

$$
f(x) \xrightarrow{\text { operator } A} g(x)=A f(x)
$$

Some simple examples of operators:

$$
\begin{aligned}
& f(x) \xrightarrow{\widehat{x}} g(x)=x f(x) \\
& f(x) \longrightarrow g(x)=f^{\prime}(x)
\end{aligned}
$$

Note that a hat is often used to indicate operators; for example, $\widehat{x}$ is the symbol for the operator that corresponds to multiplying by $x$. If it is clear that something is an operator, such as $\mathrm{d} / \mathrm{d} x$, no hat will be used.

It should really be noted that the operators that you are interested in in quantum mechanics are "linear" operators. If you increase a function $f$ by a factor, $A f$ increases by that same factor. Also, for any two functions $f$ and $g$, $A(f+g)$ will be $(A f)+(A g)$. For example, differentiation is a linear operator:

$$
\frac{\mathrm{d}\left(c_{1} f(x)+c_{2} g(x)\right)}{\mathrm{d} x}=c_{1} \frac{\mathrm{~d} f(x)}{\mathrm{d} x}+c_{2} \frac{\mathrm{~d} g(x)}{\mathrm{d} x}
$$

Squaring is not a linear operator:

$$
\left(c_{1} f(x)+c_{2} g(x)\right)^{2}=c_{1}^{2} f^{2}(x)+2 c_{1} c_{2} f(x) g(x)+c_{2}^{2} g^{2}(x) \neq c_{1} f^{2}(x)+c_{2} g^{2}(x)
$$

However, it is not something to really worry about. You will not find a single nonlinear operator in the rest of this entire book.

## Key Points

$0-$ Matrices turn vectors into other vectors.
$0-$ Operators turn functions into other functions.

### 2.4 Review Questions

1. So what is the result if the operator $\mathrm{d} / \mathrm{d} x$ is applied to the function $\sin (x)$ ? Solution mathops-a
2. If, say, $\widehat{x^{2}} \sin (x)$ is simply the function $x^{2} \sin (x)$, then what $i s$ the difference between $\widehat{x^{2}}$ and $x^{2}$ ?

Solution mathops-b
3. A less self-evident operator than the above examples is a translation operator like $\mathcal{T}_{\pi / 2}$ that translates the graph of a function towards the left by an amount $\pi / 2: \mathcal{T}_{\pi / 2} f(x)=f\left(x+\frac{1}{2} \pi\right)$. (Curiously enough, translation operators turn out to be responsible for the law of conservation of momentum.) Show that $\mathcal{T}_{\pi / 2}$ turns $\sin (x)$ into $\cos (x)$.
Solution mathops-c
4. The inversion, or parity, operator $\Pi$ turns $f(x)$ into $f(-x)$. (It plays a part in the question to what extent physics looks the same when seen in the mirror.) Show that $\Pi$ leaves $\cos (x)$ unchanged, but turns $\sin (x)$ into $-\sin (x)$.

Solution mathops-d

### 2.5 Eigenvalue Problems

To analyze quantum mechanical systems, it is normally necessary to find socalled eigenvalues and eigenvectors or eigenfunctions. This section defines what they are.

A nonzero vector $\vec{v}$ is called an eigenvector of a matrix $A$ if $A \vec{v}$ is a multiple of the same vector:

$$
\begin{equation*}
A \vec{v}=a \vec{v} \text { iff } \vec{v} \text { is an eigenvector of } A \tag{2.13}
\end{equation*}
$$

The multiple $a$ is called the eigenvalue. It is just a number.
A nonzero function $f$ is called an eigenfunction of an operator $A$ if $A f$ is a multiple of the same function:

$$
\begin{equation*}
A f=a f \text { iff } f \text { is an eigenfunction of } A \tag{2.14}
\end{equation*}
$$

Figure 2.8: Illustration of the eigenfunction concept. Function $\sin (2 x)$ is shown in black. Its first derivative $2 \cos (2 x)$, shown in red, is not just a multiple of $\sin (2 x)$. Therefore $\sin (2 x)$ is not an eigenfunction of the first derivative operator. However, the second derivative of $\sin (2 x)$ is $-4 \sin (2 x)$, which is shown in green, and that is indeed a multiple of $\sin (2 x)$. So $\sin (2 x)$ is an eigenfunction of the second derivative operator, and with eigenvalue -4 .

For example, $e^{x}$ is an eigenfunction of the operator $\mathrm{d} / \mathrm{d} x$ with eigenvalue 1 , since $\mathrm{d} e^{x} / \mathrm{d} x=1 e^{x}$. Another simple example is illustrated in figure 2.8; the function $\sin (2 x)$ is not an eigenfunction of the first derivative operator $\mathrm{d} / \mathrm{d} x$. However it is an eigenfunction of the second derivative operator $\mathrm{d}^{2} / \mathrm{d} x^{2}$, and with eigenvalue -4 .

Eigenfunctions like $e^{x}$ are not very common in quantum mechanics since they become very large at large $x$, and that typically does not describe physical situations. The eigenfunctions of the first derivative operator $\mathrm{d} / \mathrm{d} x$ that do appear a lot are of the form $e^{\mathrm{i} k x}$, where $\mathrm{i}=\sqrt{-1}$ and $k$ is an arbitrary real number. The eigenvalue is $i k$ :

$$
\frac{\mathrm{d}}{\mathrm{~d} x} e^{\mathrm{i} k x}=\mathrm{i} k e^{\mathrm{i} k x}
$$

Function $e^{\text {ikx }}$ does not blow up at large $x$; in particular, the Euler formula (2.5) says:

$$
e^{\mathrm{i} k x}=\cos (k x)+\mathrm{i} \sin (k x)
$$

The constant $k$ is called the "wave number."

## Key Points

$0-$ If a matrix turns a nonzero vector into a multiple of that vector, then that vector is an eigenvector of the matrix, and the multiple is the eigenvalue.
0- If an operator turns a nonzero function into a multiple of that function, then that function is an eigenfunction of the operator, and the multiple is the eigenvalue.

### 2.5 Review Questions

1. Show that $e^{\mathrm{i} k x}$, above, is also an eigenfunction of $\mathrm{d}^{2} / \mathrm{d} x^{2}$, but with eigenvalue $-k^{2}$. In fact, it is easy to see that the square of any operator has the same eigenfunctions, but with the square eigenvalues.

Solution eigvals-a
2. Show that any function of the form $\sin (k x)$ and any function of the form $\cos (k x)$, where $k$ is a constant called the wave number, is an eigenfunction of the operator $\mathrm{d}^{2} / \mathrm{d} x^{2}$, though they are not eigenfunctions of $\mathrm{d} / \mathrm{d} x$. Solution eigvals-b
3. Show that $\sin (k x)$ and $\cos (k x)$, with $k$ a constant, are eigenfunctions of the inversion operator $\Pi$, which turns any function $f(x)$ into $f(-x)$, and find the eigenvalues.

Solution eigvals-c

### 2.6 Hermitian Operators

Most operators in quantum mechanics are of a special kind called "Hermitian". This section lists their most important properties.

An operator is called Hermitian when it can always be flipped over to the other side if it appears in a inner product:

$$
\begin{equation*}
\langle f \mid A g\rangle=\langle A f \mid g\rangle \text { always iff } A \text { is Hermitian. } \tag{2.15}
\end{equation*}
$$

That is the definition, but Hermitian operators have the following additional special properties:

- They always have real eigenvalues, not involving $\mathrm{i}=\sqrt{-1}$. (But the eigenfunctions, or eigenvectors if the operator is a matrix, might be complex.) Physical values such as position, momentum, and energy are ordinary real numbers since they are eigenvalues of Hermitian operators $\{\mathrm{N} .3\}$.
- Their eigenfunctions can always be chosen so that they are normalized and mutually orthogonal, in other words, an orthonormal set. This tends to simplify the various mathematics a lot.
- Their eigenfunctions form a "complete" set. This means that any function can be written as some linear combination of the eigenfunctions. (There is a proof in derivation $\{D .8\}$ for an important example. But see also $\{\mathrm{N} .4\}$.) In practical terms, it means that you only need to look at the eigenfunctions to completely understand what the operator does.
In the linear algebra of real matrices, Hermitian operators are simply symmetric matrices. A basic example is the inertia matrix of a solid body in Newtonian dynamics. The orthonormal eigenvectors of the inertia matrix give the directions of the principal axes of inertia of the body.

An orthonormal complete set of eigenvectors or eigenfunctions is an example of a so-called "basis." In general, a basis is a minimal set of vectors or functions that you can write all other vectors or functions in terms of. For example, the unit vectors $\hat{\imath}, \hat{\jmath}$, and $\hat{k}$ are a basis for normal three-dimensional space. Every three-dimensional vector can be written as a linear combination of the three.

The following properties of inner products involving Hermitian operators are often needed, so they are listed here:

$$
\begin{equation*}
\text { If } A \text { is Hermitian: } \quad\langle g \mid A f\rangle=\langle f \mid A g\rangle^{*}, \quad\langle f \mid A f\rangle \text { is real. } \tag{2.16}
\end{equation*}
$$

The first says that you can swap $f$ and $g$ if you take the complex conjugate. (It is simply a reflection of the fact that if you change the sides in an inner product, you turn it into its complex conjugate. Normally, that puts the operator at the other side, but for a Hermitian operator, it does not make a difference.) The second is important because ordinary real numbers typically occupy a special place in the grand scheme of things. (The fact that the inner product is real merely reflects the fact that if a number is equal to its complex conjugate, it must be real; if there was an i in it, the number would change by a complex conjugate.)

## Key Points

$0-$ Hermitian operators can be flipped over to the other side in inner products.
0- Hermitian operators have only real eigenvalues.
$0-$ Hermitian operators have a complete set of orthonormal eigenfunctions (or eigenvectors).

Note: $\cos 45^{\circ}=\sin 45^{\circ}=\frac{1}{2} \sqrt{2}$.
Solution herm-b
3. Show that the operator $\widehat{2}$ is a Hermitian operator, but $\hat{\mathrm{i}}$ is not. Solution herm-c
4. Generalize the previous question, by showing that any complex constant $c$ comes out of the right hand side of an inner product unchanged, but out of the left hand side as its complex conjugate;

$$
\langle f \mid c g\rangle=c\langle f \mid g\rangle \quad\langle c f \mid g\rangle=c^{*}\langle f \mid g\rangle
$$

As a result, a number $c$ is only a Hermitian operator if it is real: if $c$ is complex, the two expressions above are not the same.

Solution herm-d
5. Show that an operator such as $\widehat{x}^{2}$, corresponding to multiplying by a real function, is an Hermitian operator.

Solution herm-e
6. Show that the operator $\mathrm{d} / \mathrm{d} x$ is not a Hermitian operator, but $\mathrm{id} / \mathrm{d} x$ is, assuming that the functions on which they act vanish at the ends of the interval $a \leqslant x \leqslant b$ on which they are defined. (Less restrictively, it is only required that the functions are "periodic"; they must return to the same value at $x=b$ that they had at $x=a$.)
Solution herm- $f$
7. Show that if $A$ is a Hermitian operator, then so is $A^{2}$. As a result, under the conditions of the previous question, $-\mathrm{d}^{2} / \mathrm{d} x^{2}$ is a Hermitian operator too. (And so is just $\mathrm{d}^{2} / \mathrm{d} x^{2}$, of course, but $-\mathrm{d}^{2} / \mathrm{d} x^{2}$ is the one with the positive eigenvalues, the squares of the eigenvalues of $\mathrm{id} / \mathrm{d} x$.)

Solution herm-g
8. A complete set of orthonormal eigenfunctions of $-d^{2} / d x^{2}$ on the interval $0 \leqslant x \leqslant \pi$ that are zero at the end points is the infinite set of functions

$$
\frac{\sin (x)}{\sqrt{\pi / 2}}, \frac{\sin (2 x)}{\sqrt{\pi / 2}}, \frac{\sin (3 x)}{\sqrt{\pi / 2}}, \frac{\sin (4 x)}{\sqrt{\pi / 2}}, \ldots
$$

Check that these functions are indeed zero at $x=0$ and $x=\pi$, that they are indeed orthonormal, and that they are eigenfunctions of $-d^{2} / d x^{2}$ with the positive real eigenvalues

$$
1,4,9,16, \ldots
$$

Completeness is a much more difficult thing to prove, but they are. The completeness proof in the notes covers this case.

Solution herm-h
9. A complete set of orthonormal eigenfunctions of the operator $\mathrm{id} / \mathrm{d} x$ that are periodic on the interval $0 \leqslant x \leqslant 2 \pi$ are the infinite set of functions

$$
\ldots, \frac{e^{-3 \mathrm{i} x}}{\sqrt{2 \pi}}, \frac{e^{-2 \mathrm{i} x}}{\sqrt{2 \pi}}, \frac{e^{-\mathrm{i} x}}{\sqrt{2 \pi}}, \frac{1}{\sqrt{2 \pi}}, \frac{e^{\mathrm{i} x}}{\sqrt{2 \pi}}, \frac{e^{2 \mathrm{i} x}}{\sqrt{2 \pi}}, \frac{e^{3 \mathrm{i} x}}{\sqrt{2 \pi}}, \ldots
$$

Check that these functions are indeed periodic, orthonormal, and that they are eigenfunctions of $\mathrm{id} / \mathrm{d} x$ with the real eigenvalues

$$
\ldots, 3,2,1,0,-1,-2,-3, \ldots
$$

Completeness is a much more difficult thing to prove, but they are. The completeness proof in the notes covers this case.

### 2.7 Additional Points

This subsection describes a few further issues of importance for this book.

### 2.7.1 Dirac notation

Physicists like to write inner products such as $\langle f \mid A g\rangle$ in "Dirac notation":

$$
\langle f| A|g\rangle \equiv\langle f \mid A g\rangle
$$

since this conforms more closely to how you would think of it in linear algebra:

| $\langle f\|$ | $A$ | $\|g\rangle$ |
| :---: | :---: | :---: |
| bra | operator | ket |

The various advanced ideas of linear algebra can be extended to operators in this way, but they will not be needed in this book.

One thing will be needed in some more advanced addenda, however. That is the case that operator $A$ is not Hermitian. In that case, if you want to take $A$ to the other side of the inner product, you need to change it into a different operator. That operator is called the "Hermitian conjugate" of $A$. In physics, it is almost always indicated as $A^{\dagger}$. So, simply by definition,

$$
\langle f \mid A g\rangle \equiv \int_{\text {all } x} f^{*}(x)(A g(x)) \mathrm{d} x \equiv \int_{\text {all } x}\left(A^{\dagger} f(x)\right)^{*} g(x) \mathrm{d} x \equiv\left\langle A^{\dagger} f \mid g\right\rangle
$$

Then there are some more things that this book will not use. However, you will almost surely encounter these when you read other books on quantum mechanics.

First, the dagger is used much like a generalization of "complex conjugate,"

$$
f^{\dagger} \equiv f^{*} \quad|f\rangle^{\dagger} \equiv\langle f|
$$

etcetera. Applying a dagger a second time gives the original back. Also, if you work out the dagger on a product, you need to reverse the order of the factors. For example

$$
\left(A^{\dagger}|f\rangle\right)^{\dagger}|g\rangle=\langle f| A|g\rangle
$$

In words, putting $A^{\dagger}|f\rangle$ into the left side of an inner product gives $\langle f| A$.
The second point will be illustrated for the case of vectors in three dimensions. Such a vector can be written as

$$
\vec{v}=\hat{\imath} v_{x}+\hat{\jmath} v_{y}+\hat{k} v_{z}
$$

Here $\hat{\imath}, \hat{\jmath}$, and $\hat{k}$ are the three unit vectors in the axial directions. The components $v_{x}, v_{y}$ and $v_{z}$ can be found using dot products:

$$
\vec{v}=\hat{\imath}(\hat{\imath} \cdot \vec{v})+\hat{\jmath}(\hat{\jmath} \cdot \vec{v})+\hat{k}(\hat{k} \cdot \vec{v})
$$

Symbolically, you can write this as

$$
\vec{v}=(\hat{\imath} \hat{\imath} \cdot+\hat{\jmath} \hat{\jmath} \cdot+\hat{k} \hat{k} \cdot) \vec{v}
$$

In fact, the operator in parentheses can be defined by saying that for any vector $\vec{v}$, it gives the exact same vector back. Such an operator is called an "identity operator."

The relation

$$
(\hat{\imath} \hat{\imath} \cdot+\hat{\jmath} \hat{\jmath} \cdot+\hat{k} \hat{k} \cdot)=1
$$

is called the "completeness relation." To see why, suppose you leave off the third part of the operator. Then

$$
(\hat{\imath} \hat{\imath} \cdot+\hat{\jmath} \hat{\jmath}) \vec{v}=\hat{\imath} v_{x}+\hat{\jmath} v_{y}
$$

The $z$-component is gone! Now the vector $\vec{v}$ gets projected onto the $x, y$-plane. The operator has become a "projection operator" instead of an identity operator by not suming over the complete set of unit vectors.

You will almost always find these things in terms of bras and kets. To see how that looks, define

$$
\hat{\imath} \equiv|1\rangle \quad \hat{\jmath} \equiv|2\rangle \quad \hat{k} \equiv|3\rangle \quad \vec{v} \equiv|v\rangle
$$

Then

$$
|v\rangle=|1\rangle\langle 1||v\rangle+|2\rangle\langle 2||v\rangle+|3\rangle\langle 3 \| v\rangle=\sum_{\text {all } i}|i\rangle\langle i \| v\rangle
$$

so the completeness relation looks like

$$
\sum_{\text {all } i}|i\rangle\langle i|=1
$$

If you do not sum over the complete set of kets, you get a projection operator instead of an identity one.

### 2.7.2 Additional independent variables

In many cases, the functions involved in an inner product may depend on more than a single variable $x$. For example, they might depend on the position $(x, y, z)$ in three-dimensional space.

The rule to deal with that is to ensure that the inner product integrations are over all independent variables. For example, in three spatial dimensions:

$$
\langle f \mid g\rangle=\int_{\operatorname{all} x} \int_{\operatorname{all} y} \int_{\operatorname{all} z} f^{*}(x, y, z) g(x, y, z) \mathrm{d} x \mathrm{~d} y \mathrm{~d} z
$$

Note that the time $t$ is a somewhat different variable from the rest, and time is not included in the inner product integrations.

## Chapter 3

## Basic Ideas of Quantum Mechanics

#### Abstract

\section*{Abstract}

In this chapter the basic ideas of quantum mechanics are described and then a basic but very important example is worked out.

Before embarking on this chapter, do take note of the very sage advice given by Richard Feynman, Nobel-prize winning pioneer of relativistic quantum mechanics: "Do not keep saying to yourself, if you can possibly avoid it, 'But how can it be like that?' because you will get 'down the drain,' into a blind alley from which nobody has yet escaped. Nobody knows how it can be like that." [Richard P. Feynman (1965) The Character of Physical Law 129. BBC/Penguin] "So do not take the lecture too seriously, ..., but just relax and enjoy it." [ibid.]

And it may be uncertain whether Niels Bohr, Nobel-prize winning pioneer of early quantum mechanics actually said it to Albert Einstein, and if so, exactly what he said, but it may be the sanest statement about quantum mechanics of all: "Stop telling God what to do." [Neils Bohr, reputed]. First of all, this chapter will throw out the classical picture of particles with positions and velocities. Completely. Quantum mechanics substitutes instead a function called the "wave function" that associates a numerical value with every possible state of the universe. If the "universe" that you are considering is just a single particle, the wave function of interest associates a numerical value with every possible position of that particle, at every time.

The physical meaning of the value of the wave function, also called the "quantum amplitude," itself is somewhat hazy. It is just a complex number. However, the square magnitude of the number has a clear meaning, first stated by Born: The square magnitude of the wave function at a point is a measure of the probability of finding the particle at that point, if you conduct such a search.

But if you do, watch out. Heisenberg has shown that if you eliminate the uncertainty in the position of a particle, its linear momentum explodes. If the position is precise, the linear momentum has infinite uncertainty. The same thing also applies in reverse. Neither position nor linear momentum can have an precise value for a particle. And usually other quantities like energy do not either.

Which brings up the question what meaning to attach to such physical quantities. Quantum mechanics answers that by associating a separate Hermitian operator with every physical quantity. The most important ones will be described. These operators act on the wave function. If, and only if, the wave function is an eigenfunction of such a Hermitian operator, only then does the corresponding physical quantity have a definite value: the eigenvalue. In all other cases the physical quantity is uncertain.

The most important Hermitian operator is called the "Hamiltonian." It is associated with the total energy of the particle. The eigenvalues of the Hamiltonian describe the only possible values that the total energy of the particle can have.

The chapter will conclude by analyzing a simple quantum system in detail. It is a particle stuck in a pipe of square cross section. While relatively simple, this case describes some of the quantum effects encountered in nanotechnology. In later chapters, it will be found that this case also provides a basic model for such systems as valence electrons in metals, molecules in ideal gases, nucleons in nuclei, and much more.

### 3.1 The Revised Picture of Nature

This section describes the view quantum mechanics has of nature, which is in terms of a mysterious function called the "wave function".

According to quantum mechanics, the way that the old Newtonian physics describes nature is wrong if examined closely enough. Not just a bit wrong. Totally wrong. For example, the Newtonian picture for a particle of mass $m$ looks like figure 3.1:

Figure 3.1: The old incorrect Newtonian physics.
The problems? A numerical position for the particle simply does not exist. A numerical velocity or linear momentum for the particle does not exist.

What does exist according to quantum mechanics is the so-called wave function $\Psi(x, y, z ; t)$. Its square magnitude, $|\Psi|^{2}$, can be shown as grey tones (darker where the magnitude is larger), as in figure 3.2:

A precise position does not exist. Neither does a precise velocity or linear momentum.

Quantum mechanics does not use forces, but the potential energy $V$. It is implicitly defined by:

$$
F_{x}=-\frac{\partial V}{\partial x} \quad F_{y}=-\frac{\partial V}{\partial y} \quad F_{z}=-\frac{\partial V}{\partial z}
$$

Figure 3.2: The correct quantum physics.
The physical meaning of the wave function is known as "Born's statistical interpretation": darker regions are regions where the particle is more likely to be found if the location is narrowed down. More precisely, if $\vec{r}=(x, y, z)$ is a given location, then

$$
\begin{equation*}
|\Psi(\vec{r} ; t)|^{2} \mathrm{~d}^{3} \vec{r} \tag{3.1}
\end{equation*}
$$

is the probability of finding the particle within a small volume, of size $\mathrm{d}^{3} \vec{r}=$ $\mathrm{d} x \mathrm{~d} y \mathrm{~d} z$, around that given location, if such a measurement is attempted.
(And if such a position measurement is actually done, it affects the wave function: after the measurement, the new wave function will be restricted to the volume to which the position was narrowed down. But it will spread out again in time if allowed to do so afterwards.)

The particle must be found somewhere if you look everywhere. In quantum mechanics, that is expressed by the fact that the total probability to find the particle, integrated over all possible locations, must be $100 \%$ (certainty):

$$
\begin{equation*}
\int_{\text {all } \vec{r}}|\Psi(\vec{r} ; t)|^{2} \mathrm{~d}^{3} \vec{r}=1 \tag{3.2}
\end{equation*}
$$

In other words, proper wave functions are normalized, $\langle\Psi \mid \Psi\rangle=1$.
The position of macroscopic particles is typically very much narrowed down by incident light, surrounding objects, earlier history, etcetera. For such particles, the "blob size" of the wave function is extremely small. As a result, claiming that a macroscopic particle, is, say, at the center point of the wave function blob may be just fine in practical applications. But when you are interested in what happens on very small scales, the nonzero blob size can make a big difference.

In addition, even on macroscopic scales, position can be ill defined. Consider what happens if you take the wave function blob apart and send half to Mars and half to Venus. Quantum mechanics allows it; this is what happens in a "scattering" experiment. You would presumably need to be extremely careful to do it on such a large scale, but there is no fundamental theoretical objection in quantum mechanics. So, where is the particle now? Hiding on Mars? Hiding on Venus?

Orthodox quantum mechanics says: neither. It will pop up on one of the two planets if measurements force it to reveal its presence. But until that moment, it is just as ready to pop up on Mars as on Venus, at an instant's notice. If it was hiding on Mars, it could not possibly pop up on Venus on an instant's notice; the fastest it would be allowed to move is at the speed of light. Worse, when the electron does pop up on Mars, it must communicate that fact instantaneously to Venus to prevent itself from also popping up there. That requires that quantum mechanics internally communicates at speeds faster than the speed of light. That is called the Einstein-Podolski-Rosen paradox. A famous theorem by John Bell in 1964 implies that nature really does communicate instantaneously; it is not just some unknown deficiency in the theory of quantum mechanics, chapter 8.2.

Of course, quantum mechanics is largely a matter of inference. The wave function cannot be directly observed. But that is not as strong an argument against quantum mechanics as it may seem. The more you learn about quantum mechanics, the more its weirdness will probably become inescapable. After almost a century, quantum mechanics is still standing, with no real "more reasonable" competitors, ones that stay closer to the common sense picture. And the best minds in physics have tried.

From a more practical point of view, you might object that the Born interpretation cheats: it only explains what the absolute value of the wave function is, not what the wave function itself is. And you would have a very good point there. Ahem. The wave function $\Psi(\vec{r}, t)$ itself gives the "quantum amplitude" that the particle can be found at position $\vec{r}$. No, indeed that does not help at all. That is just a definition.

However, for unknown reasons nature always "computes" with a wave function, never with probabilities. The classical example is where you shoot electrons at random at a tiny pinhole in a wall. Open up a second hole, and you would
expect that every point behind the wall would receive more electrons, with another hole open. The probability of getting the electron from the second hole should add to the probability of getting it from the first one. But that is not what happens. Some points may now get no electrons at all. The wave function trace passing through the second hole may arrive with the opposite sign of the wave function trace passing through the first hole. If that happens, the net wave function becomes zero, and so its square magnitude, the probability of finding an electron, does too. Electrons are prevented from reaching the location by giving them an additional way to get there. It is weird. Then again, there is little profit in worrying about it.

## Key Points

$0-$ According to quantum mechanics, particles do not have precise values of position or velocity when examined closely enough.
$0-$ What they do have is a "wave function" that depends on position.
$0-$ Larger values of the magnitude of the wave function, (indicated in this book by darker regions,) correspond to regions where the particle is more likely to be found if a location measurement is done.
$0-$ Such a measurement changes the wave function; the measurement itself creates the reduced uncertainty in position that exists immediately after the measurement.
$0-$ In other words, the wave function is all there is; you cannot identify a hidden position in a given wave function, just create a new wave function that more precisely locates the particle.
$0-$ The creation of such a more localized wave function during a position measurement is governed by laws of chance: the more localized wave function is more likely to end up in regions where the initial wave function had a larger magnitude.
$0=$ Proper wave functions are normalized.

### 3.2 The Heisenberg Uncertainty Principle

The Heisenberg uncertainty principle is a way of expressing the qualitative properties of quantum mechanics in an easy to visualize way.

Figure 3.3 is a combination plot of the position $x$ of a particle and the corresponding linear momentum $p_{x}=m v_{x}$, (with $m$ the mass and $v_{x}$ the velocity in the $x$-direction). To the left in the figure, both the position and the linear momentum have some uncertainty.

The right of the figure shows what happens if you squeeze down on the particle to try to restrict it to one position $x$ : it stretches out in the momentum direction.

Figure 3.3: Illustration of the Heisenberg uncertainty principle. A combination plot of position and linear momentum components in a single direction is shown. Left: Fairly localized state with fairly low linear momentum. Right: narrowing down the position makes the linear momentum explode.

Heisenberg showed that according to quantum mechanics, the area of the "blob" cannot be contracted to a point. When you try to narrow down the position of a particle, you get into trouble with momentum. Conversely, if you try to pin down a precise momentum, you lose all hold on the position.

The area of the blob has a minimum value below which you cannot go. This minimum area is comparable in size to the so-called "Planck constant," roughly $10^{-34} \mathrm{~kg} \mathrm{~m}^{2} / \mathrm{s}$. That is an extremely small area for macroscopic systems, relatively speaking. But it is big enough to dominate the motion of microscopic systems, like say electrons in atoms.

## Key Points

$0-$ The Heisenberg uncertainty principle says that there is always a minimum combined uncertainty in position and linear momentum.
$0-$ It implies that a particle cannot have a mathematically precise position, because that would require an infinite uncertainty in linear momentum.
$0-$ It also implies that a particle cannot have a mathematically precise linear momentum (velocity), since that would imply an infinite uncertainty in position.

### 3.3 The Operators of Quantum Mechanics

The numerical quantities that the old Newtonian physics uses, (position, momentum, energy, ...), are just "shadows" of what really describes nature: operators. The operators described in this section are the key to quantum mechanics.

As the first example, while a mathematically precise value of the position $x$ of a particle never exists, instead there is an $x$-position operator $\widehat{x}$. It turns the wave function $\Psi$ into $x \Psi$ :

$$
\begin{equation*}
\Psi(x, y, z, t) \xrightarrow{\widehat{x}} x \Psi(x, y, z, t) \tag{3.3}
\end{equation*}
$$

The operators $\widehat{y}$ and $\widehat{z}$ are defined similarly as $\widehat{x}$.
Instead of a linear momentum $p_{x}=m u$, there is an $x$-momentum operator

$$
\begin{equation*}
\widehat{p}_{x}=\frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial x} \tag{3.4}
\end{equation*}
$$

that turns $\Psi$ into its $x$-derivative:

$$
\begin{equation*}
\Psi(x, y, z, t) \xrightarrow{\widehat{p}_{x}=\frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial x}} \frac{\hbar}{\mathrm{i}} \Psi_{x}(x, y, z, t) \tag{3.5}
\end{equation*}
$$

The constant $\hbar$ is called "Planck's constant." (Or rather, it is Planck's original constant $h$ divided by $2 \pi$.) If it would have been zero, all these troubles with quantum mechanics would not occur. The blobs would become points. Unfortunately, $\hbar$ is very small, but nonzero. It is about $10^{-34} \mathrm{~kg} \mathrm{~m}^{2} / \mathrm{s}$.

The factor i in $\widehat{p}_{x}$ makes it a Hermitian operator (a proof of that is in derivation $\{$ D. 9$\}$ ). All operators reflecting macroscopic physical quantities are Hermitian.

The operators $\widehat{p}_{y}$ and $\widehat{p}_{z}$ are defined similarly as $\widehat{p}_{x}$ :

$$
\begin{equation*}
\widehat{p}_{y}=\frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial y} \quad \widehat{p}_{z}=\frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial z} \tag{3.6}
\end{equation*}
$$

The kinetic energy operator $\widehat{T}$ is:

$$
\begin{equation*}
\widehat{T}=\frac{\widehat{p}_{x}^{2}+\widehat{p}_{y}^{2}+\widehat{p}_{z}^{2}}{2 m} \tag{3.7}
\end{equation*}
$$

Its shadow is the Newtonian notion that the kinetic energy equals:

$$
T=\frac{1}{2} m\left(u^{2}+v^{2}+w^{2}\right)=\frac{(m u)^{2}+(m v)^{2}+(m w)^{2}}{2 m}
$$

This is an example of the "Newtonian analogy": the relationships between the different operators in quantum mechanics are in general the same as those between the corresponding numerical values in Newtonian physics. But since the momentum operators are gradients, the actual kinetic energy operator is, from the momentum operators above:

$$
\begin{equation*}
\widehat{T}=-\frac{\hbar^{2}}{2 m}\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}\right) \tag{3.8}
\end{equation*}
$$

Mathematicians call the set of second order derivative operators in the kinetic energy operator the "Laplacian", and indicate it by $\nabla^{2}$ :

$$
\begin{equation*}
\nabla^{2} \equiv \frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}} \tag{3.9}
\end{equation*}
$$

In those terms, the kinetic energy operator can be written more concisely as:

$$
\begin{equation*}
\widehat{T}=-\frac{\hbar^{2}}{2 m} \nabla^{2} \tag{3.10}
\end{equation*}
$$

Following the Newtonian analogy once more, the total energy operator, indicated by $H$, is the the sum of the kinetic energy operator above and the potential energy operator $V(x, y, z, t)$ :

$$
\begin{equation*}
H=-\frac{\hbar^{2}}{2 m} \nabla^{2}+V \tag{3.11}
\end{equation*}
$$

This total energy operator $H$ is called the Hamiltonian and it is very important. Its eigenvalues are indicated by $E$ (for energy), for example $E_{1}, E_{2}, E_{3}$, ... with:

$$
\begin{equation*}
H \psi_{n}=E_{n} \psi_{n} \quad \text { for } n=1,2,3, \ldots \tag{3.12}
\end{equation*}
$$

where $\psi_{n}$ is eigenfunction number $n$ of the Hamiltonian.
It is seen later that in many cases a more elaborate numbering of the eigenvalues and eigenvectors of the Hamiltonian is desirable instead of using a single counter $n$. For example, for the electron of the hydrogen atom, there is more than one eigenfunction for each different eigenvalue $E_{n}$, and additional counters $l$ and $m$ are used to distinguish them. It is usually best to solve the eigenvalue problem first and decide on how to number the solutions afterwards.
(It is also important to remember that in the literature, the Hamiltonian eigenvalue problem is commonly referred to as the "time-independent Schrödinger equation." However, this book prefers to reserve the term Schrödinger equation for the unsteady evolution of the wave function.)

## Key Points

$0-$ Physical quantities correspond to operators in quantum mechanics.
$0-$ Expressions for various important operators were given.
$0-$ Kinetic energy is in terms of the so-called Laplacian operator.
0 - The important total energy operator, (kinetic plus potential energy,) is called the Hamiltonian.

### 3.4 The Orthodox Statistical Interpretation

In addition to the operators defined in the previous section, quantum mechanics requires rules on how to use them. This section gives those rules, along with a critical discussion what they really mean.

### 3.4.1 Only eigenvalues

According to quantum mechanics, the only "measurable values" of position, momentum, energy, etcetera, are the eigenvalues of the corresponding operator. For example, if the total energy of a particle is "measured", the only numbers that can come out are the eigenvalues of the total energy Hamiltonian.

There is really no controversy that only the eigenvalues come out; this has been verified overwhelmingly in experiments, often to astonishingly many digits accuracy. It is the reason for the line spectra that allow the elements to be recognized, either on earth or halfway across the observable universe, for lasers, for the blackbody radiation spectrum, for the value of the speed of sound, for the accuracy of atomic clocks, for the properties of chemical bonds, for the fact that a Stern-Gerlach apparatus does not fan out a beam of atoms but splits it into discrete rays, and countless other basic properties of nature.

But the question why and how only the eigenvalues come out is much more tricky. In general the wave function that describes physics is a combination of eigenfunctions, not a single eigenfunction. (Even if the wave function was an eigenfunction of one operator, it would not be one of another operator.) If the wave function is a combination of eigenfunctions, then why is the measured value not a combination, (maybe some average), of eigenvalues, but a single eigenvalue? And what happens to the eigenvalues in the combination that do not come out? It is a question that has plagued quantum mechanics since the beginning.

The most generally given answer in the physics community is the "orthodox interpretation." It is commonly referred to as the "Copenhagen Interpretation", though that interpretation, as promoted by Niels Bohr, was actually much more circumspect than what is usually presented.

> According to the orthodox interpretation, "measurement" causes the wave function $\Psi$ to "collapse" into one of the eigenfunctions of the quantity being measured.

Staying with energy measurements as the example, any total energy "measurement" will cause the wave function to collapse into one of the eigenfunctions $\psi_{n}$ of the total energy Hamiltonian. The energy that is measured is the corresponding eigenvalue:
$\left.\begin{array}{l}\Psi=c_{1} \psi_{1}+c_{2} \psi_{2}+\ldots \\ \text { Energy is uncertain }\end{array}\right\} \xrightarrow{\text { energy measurement }}\left\{\begin{array}{l}\Psi=c_{n} \psi_{n} \\ \text { Energy }=E_{n}\end{array}\right.$ for some $n$

This story, of course, is nonsense. It makes a distinction between "nature" (the particle, say) and the "measurement device" supposedly producing an exact value. But the measurement device is a part of nature too, and therefore also uncertain. What measures the measurement device?

Worse, there is no definition at all of what "measurement" is or is not, so anything physicists, and philosophers, want to put there goes. Needless to say, theories have proliferated, many totally devoid of common sense. The more reasonable "interpretations of the interpretation" tend to identify measurements as interactions with macroscopic systems. Still, there is no indication how and when a system would be sufficiently macroscopic, and how that would produce a collapse or at least something approximating it.

If that is not bad enough, quantum mechanics already has a law, called the Schrödinger equation (chapter 7.1), that says how the wave function evolves. This equation contradicts the collapse, (chapter 8.5.)

The collapse in the orthodox interpretation is what the classical theater world would have called "Deus ex Machina". It is a god that appears out of thin air to make things right. A god that has the power to distort the normal laws of nature at will. Mere humans may not question the god. In fact, physicists tend to actually get upset if you do.

However, it is a fact that after a real-life measurement has been made, further follow-up measurements have statistics that are consistent with a collapsed wave function, (which can be computed.) The orthodox interpretation does describe what happens practically in actual laboratory settings well. It just offers no practical help in circumstances that are not so clear cut, being phrased in terms that are essentially meaningless.

## Key Points

$0-$ Even if a system is initially in a combination of the eigenfunctions of a physical quantity, a measurement of that quantity pushes the measured system into a single eigenfunction.

0 - The measured value is the corresponding eigenvalue.

### 3.4.2 Statistical selection

There is another hot potato besides the collapse itself; it is the selection of the eigenfunction to collapse to. If the wave function before a "measurement" is a combination of many different eigenfunctions, then what eigenfunction will the measurement produce? Will it be $\psi_{1} ? \psi_{2}$ ? $\psi_{10}$ ?

The answer of the orthodox interpretation is that nature contains a mysterious random number generator. If the wave function $\Psi$ before the "measurement"
equals, in terms of the eigenfunctions,

$$
\Psi=c_{1} \psi_{1}+c_{2} \psi_{2}+c_{3} \psi_{3}+\ldots
$$

then this random number generator will, in Einstein's words, "throw the dice" and select one of the eigenfunctions based on the result. It will collapse the wave function to eigenfunction $\psi_{1}$ in on average a fraction $\left|c_{1}\right|^{2}$ of the cases, it will collapse the wave function to $\psi_{2}$ in a fraction $\left|c_{2}\right|^{2}$ of the cases, etc.

> The orthodox interpretation says that the square magnitudes of the coefficients of the eigenfunctions give the probabilities of the corresponding eigenvalues.

This too describes very well what happens practically in laboratory experiments, but offers again no insight into why and when. And the notion that nature would somehow come with, maybe not a physical random number generator, but certainly an endless sequence of truly random numbers seemed very hard to believe even for an early pioneer of quantum mechanics like Einstein. Many have proposed that the eigenfunction selections are not truly random, but reflect unobserved "hidden variables" that merely seem random to us humans. Yet, after almost a century, none of these theories have found convincing evidence or general acceptance. Physicists still tend to insist quite forcefully on a literal random number generator. Somehow, when belief is based on faith, rather than solid facts, tolerance of alternative views is much less, even among scientists.

While the usual philosophy about the orthodox interpretation can be taken with a big grain of salt, the bottom line to remember is:

Random collapse of the wave function, with chances governed by the square magnitudes of the coefficients, is indeed the correct way for us humans to describe what happens in our observations.

As explained in chapter 8.6, this is despite the fact that the wave function does not collapse: the collapse is an artifact produced by limitations in our capability to see the entire picture. We humans have no choice but to work within our limitations, and within these, the rules of the orthodox interpretation do apply.

Schrödinger gave a famous, rather cruel, example of a cat in a box to show how weird the predictions of quantum mechanics really are. It is discussed in chapter 8.1.

## Key Points

0- If a system is initially in a combination of the eigenfunctions of a physical quantity, a measurement of that quantity picks one of the eigenvalues at random.
$0-$ The chances of a given eigenvalue being picked are proportional to the square magnitude of the coefficient of the corresponding eigenfunction in the combination.

### 3.5 A Particle Confined Inside a Pipe

This section demonstrates the general procedure for analyzing quantum systems using a very elementary example. The system to be studied is that of a particle, say an electron, confined to the inside of a narrow pipe with sealed ends. This example will be studied in some detail, since if you understand it thoroughly, it becomes much easier not to get lost in the more advanced examples of quantum mechanics discussed later. And as the final subsection 3.5.9 shows, as well as much of chapter 6 , the particle in a pipe is really quite interesting despite its simplicity.

### 3.5.1 The physical system

The system to be analyzed is shown in figure 3.4 as it would appear in classical nonquantum physics. A particle is bouncing around between the two ends of a

Figure 3.4: Classical picture of a particle in a closed pipe.
pipe. It is assumed that there is no friction, so the particle will keep bouncing back and forward forever. (Friction is a macroscopic effect that has no place in the sort of quantum-scale systems analyzed here.) Typically, classical physics draws the particles that it describes as little spheres, so that is what figure 3.4 shows.

The actual quantum system to be analyzed is shown in figure 3.5. A particle

Figure 3.5: Quantum mechanics picture of a particle in a closed pipe.
like an electron has no (known) specific shape or size, but it does have a wave function "blob." So in quantum mechanics the equivalent of a particle bouncing around is a wave function blob bouncing around between the ends of the pipe.

Please do not ask what this impenetrable pipe is made off. It is obviously a crude idealization. You could imagine that the electron is a valence electron in
a very tiny bar of copper. In that case the pipe walls would correspond to the surface of the copper bar, and it is assumed that the electron cannot get off the bar.

But of course, a copper bar would have nuclei, and other electrons, and the analysis here does not consider those. So maybe it is better to think of the particle as being a lone helium atom stuck inside a carbon nanotube.

## Key Points

$0-$ An idealized problem of a particle bouncing about in a pipe will be considered.

### 3.5.2 Mathematical notations

The first step in the solution process is to describe the problem mathematically. To do so, an $x$-coordinate that measures longitudinal position inside the pipe will be used, as shown in figure 3.6. Also, the length of the pipe will be called $\ell_{x}$.

Figure 3.6: Definitions for one-dimensional motion in a pipe.
To make the problem as easy to solve as possible, it will be assumed that the only position coordinate that exists is the longitudinal position $x$ along the pipe. For now, the existence of any coordinates $y$ and $z$ that measure the location in cross section will be completely ignored.

## Key Points

$0-$ The only position coordinate to be considered for now is $x$.
$0-$ The notations have been defined.

### 3.5.3 The Hamiltonian

To analyze a quantum system you must find the Hamiltonian. The Hamiltonian is the total energy operator, equal to the sum of kinetic plus potential energy.

The potential energy $V$ is the easiest to find: since it is assumed that the particle does not experience forces inside the pipe, (until it hits the ends of the pipe, that is), the potential energy must be constant inside the pipe:

$$
V=\text { constant }
$$

(The force is the derivative of the potential energy, so a constant potential energy produces zero force.) Further, since the value of the constant does not make any difference physically, you may as well assume that it is zero and save some writing:

$$
V=0
$$

Next, the kinetic energy operator $\widehat{T}$ is needed. You can just look up its precise form in section 3.3 and find it is:

$$
\widehat{T}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial x^{2}}
$$

Note that only the $x$ term is used here; the existence of the other two coordinates $y$ and $z$ is completely ignored. The constant $m$ is the mass of the particle, and $\hbar$ is Planck's constant.

Since the potential energy is zero, the Hamiltonian $H$ is just this kinetic energy:

$$
\begin{equation*}
H=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial x^{2}} \tag{3.13}
\end{equation*}
$$

## Key Points

0- The one-dimensional Hamiltonian (3.13) has been written down.

### 3.5.4 The Hamiltonian eigenvalue problem

With the Hamiltonian $H$ found, the next step is to formulate the Hamiltonian eigenvalue problem, (or "time-independent Schrödinger equation."). This problem is always of the form

$$
H \psi=E \psi
$$

Any nonzero solution $\psi$ of this equation is called an energy eigenfunction and the corresponding constant $E$ is called the energy eigenvalue.

Substituting the Hamiltonian for the pipe as found in the previous subsection, the eigenvalue problem is:

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \psi}{\partial x^{2}}=E \psi \tag{3.14}
\end{equation*}
$$

The problem is not complete yet. These problems also need so called "boundary conditions", conditions that say what happens at the ends of the $x$ range. In this case, the ends of the $x$ range are the ends of the pipe. Now recall that the square magnitude of the wave function gives the probability of finding the particle. So the wave function must be zero wherever there is no possibility of finding the particle. That is outside the pipe: it is assumed that the particle is confined to the pipe. So the wave function is zero outside the pipe. And since the outside of the pipe starts at the ends of the pipe, that means that the wave function must be zero at the ends $\{\mathrm{N} .5\}$ :

$$
\begin{equation*}
\psi=0 \text { at } x=0 \quad \text { and } \quad \psi=0 \text { at } x=\ell_{x} \tag{3.15}
\end{equation*}
$$

## Key Points

$0-$ The Hamiltonian eigenvalue problem (3.14)has been found.
$0=$ It also includes the boundary conditions (3.15).

### 3.5.5 All solutions of the eigenvalue problem

The previous section found the Hamiltonian eigenvalue problem to be:

$$
-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \psi}{\partial x^{2}}=E \psi
$$

Now you need to solve this equation. Mathematicians call an equation of this type an ordinary differential equation; "differential" because it has a derivative in it, and "ordinary" since there are no derivatives with respect to variables other than $x$.

If you do not know how to solve ordinary differential equations, it is no big deal. The best way is usually to look them up anyway. The equation above can be found in most mathematical table books, e.g. [41, item 19.7]. According to what it says there, (with changes in notation), if you assume that the energy $E$ is negative, the solution is

$$
\psi=C_{1} e^{\kappa x}+C_{2} e^{-\kappa x} \quad \kappa=\frac{\sqrt{-2 m E}}{\hbar}
$$

This solution may easily by checked by simply substituting it into the ordinary differential equation.

As far as the ordinary differential equation is concerned, the constants $C_{1}$ and $C_{2}$ could be any two numbers. But you also need to satisfy the two boundary conditions given in the previous subsection. The boundary condition that $\psi=$ 0 when $x=0$ produces, if $\psi$ is as above,

$$
C_{1} e^{0}+C_{2} e^{0}=0
$$

and since $e^{0}=1$, this can be used to find an expression for $C_{2}$ :

$$
C_{2}=-C_{1}
$$

The second boundary condition, that $\psi=0$ at $x=\ell_{x}$, produces

$$
C_{1} e^{\kappa \ell_{x}}+C_{2} e^{-\kappa \ell_{x}}=0
$$

or, since you just found out that $C_{2}=-C_{1}$,

$$
C_{1}\left(e^{\kappa \ell_{x}}-e^{-\kappa \ell_{x}}\right)=0
$$

This equation spells trouble because the term between parentheses cannot be zero; the exponentials are not equal. Instead $C_{1}$ will have to be zero; that is bad news since it implies that $C_{2}=-C_{1}$ is zero too, and then so is the wave function $\psi$ :

$$
\psi=C_{1} e^{\kappa x}+C_{2} e^{-\kappa x}=0
$$

A zero wave function is not acceptable, since there would be no possibility to find the particle anywhere!

Everything was done right. So the problem must be the initial assumption that the energy is negative. Apparently, the energy cannot be negative. This can be understood from the fact that for this particle, the energy is all kinetic energy. Classical physics would say that the kinetic energy cannot be negative because it is proportional to the square of the velocity. You now see that quantum mechanics agrees that the kinetic energy cannot be negative, but says it is because of the boundary conditions on the wave function.

Try again, but now assume that the energy $E$ is zero instead of negative. In that case the solution of the ordinary differential equation is according to [41, item 19.7]

$$
\psi=C_{1}+C_{2} x
$$

The boundary condition that $\psi=0$ at $x=0$ now produces:

$$
C_{1}+C_{2} 0=C_{1}=0
$$

so $C_{1}$ must be zero. The boundary condition that $\psi=0$ at $x=\ell_{x}$ gives:

$$
0+C_{2} \ell_{x}=0
$$

so $C_{2}$ must be zero too. Once again there is no nonzero solution, so the assumption that the energy $E$ can be zero must be wrong too.

Note that classically, it is perfectly OK for the energy to be zero: it would simply mean that the particle is sitting in the pipe at rest. But in quantum mechanics, zero kinetic energy is not acceptable, and it all has to do with Heisenberg's uncertainty principle. Since the particle is restricted to the inside
of the pipe, its position is constrained, and so the uncertainty principle requires that the linear momentum must be uncertain. Uncertain momentum cannot be zero momentum; measurements will show a range of values for the momentum of the particle, implying that it is in motion and therefore has kinetic energy.

Try, try again. The only possibility left is that the energy $E$ is positive. In that case, the solution of the ordinary differential equation is according to [41, item 19.7]:

$$
\psi=C_{1} \cos (k x)+C_{2} \sin (k x) \quad k=\frac{\sqrt{2 m E}}{\hbar}
$$

Here the constant $k$ is called the "wave number."
The boundary condition that $\psi=0$ at $x=0$ is:

$$
C_{1} 1+C_{2} 0=C_{1}=0
$$

so $C_{1}$ must be zero. The boundary condition $\psi=0$ at $x=\ell_{x}$ is then:

$$
0+C_{2} \sin \left(k \ell_{x}\right)=0
$$

There finally is possibility to get a nonzero coefficient $C_{2}$ : this equation can be satisfied if $\sin \left(k \ell_{x}\right)=0$ instead of $C_{2}$. In fact, there is not just one possibility for this to happen: a sine is zero when its argument equals $\pi, 2 \pi, 3 \pi, \ldots$. So there is a nonzero solution for each of the following values of the positive constant $k$ :

$$
k=\frac{\pi}{\ell_{x}}, k=\frac{2 \pi}{\ell_{x}}, k=\frac{3 \pi}{\ell_{x}}, \ldots
$$

Each of these possibilities gives one solution $\psi$. Different solutions $\psi$ will be distinguished by giving them a numeric subscript:

$$
\psi_{1}=C_{2} \sin \left(\frac{\pi}{\ell_{x}} x\right), \psi_{2}=C_{2} \sin \left(\frac{2 \pi}{\ell_{x}} x\right), \psi_{3}=C_{2} \sin \left(\frac{3 \pi}{\ell_{x}} x\right), \ldots
$$

The generic solution can be written more concisely using a counter $n$ as:

$$
\psi_{n}=C_{2} \sin \left(\frac{n \pi}{\ell_{x}} x\right) \quad \text { for } n=1,2,3, \ldots
$$

Let's check the solutions. Clearly each is zero when $x=0$ and when $x=\ell_{x}$. Also, substitution of each of the solutions into the ordinary differential equation

$$
-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \psi}{\partial x^{2}}=E \psi
$$

shows that they all satisfy it, provided that their energy values are, respectively:

$$
E_{1}=\frac{\hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}, E_{2}=\frac{2^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}, E_{3}=\frac{3^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}, \ldots
$$

or generically:

$$
E_{n}=\frac{n^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}} \quad \text { for } n=1,2,3, \ldots
$$

There is one more condition that must be satisfied: each solution must be normalized so that the total probability of finding the particle integrated over all possible positions is 1 (certainty). That requires:

$$
1=\left\langle\psi_{n} \mid \psi_{n}\right\rangle=\int_{x=0}^{\ell_{x}}\left|C_{2}\right|^{2} \sin ^{2}\left(\frac{n \pi}{\ell_{x}} x\right) \mathrm{d} x
$$

which after integration fixes $C_{2}$ (assuming you choose it to be a positive real number):

$$
C_{2}=\sqrt{\frac{2}{\ell_{x}}}
$$

Summarizing the results of this subsection, there is not just one energy eigenfunction and corresponding eigenvalue, but an infinite set of them:

$$
\begin{align*}
& \psi_{1}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{\pi}{\ell_{x}} x\right) \quad E_{1}=\frac{\hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}} \\
& \psi_{2}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{2 \pi}{\ell_{x}} x\right) \quad E_{2}=\frac{2^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}  \tag{3.16}\\
& \psi_{3}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{3 \pi}{\ell_{x}} x\right) \quad E_{3}=\frac{3^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}
\end{align*}
$$

or in generic form:

$$
\begin{equation*}
\psi_{n}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{n \pi}{\ell_{x}} x\right) \quad E_{n}=\frac{n^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}} \quad \text { for } n=1,2,3,4,5, \ldots \tag{3.17}
\end{equation*}
$$

The next thing will be to take a better look at these results.

## Key Points

### 3.5.6 Discussion of the energy values

This subsection discusses the energy that the particle in the pipe can have. It was already discovered in the previous subsection that the particle cannot have negative energy, nor zero energy. In fact, according to the orthodox interpretation, the only values that the total energy of the particle can take are the energy eigenvalues

$$
E_{1}=\frac{\hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}, E_{2}=\frac{2^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}, E_{3}=\frac{3^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}, \ldots
$$

derived in the previous subsection.
Energy values are typically shown graphically in the form of an "energy spectrum", as in figure 3.7. Energy is plotted upwards, so the vertical height

Figure 3.7: One-dimensional energy spectrum for a particle in a pipe.
of each energy level indicates the amount of energy it has. To the right of each energy level, the solution counter, or "quantum number", $n$ is listed.

Classically, the total energy of the particle can have any nonnegative value. But according to quantum mechanics, that is not true: the total energy must be one of the levels shown in the energy spectrum figure 3.7. It should be noted that for a macroscopic particle, you would not know the difference; the spacing between the energy levels is macroscopically very fine, since Planck's constant $\hbar$ is so small. However, for a quantum-scale system, the discreteness of the energy values can make a major difference.

Another point: at absolute zero temperature, the particle will be stuck in the lowest possible energy level, $E_{1}=\hbar^{2} \pi^{2} / 2 m \ell_{x}^{2}$, in the spectrum figure 3.7.

This lowest possible energy level is called the "ground state." Classically you would expect that at absolute zero the particle has no kinetic energy, so zero total energy. But quantum mechanics does not allow it. Heisenberg's principle requires some momentum, hence kinetic energy to remain for a confined particle even at zero temperature.

## Key Points

$0-$ Energy values can be shown as an energy spectrum.
$0-$ The possible energy levels are discrete.
$0-$ But for a macroscopic particle, they are extremely close together.
$0-$ The ground state of lowest energy has nonzero kinetic energy.

3. What is the eigenfunction number, or quantum number, $n$ that produces a macroscopic amount of energy, 1 J , for macroscopic values $m=1 \mathrm{~kg}$ and $\ell_{x}=1 \mathrm{~m}$ ? With that many energy levels involved, would you see the difference between successive ones?

Solution pipee-c

### 3.5.7 Discussion of the eigenfunctions

This subsection discusses the one-dimensional energy eigenfunctions of the particle in the pipe. The solution of subsection 3.5.5 found them to be:

$$
\psi_{1}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{\pi}{\ell_{x}} x\right), \psi_{2}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{2 \pi}{\ell_{x}} x\right), \psi_{3}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{3 \pi}{\ell_{x}} x\right), \ldots
$$

The first one to look at is the ground state eigenfunction

$$
\psi_{1}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{\pi}{\ell_{x}} x\right)
$$

It is plotted at the top of figure 3.8. As noted in section 3.1, it is the square magnitude of a wave function that gives the probability of finding the particle.

So, the second graph in figure 3.8 shows the square of the ground state wave function, and the higher values of this function then give the locations where the particle is more likely to be found. This book shows regions where the particle is more likely to be found as darker regions, and in those terms the probability of finding the particle is as shown in the bottom graphic of figure 3.8. It is seen

Figure 3.8: One-dimensional ground state of a particle in a pipe.
that in the ground state, the particle is much more likely to be found somewhere in the middle of the pipe than close to the ends.

Figure 3.9: Second and third lowest one-dimensional energy states.
Figure 3.9 shows the two next lowest energy states

$$
\psi_{2}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{2 \pi}{\ell_{x}} x\right) \text { and } \psi_{3}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{3 \pi}{\ell_{x}} x\right)
$$

as grey tones. Regions where the particle is relatively likely to be found alternate with ones where it is less likely to be found. And the higher the energy, the more such regions there are. Also note that in sharp contrast to the ground state, for eigenfunction $\psi_{2}$ there is almost no likelihood of finding the particle close to the center.

Needless to say, none of those energy states looks at all like the wave function blob bouncing around in figure 3.5. Moreover, it turns out that energy eigenstates are stationary states: the probabilities shown in figures 3.8 and 3.9 do not change with time.

In order to describe a localized wave function blob bouncing around, states of different energy must be combined. It will take until chapter 7.11 .4 before the analytical tools to do so have been described. For now, the discussion must remain restricted to just finding the energy levels. And these are important enough by themselves anyway, sufficient for many practical applications of quantum mechanics.

## Key Points

$0-$ In the energy eigenfunctions, the particle is not localized to within any particular small region of the pipe.
$0-$ In general there are regions where the particle may be found separated by regions in which there is little chance to find the particle.
$0-$ The higher the energy level, the more such regions there are.

### 3.5.7 Review Questions

1. So how does, say, the one-dimensional eigenstate $\psi_{6}$ look? Solution pipef-a
2. Generalizing the results above, for eigenfunction $\psi_{n}$, any $n$, how many distinct regions are there where the particle may be found? Solution pipef-b
3. If you are up to a trick question, consider the following. There are no forces inside the pipe, so the particle has to keep moving until it hits an end of the pipe, then reflect backward until it hits the other side and so on. So, it has to cross the center of the pipe regularly. But in the energy eigenstate $\psi_{2}$, the particle has zero chance of ever being found at the center of the pipe. What gives?

Solution pipef-c

### 3.5.8 Three-dimensional solution

The solution for the particle stuck in a pipe that was obtained in the previous subsections cheated. It pretended that there was only one spatial coordinate $x$.

Real life is three-dimensional. And yes, as a result, the solution as obtained is simply wrong.

Fortunately, it turns out that you can fix up the problem pretty easily if you assume that the pipe has a square cross section. There is a way of combining one-dimensional solutions for all three coordinates into full three-dimensional solutions. This is called the "separation of variables" idea: Solve each of the three variables $x, y$, and $z$ separately, then combine the results.

The full coordinate system for the problem is shown in figure 3.10: in addition to the $x$-coordinate along the length of the pipe, there is also a $y$-coordinate giving the vertical position in cross section, and similarly a $z$-coordinate giving the position in cross section towards you.

Figure 3.10: Definition of all variables for motion in a pipe.
Now recall the one-dimensional solutions that were obtained assuming there is just an $x$-coordinate, but add subscripts " $x$ " to keep them apart from any solutions for $y$ and $z$ :

$$
\begin{align*}
& \psi_{x 1}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{\pi}{\ell_{x}} x\right) \quad E_{x 1}=\frac{\hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}} \\
& \psi_{x 2}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{2 \pi}{\ell_{x}} x\right) \quad E_{x 2}=\frac{2^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}  \tag{3.18}\\
& \psi_{x 3}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{3 \pi}{\ell_{x}} x\right) \quad E_{x 3}=\frac{3^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}
\end{align*}
$$

or in generic form:

$$
\begin{equation*}
\psi_{x n_{x}}=\sqrt{\frac{2}{\ell_{x}}} \sin \left(\frac{n_{x} \pi}{\ell_{x}} x\right) \quad E_{x n_{x}}=\frac{n_{x}^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}} \quad \text { for } n_{x}=1,2,3, \ldots \tag{3.19}
\end{equation*}
$$

Since it is assumed that the cross section of the pipe is square or rectangular of dimensions $\ell_{y} \times \ell_{z}$, the $y$ and $z$ directions have one-dimensional solutions
completely equivalent to the $x$ direction:

$$
\begin{equation*}
\psi_{y n_{y}}=\sqrt{\frac{2}{\ell_{y}}} \sin \left(\frac{n_{y} \pi}{\ell_{y}} y\right) \quad E_{y n_{y}}=\frac{n_{y}^{2} \hbar^{2} \pi^{2}}{2 m \ell_{y}^{2}} \quad \text { for } n_{y}=1,2,3, \ldots \tag{3.20}
\end{equation*}
$$

and

$$
\begin{equation*}
\psi_{z n_{z}}=\sqrt{\frac{2}{\ell_{z}}} \sin \left(\frac{n_{z} \pi}{\ell_{z}} z\right) \quad E_{z n_{z}}=\frac{n_{z}^{2} \hbar^{2} \pi^{2}}{2 m \ell_{z}^{2}} \quad \text { for } n_{z}=1,2,3, \ldots \tag{3.21}
\end{equation*}
$$

After all, there is no fundamental difference between the three coordinate directions; each is along an edge of a rectangular box.

Now it turns out, $\{\mathrm{D} .11\}$, that the full three-dimensional problem has eigenfunctions $\psi_{n_{x} n_{y} n_{z}}$ that are simply products of the one-dimensional ones:

$$
\begin{equation*}
\psi_{n_{x} n_{y} n_{z}}=\sqrt{\frac{8}{\ell_{x} \ell_{y} \ell_{z}}} \sin \left(\frac{n_{x} \pi}{\ell_{x}} x\right) \sin \left(\frac{n_{y} \pi}{\ell_{y}} y\right) \sin \left(\frac{n_{z} \pi}{\ell_{z}} z\right) \tag{3.22}
\end{equation*}
$$

There is one such three-dimensional eigenfunction for each set of three numbers $\left(n_{x}, n_{y}, n_{z}\right)$. These numbers are the three "quantum numbers" of the eigenfunction.

Further, the energy eigenvalues $E_{n_{x} n_{y} n_{z}}$ of the three-dimensional problem are the sum of those of the one-dimensional problems:

$$
\begin{equation*}
E_{n_{x} n_{y} n_{z}}=\frac{n_{x}^{2} \hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}+\frac{n_{y}^{2} \hbar^{2} \pi^{2}}{2 m \ell_{y}^{2}}+\frac{n_{z}^{2} \hbar^{2} \pi^{2}}{2 m \ell_{z}^{2}} \tag{3.23}
\end{equation*}
$$

For example, the ground state of lowest energy occurs when all three quantum numbers are lowest, $n_{x}=n_{y}=n_{z}=1$. The three-dimensional ground state wave function is therefore:

$$
\begin{equation*}
\psi_{111}=\sqrt{\frac{8}{\ell_{x} \ell_{y} \ell_{z}}} \sin \left(\frac{\pi}{\ell_{x}} x\right) \sin \left(\frac{\pi}{\ell_{y}} y\right) \sin \left(\frac{\pi}{\ell_{z}} z\right) \tag{3.24}
\end{equation*}
$$

This ground state is shown in figure 3.11. The $y$ and $z$ factors ensure that the wave function is now zero at all the surfaces of the pipe.

The ground state energy is:

$$
\begin{equation*}
E_{111}=\frac{\hbar^{2} \pi^{2}}{2 m \ell_{x}^{2}}+\frac{\hbar^{2} \pi^{2}}{2 m \ell_{y}^{2}}+\frac{\hbar^{2} \pi^{2}}{2 m \ell_{z}^{2}} \tag{3.25}
\end{equation*}
$$

### 3.5.8 Review Questions

1. If the cross section dimensions $\ell_{y}$ and $\ell_{z}$ are one tenth the size of the pipe length, how much bigger are the energies $E_{y 1}$ and $E_{z 1}$ compared to $E_{x 1}$ ? So, by what percentage is the one-dimensional ground state energy $E_{x 1}$ as an approximation to the three-dimensional one, $E_{111}$, then in error? Solution pipeg-a
2. At what ratio of $\ell_{y} / \ell_{x}$ does the energy $E_{121}$ become higher than the energy $E_{311}$ ?
Solution pipeg-b
3. Shade the regions where the particle is likely to be found in the $\psi_{322}$ energy eigenstate.

### 3.5.9 Quantum confinement

Normally, motion in physics occurs in three dimensions. Even in a narrow pipe, in classical physics a point particle of zero size would be able to move in all three directions. But in quantum mechanics, if the pipe gets very narrow, the motion becomes truly one-dimensional.

To understand why, the first problem that must be addressed is what "motion" means in the first place, because normally motion is defined as change in position, and in quantum mechanics particles do not have a well-defined position.

Consider the particle in the ground state of lowest energy, shown in figure 3.11. This is one boring state; the picture never changes. You might be surprised by that; after all, it was found that the ground state has energy, and it is all kinetic energy. If the particle has kinetic energy, should not the positions where the particle is likely to be found change with time?

The answer is no; kinetic energy is not directly related to changes in likely positions of a particle; that is only an approximation valid for macroscopic systems. It is not necessarily true for quantum-scale systems, certainly not if they are in the ground state. Like it or not, in quantum mechanics kinetic energy is second-order derivatives of the wave function, and nothing else.

Next, as already pointed out, all the other energy eigenstates, like those in figure 3.12, have the same boring property of not changing with time.

Things only become somewhat interesting when you combine states of different energy. As the simplest possible example, consider the possibility that the particle has the wave function:

$$
\Psi=\sqrt{\frac{4}{5}} \psi_{111}+\sqrt{\frac{1}{5}} \psi_{211}
$$

at some starting time, which will be taken as $t=0$. According to the orthodox interpretation, in an energy measurement this particle would have a $\frac{4}{5}=80 \%$ chance of being found at the ground state energy $E_{111}$ and a $20 \%$ chance of being found at the elevated energy level $E_{211}$. So there is now uncertainty in energy; that is critical.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/pipemv.gif
Figure 3.13: A combination of $\psi_{111}$ and $\psi_{211}$ seen at some typical times.
In chapter 7.1 it will be found that for nonzero times, the wave function of this particle is given by

$$
\Psi=\sqrt{\frac{4}{5}} e^{-\mathrm{i} E_{111} t / \hbar} \psi_{111}+\sqrt{\frac{1}{5}} e^{-\mathrm{i} E_{211} t / \hbar} \psi_{211}
$$

Using this expression, the probability of finding the particle, $|\Psi|^{2}$, can be plotted for various times. That is done in figure 3.13 for four typical times. It shows that with uncertainty in energy, the wave function blob does move. It performs a periodic oscillation: after figure $3.13(d)$, the wave function returns to state $3.13(a)$, and the cycle repeats.

You would not yet want to call the particle localized, but at least the locations where the particle can be found are now bouncing back and forwards between the ends of the pipe. And if you add additional wave functions $\psi_{311}$, $\psi_{411}, \ldots$, you can get closer and closer to a localized wave function blob bouncing around.

But if you look closer at figure 3.13, you will note that the wave function blob does not move at all in the $y$-direction; it remains at all times centered around the horizontal pipe centerline. It may seem that this is no big deal; just add one or more wave functions with an $n_{y}$ value greater than one, like $\psi_{121}$, and bingo, there will be interesting motion in the $y$-direction too.

But there is a catch, and it has to do with the required energy. According to the previous section, the kinetic energy in the $y$-direction takes the values

$$
E_{y 1}=\frac{\hbar^{2} \pi^{2}}{2 m \ell_{y}^{2}}, E_{y 2}=\frac{4 \hbar^{2} \pi^{2}}{2 m \ell_{y}^{2}}, E_{y 3}=\frac{9 \hbar^{2} \pi^{2}}{2 m \ell_{y}^{2}},
$$

That will be very large energies for a narrow pipe in which $\ell_{y}$ is small. The particle will certainly have the large energy $E_{y 1}$ in the $y$-direction; if it is in the pipe at all it has at least that amount of energy. But if the pipe is really narrow, it will simply not have enough additional, say thermal, energy to get anywhere close to the next level $E_{y 2}$. The kinetic energy in the $y$-direction will therefore be stuck at the lowest possible level $E_{y 1}$.

The result is that absolutely nothing interesting goes on in the $y$-direction. As far as a particle in a narrow pipe is concerned, the $y$-direction might just as well not exist. It is ironic that while the kinetic energy in the $y$-direction, $E_{y 1}$, is very large, nothing actually happens in that direction.

If the pipe is also narrow in the $z$-direction, the only interesting motion is in the $x$-direction, making the nontrivial physics truly one-dimensional. It becomes a "quantum wire". However, if the pipe size in the $z$-direction is relatively wide, the particle will have lots of different energy states in the $z$-direction available too and the motion will be two-dimensional, a "quantum well". Conversely, if the pipe is narrow in all three directions, you get a zero-dimensional "quantum dot" in which the particle does nothing unless it gets a sizable chunk of energy.

An isolated atom can be regarded as an example of a quantum dot; the electrons are confined to a small region around the nucleus and will be at a single energy level unless they are given a considerable amount of energy. But note that when people talk about quantum confinement, they are normally talking about semi-conductors, for which similar effects occur at significantly larger scales, maybe tens of times as large, making them much easier to manufacture. An actual quantum dot is often referred to as an "artificial atom", and has similar properties as a real atom.

It may give you a rough idea of all the interesting things you can do in nanotechnology when you restrict the motion of particles, in particular of electrons, in various directions. You truly change the dimensionality of the normal three-dimensional world into a lower dimensional one. Only quantum mechanics can explain why, by making the energy levels discrete instead of continuously varying. And the lower dimensional worlds can have your choice of topology (a ring, a letter 8, a sphere, a cylinder, a Möbius strip?, ..., ) to make things really exciting.

## Key Points

$0-$ Quantum mechanics allows you to create lower-dimensional worlds for particles.

## Single-Particle Systems

#### Abstract

\section*{Abstract}

In this chapter, the machinery to deal with single particles is worked out, culminating in the vital solutions for the hydrogen atom and hydrogen molecular ion.

The first section covers the harmonic oscillator. This vibrating system is a simple model for such systems as an atom in a trap, crystal vibrations, and electromagnetic waves.

Next, before the hydrogen atom can be discussed, first the quantum mechanics of angular momentum needs to be covered. Just like you need angular momentum to solve the motion of a planet around the sun in classical physics, so do you need angular momentum for the motion of an electron around a nucleus in quantum mechanics. The eigenvalues of angular momentum and their quantum numbers are critically important for many other reasons besides the hydrogen atom.

After angular momentum, the hydrogen atom can be discussed. The solution is messy, but fundamentally not much different from that of the particle in the pipe or the harmonic oscillator of the previous chapter.

The hydrogen atom is the major step towards explaining heavier atoms and then chemical bonds. One rather unusual chemical bond can already be discussed in this chapter: that of a ionized hydrogen molecule. A hydrogen molecular ion has only one electron.

But the hydrogen molecular ion cannot readily be solved exactly, even if the motion of the nuclei is ignored. So an approximate method will be used. Before this can be done, however, a problem must be addressed. The hydrogen molecular ion ground state is defined to be the state of lowest energy. But an approximate ground state is not an exact energy eigenfunction and has uncertain energy. So how should the term "lowest energy" be defined for the approximation?

To answer that, before tackling the molecular ion, first systems with uncertainty in a variable of interest are discussed. The "expectation value" of a variable will be defined to be the average of the eigenvalues, weighted by their probability. The "standard deviation" will be defined as a measure of how much uncertainty there is to that expectation value.
With a precise mathematical definition of uncertainty, the obvious next question is whether two different variables can be certain at the same time. The "commutator" of the two operators will be introduced to answer it. That then allows the Heisenberg uncertainty relationship to be formulated. Not only can position and linear momentum not be certain at the same time; a specific equation can be written down for how big the uncertainty must be, at the very least.

With the mathematical machinery of uncertainty defined, the hydrogen molecular ion is solved last.

### 4.1 The Harmonic Oscillator

This section provides an in-depth discussion of a basic quantum system. The case to be analyzed is a particle that is constrained by some kind of forces to remain at approximately the same position. This can describe systems such as an atom in a solid or in a molecule. If the forces pushing the particle back to its nominal position are proportional to the distance that the particle moves away from it, you have what is called an harmonic oscillator. Even if the forces vary nonlinearly with position, they can often still be approximated to vary linearly as long as the distances from the nominal position remain small.

The particle's displacement from the nominal position will be indicated by $(x, y, z)$. The forces keeping the particle constrained can be modeled as springs, as sketched in figure 4.1. The stiffness of the springs is characterized by the

Figure 4.1: Classical picture of an harmonic oscillator.
so called "spring constant" $c$, giving the ratio between force and displacement. Note that it will be assumed that the three spring stiffnesses are equal.

For a quantum picture of a harmonic oscillator, imagine a light atom like a carbon atom surrounded by much heavier atoms. When the carbon atom tries to move away from its nominal position, the heavy atoms push it back. The harmonic oscillator is also the basic relativistic model for the quantum electromagnetic field.

According to classical Newtonian physics, the particle vibrates back and forth around its nominal position with a frequency

$$
\begin{equation*}
\omega=\sqrt{\frac{c}{m}} \tag{4.1}
\end{equation*}
$$

in radians per second. In quantum mechanics, a particle does not have a precise position. But the natural frequency above remains a convenient computational quantity in the quantum solution.

## Key Points

0 - The system to be described is that of a particle held in place by forces that increase proportional to the distance that the particle moves away from its equilibrium position.
$0-$ The relation between distance and force is assumed to be the same in all three coordinate directions.
$0-$ Number $c$ is a measure of the strength of the forces and $\omega$ is the frequency of vibration according to classical physics.

### 4.1.1 The Hamiltonian

In order to find the energy levels that the oscillating particle can have, you must first write down the total energy Hamiltonian.

As far as the potential energy is concerned, the spring in the $x$-direction holds an amount of potential energy equal to $\frac{1}{2} c x^{2}$, and similarly the ones in the $y$ and $z$ directions.

To this total potential energy, you need to add the kinetic energy operator $\widehat{T}$ from section 3.3 to get the Hamiltonian:

$$
\begin{equation*}
H=-\frac{\hbar^{2}}{2 m}\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}\right)+\frac{1}{2} c\left(x^{2}+y^{2}+z^{2}\right) \tag{4.2}
\end{equation*}
$$

## Key Points

$0=$ The Hamiltonian (4.2) has been found.

### 4.1.2 Solution using separation of variables

This section finds the energy eigenfunctions and eigenvalues of the harmonic oscillator using the Hamiltonian as found in the previous subsection. Every energy eigenfunction $\psi$ and its eigenvalue $E$ must satisfy the Hamiltonian eigenvalue problem, (or "time-independent Schrödinger equation"):

$$
\begin{equation*}
\left[-\frac{\hbar^{2}}{2 m}\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}\right)+\frac{1}{2} c\left(x^{2}+y^{2}+z^{2}\right)\right] \psi=E \psi \tag{4.3}
\end{equation*}
$$

The boundary condition is that $\psi$ becomes zero at large distance from the nominal position. After all, the magnitude of $\psi$ tells you the relative probability of finding the particle at that position, and because of the rapidly increasing potential energy, the chances of finding the particle very far from the nominal position should be vanishingly small.

Like for the particle in the pipe of the previous section, it will be assumed that each eigenfunction is a product of one-dimensional eigenfunctions, one in each direction:

$$
\begin{equation*}
\psi=\psi_{x}(x) \psi_{y}(y) \psi_{z}(z) \tag{4.4}
\end{equation*}
$$

Finding the eigenfunctions and eigenvalues by making such an assumption is known in mathematics as the "method of separation of variables".

Substituting the assumption in the eigenvalue problem above, and dividing everything by $\psi_{x}(x) \psi_{y}(y) \psi_{z}(z)$ reveals that E consists of three parts that will be called $E_{x}, E_{y}$, and $E_{z}$ :

$$
\begin{align*}
& E=E_{x}+E_{y}+E_{z} \\
& E_{x}=-\frac{\hbar^{2}}{2 m} \frac{\psi_{x}^{\prime \prime}(x)}{\psi_{x}(x)}+\frac{1}{2} c x^{2} \\
& E_{y}=-\frac{\hbar^{2}}{2 m} \frac{\psi_{y}^{\prime \prime}(y)}{\psi_{y}(y)}+\frac{1}{2} c y^{2}  \tag{4.5}\\
& E_{z}=-\frac{\hbar^{2}}{2 m} \frac{\psi_{z}^{\prime \prime}(z)}{\psi_{z}(z)}+\frac{1}{2} c z^{2}
\end{align*}
$$

where the primes indicate derivatives. The three parts represent the $x, y$, and $z$ dependent terms.

By the definition above, the quantity $E_{x}$ can only depend on $x$; variables $y$ and $z$ do not appear in its definition. But actually, $E_{x}$ cannot depend on $x$ either, since $E_{x}=E-E_{y}-E_{z}$, and none of those quantities depends on $x$. The inescapable conclusion is that $E_{x}$ must be a constant, independent of all three variables $(x, y, z)$. The same way $E_{y}$ and $E_{z}$ must be constants.

If now in the definition of $E_{x}$ above, both sides are multiplied by $\psi_{x}(x)$, a one-dimensional eigenvalue problem results:

$$
\begin{equation*}
\left[-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial x^{2}}+\frac{1}{2} c x^{2}\right] \psi_{x}=E_{x} \psi_{x} \tag{4.6}
\end{equation*}
$$

The operator within the square brackets here, call it $H_{x}$, involves only the $x$ related terms in the full Hamiltonian. Similar problems can be written down for $E_{y}$ and $E_{z}$. Separate problems in each of the three variables $x, y$, and $z$ have been obtained, explaining why this mathematical method is called separation of variables.

Solving the one-dimensional problem for $\psi_{x}$ can be done by fairly elementary but elaborate means. If you are interested, you can find how it is done in derivation $\{$ D. 12\}, but that is mathematics and it will not teach you much about quantum mechanics. It turns out that, like for the particle in the pipe of the previous section, there is again an infinite number of different solutions for $E_{x}$ and $\psi_{x}$ :

$$
\begin{array}{ll}
E_{x 0}=\frac{1}{2} \hbar \omega & \psi_{x 0}(x)=h_{0}(x) \\
E_{x 1}=\frac{3}{2} \hbar \omega & \psi_{x 1}(x)=h_{1}(x)  \tag{4.7}\\
E_{x 2}=\frac{5}{2} \hbar \omega & \psi_{x 2}(x)=h_{2}(x)
\end{array}
$$

Unlike for the particle in the pipe, here by convention the solutions are numbered starting from 0 , rather than from 1 . So the first eigenvalue is $E_{x 0}$ and the first eigenfunction $\psi_{x 0}$. That is just how people choose to do it.

Also, the eigenfunctions are not sines like for the particle in the pipe; instead, as table 4.1 shows, they take the form of some polynomial times an exponential. But you will probably really not care much about what kind of functions they are anyway unless you end up writing a textbook on quantum mechanics and have to plot them. In that case, you can find a general expression, (D.4), in derivation $\{\mathrm{D} .12\}$.

But the eigenvalues are what you want to remember from this solution. According to the orthodox interpretation, these are the measurable values of the total energy in the $x$-direction (potential energy in the $x$-direction spring plus kinetic energy of the motion in the $x$-direction.) Instead of writing them all out as was done above, they can be described using the generic expression:

$$
\begin{equation*}
E_{x n_{x}}=\frac{2 n_{x}+1}{2} \hbar \omega \quad \text { for } n_{x}=0,1,2,3, \ldots \tag{4.8}
\end{equation*}
$$

The eigenvalue problem has now been solved, because the equations for $Y$ and $Z$ are mathematically the same and must therefore have corresponding solutions:

$$
\begin{equation*}
E_{y n_{y}}=\frac{2 n_{y}+1}{2} \hbar \omega \quad \text { for } n_{y}=0,1,2,3, \ldots \tag{4.9}
\end{equation*}
$$

$$
\begin{array}{l|l}
h_{0}(x)=\frac{1}{\left(\pi \ell^{2}\right)^{1 / 4}} e^{-\xi^{2} / 2} & \\
h_{1}(x)=\frac{2 \xi}{\left(4 \pi \ell^{2}\right)^{1 / 4}} e^{-\xi^{2} / 2} & \omega=\sqrt{\frac{c}{m}} \\
h_{2}(x)=\frac{2 \xi^{2}-1}{\left(4 \pi \ell^{2}\right)^{1 / 4}} e^{-\xi^{2} / 2} & \ell=\sqrt{\frac{\hbar}{m \omega}} \\
h_{3}(x)=\frac{2 \xi^{3}-3 \xi}{\left(9 \pi \ell^{2}\right)^{1 / 4}} e^{-\xi^{2} / 2} & \xi=\frac{x}{\ell} \\
h_{4}(x)=\frac{4 \xi^{4}-12 \xi^{2}+3}{\left(576 \pi \ell^{2}\right)^{1 / 4}} e^{-\xi^{2} / 2} & \\
\hline \hline
\end{array}
$$

Table 4.1: First few one-dimensional eigenfunctions of the harmonic oscillator.

$$
\begin{equation*}
E_{z n_{z}}=\frac{2 n_{z}+1}{2} \hbar \omega \quad \text { for } n_{z}=0,1,2,3, \ldots \tag{4.10}
\end{equation*}
$$

The total energy $E$ of the complete system is the sum of $E_{x}, E_{y}$, and $E_{z}$. Any nonnegative choice for number $n_{x}$, combined with any nonnegative choice for number $n_{y}$, and for $n_{z}$, produces one combined total energy value $E_{x n_{x}}+$ $E_{y n_{y}}+E_{z n_{z}}$, which will be indicated by $E_{n_{x} n_{y} n_{z}}$. Putting in the expressions for the three partial energies above, these total energy eigenvalues become:

$$
\begin{equation*}
E_{n_{x} n_{y} n_{z}}=\frac{2 n_{x}+2 n_{y}+2 n_{z}+3}{2} \hbar \omega \tag{4.11}
\end{equation*}
$$

where the "quantum numbers" $n_{x}, n_{y}$, and $n_{z}$ may each have any value in the range $0,1,2,3, \ldots$

The corresponding eigenfunction of the complete system is:

$$
\begin{equation*}
\psi_{n_{x} n_{y} n_{z}}=h_{n_{x}}(x) h_{n_{y}}(y) h_{n_{z}}(z) \tag{4.12}
\end{equation*}
$$

where the functions $h_{0}, h_{1}, \ldots$ are in table 4.1 or in (D.4) if you need them.
Note that the $n_{x}, n_{y}, n_{z}$ numbering system for the solutions arose naturally from the solution process; it was not imposed a priori.

### 4.1.3 Discussion of the eigenvalues

As the previous subsection showed, for every set of three nonnegative whole numbers $n_{x}, n_{y}, n_{z}$, there is one unique energy eigenfunction, or eigenstate, (4.12) and a corresponding energy eigenvalue (4.11). The "quantum numbers" $n_{x}, n_{y}$, and $n_{z}$ correspond to the numbering system of the one-dimensional solutions that make up the full solution.

This section will examine the energy eigenvalues. These are of great physical importance, because according to the orthodox interpretation, they are the only measurable values of the total energy, the only energy levels that the oscillator can ever be found at.

The energy levels can be plotted in the form of a so-called "energy spectrum", as in figure 4.2. The energy values are listed along the vertical axis, and the sets of quantum numbers $n_{x}, n_{y}, n_{z}$ for which they occur are shown to the right of the plot.

The first point of interest illustrated by the energy spectrum is that the energy of the oscillating particle cannot take on any arbitrary value, but only certain discrete values. Of course, that is just like for the particle in the pipe of the previous section, but for the harmonic oscillator, the energy levels are evenly spaced. In particular the energy value is always an odd multiple of $\frac{1}{2} \hbar \omega$. It contradicts the Newtonian notion that a harmonic oscillator can have any energy level. But since $\hbar$ is so small, about $10^{-34} \mathrm{~kg} \mathrm{~m}^{2} / \mathrm{s}$, macroscopically the different energy levels are extremely close together. Though the old Newtonian theory is strictly speaking incorrect, it remains an excellent approximation for macroscopic oscillators.

Also note that the energy levels have no largest value; however high the energy of the particle in a true harmonic oscillator may be, it will never escape. The further it tries to go, the larger the forces that pull it back. It can't win.

Another striking feature of the energy spectrum is that the lowest possible energy is again nonzero. The lowest energy occurs for $n_{x}=n_{y}=n_{z}=0$ and

Figure 4.2: The energy spectrum of the harmonic oscillator.
has a value:

$$
\begin{equation*}
E_{000}=\frac{3}{2} \hbar \omega \tag{4.13}
\end{equation*}
$$

So, even at absolute zero temperature, the particle is not completely at rest at its nominal position; it still has $\frac{3}{2} \hbar \omega$ worth of kinetic and potential energy left that it can never get rid of. This lowest energy state is the ground state.

The reason that the energy cannot be zero can be understood from the uncertainty principle. To get the potential energy to be zero, the particle would have to be at its nominal position for certain. But the uncertainty principle does not allow a precise position. Also, to get the kinetic energy to be zero, the linear momentum would have to be zero for certain, and the uncertainty principle does not allow that either.

The actual ground state is a compromise between uncertainties in momentum and position that make the total energy as small as Heisenberg's relationship allows. There is enough uncertainty in momentum to keep the particle near the nominal position, minimizing potential energy, but there is still enough uncertainty in position to keep the momentum low, minimizing kinetic energy. In fact, the compromise results in potential and kinetic energies that are exactly equal, $\{\mathrm{D} .13\}$.

For energy levels above the ground state, figure 4.2 shows that there is a rapidly increasing number of different sets of quantum numbers $n_{x}, n_{y}$, and $n_{z}$ that all produce that energy. Since each set represents one eigenstate, it means that multiple states produce the same energy.

## Key Points

$0-$ Energy values can be graphically represented as an energy spectrum.
$0-$ The energy values of the harmonic oscillator are equally spaced, with a constant energy difference of $\hbar \omega$ between successive levels.
$0-$ The ground state of lowest energy has nonzero kinetic and potential energy.
$0-$ For any energy level above the ground state, there is more than one eigenstate that produces that energy.

1. Verify that the sets of quantum numbers shown in the spectrum figure 4.2 do indeed produce the indicated energy levels. Solution harmc-a
2. Verify that there are no sets of quantum numbers missing in the spectrum figure 4.2; the listed ones are the only ones that produce those energy levels.

Solution harmc-b

### 4.1.4 Discussion of the eigenfunctions

This section takes a look at the energy eigenfunctions of the harmonic oscillator to see what can be said about the position of the particle at various energy levels.

At absolute zero temperature, the particle will be in the ground state of lowest energy. The eigenfunction describing this state has the lowest possible numbering $n_{x}=n_{y}=n_{z}=0$, and is according to (4.12) of subsection 4.1.2 equal to

$$
\begin{equation*}
\psi_{000}=h_{0}(x) h_{0}(y) h_{0}(z) \tag{4.14}
\end{equation*}
$$

where function $h_{0}$ is in table 4.1. The wave function in the ground state must be equal to the eigenfunction to within a constant:

$$
\begin{equation*}
\Psi_{\mathrm{gS}}=c_{000} h_{0}(x) h_{0}(y) h_{0}(z) \tag{4.15}
\end{equation*}
$$

where the magnitude of the constant $c_{000}$ must be one. Using the expression for function $h_{0}$ from table 4.1, the properties of the ground state can be explored.

As noted earlier in section 3.1, it is useful to plot the square magnitude of $\Psi$ as grey tones, because the darker regions will be the ones where the particle is more likely to be found. Such a plot for the ground state is shown in figure 4.3. It shows that in the ground state, the particle is most likely to be found near the nominal position, and that the probability of finding the particle falls off quickly to zero beyond a certain distance from the nominal position.

The region in which the particle is likely to be found extends, roughly speaking, about a distance $\ell=\sqrt{\hbar / m \omega}$ from the nominal position. For a macroscopic oscillator, this will be a very small distance because of the smallness of $\hbar$. That

Figure 4.3: Ground state of the harmonic oscillator
is somewhat comforting, because macroscopically, you would expect an oscillator to be able to be at rest at the nominal position. While quantum mechanics does not allow it, at least the distance $\ell$ from the nominal position, and the energy $\frac{3}{2} \hbar \omega$ are extremely small.

But obviously, the bad news is that the ground state probability density of figure 4.3 does not at all resemble the classical Newtonian picture of a localized particle oscillating back and forwards. In fact, the probability density does not even depend on time: the chances of finding the particle in any given location are the same for all times. The probability density is also spherically symmetric; it only depends on the distance from the nominal position, and is the same at all angular orientations. To get something that can start to resemble a Newtonian spring-mass oscillator, one requirement is that the energy is well above the ground level.

Turning now to the second lowest energy level, this energy level is achieved by three different energy eigenfunctions, $\psi_{100}, \psi_{010}$, and $\psi_{001}$. The probability distribution of each of the three takes the form of two separate "blobs"; figure 4.4 shows $\psi_{100}$ and $\psi_{010}$ when seen along the $z$-direction. In case of $\psi_{001}$, one blob hides the other, so this eigenfunction was not shown.

Obviously, these states too do not resemble a Newtonian oscillator at all. The probability distributions once again stay the same at all times. (This is a consequence of energy conservation, as discussed later in chapter 7.1.) Also, while in each case there are two blobs occupied by a single particle, the particle will never be be caught on the symmetry plane in between the blobs, which naively could be taken as a sign of the particle moving from one blob to the other.

The eigenfunctions for still higher energy levels show similar lack of resemblance to the classical motion. As an arbitrary example, figure 4.5 shows eigen-

Figure 4.4: Wave functions $\psi_{100}$ and $\psi_{010}$.
function $\psi_{213}$ when looking along the $z$-axis. To resemble a classical oscillator, the particle would need to be restricted to, maybe not an exact moving point, but at most a very small moving region. Instead, all energy eigenfunctions have steady probability distributions and the locations where the particle may be found extend over large regions. It turns out that there is an uncertainty principle involved here: in order to get some localization of the position of the particle, you need to allow some uncertainty in its energy. This will have to wait until much later, in chapter 7.11.4.

The basic reason that quantum mechanics is so slow is simple. To analyze, say the $x$ motion, classical physics says: "the value of the total energy $E_{x}$ is

$$
E_{x}=\frac{1}{2} m \dot{x}^{2}+\frac{1}{2} c x^{2}
$$

now go analyze the motion!". Quantum mechanics says: "the total energy operator $H_{x}$ is

$$
H_{x}=\frac{1}{2} m\left(\frac{\hbar}{\mathrm{i} m} \frac{\partial}{\partial x}\right)^{2}+\frac{1}{2} c \widehat{x}^{2}
$$

now first figure out the possible energy values $E_{x 0}, E_{x 1}, \ldots$ before you can even start thinking about analyzing the motion."

## Key Points

$0-$ The ground state wave function is spherically symmetric: it looks the same seen from any angle.
$0-$ In energy eigenstates the particle position is uncertain.

### 4.1.4 Review Questions

1. Write out the ground state wave function and show that it is indeed spherically symmetric.

Solution harmd-a
2. Show that the ground state wave function is maximal at the origin and, like all the other energy eigenfunctions, becomes zero at large distances from the origin.
Solution harmd-b
3. Write down the explicit expression for the eigenstate $\psi_{213}$ using table 4.1, then verify that it looks like figure 4.5 when looking along the $z$-axis, with the $x$-axis horizontal and the $y$-axis vertical.
Solution harmd-c

### 4.1.5 Degeneracy

As the energy spectrum figure 4.2 illustrated, the only energy level for which there is only a single energy eigenfunction is the ground state. All higher energy levels are what is called "degenerate"; there is more than one eigenfunction that produces that energy. (In other words, more than one set of three quantum numbers $n_{x}, n_{y}$, and $n_{z}$.)

It turns out that degeneracy always results in nonuniqueness of the eigenfunctions. That is important for a variety of reasons. For example, in the quantum mechanics of molecules, chemical bonds often select among nonunique theoretical solutions those that best fit the given conditions. Also, to find spe-
cific mathematical or numerical solutions for the eigenfunctions of a quantum system, the nonuniquenesses will somehow have to be resolved.

Nonuniqueness also poses problems for advanced analysis. For example, suppose you try to analyze the effect of various small perturbations that a harmonic oscillator might experience in real life. Analyzing the effect of small perturbations is typically a relatively easy mathematical problem: the perturbation will slightly change an eigenfunction, but it can still be approximated by the unperturbed one. So, if you know the unperturbed eigenfunction you are in business; unfortunately, if the unperturbed eigenfunction is not unique, you may not know which is the right one to use in the analysis.

The nonuniqueness arises from the fact that:
Linear combinations of eigenfunctions at the same energy level pro-
duce alternative eigenfunctions that still have that same energy level.
For example, the eigenfunctions $\psi_{100}$, and $\psi_{010}$ of the harmonic oscillator have the same energy $E_{100}=E_{010}=\frac{5}{2} \hbar \omega$ (as does $\psi_{001}$, but this example will be restricted to two eigenfunctions.) Any linear combination of the two has that energy too, so you could replace eigenfunctions $\psi_{100}$ and $\psi_{010}$ by two alternative ones such as:

$$
\frac{\psi_{100}+\psi_{010}}{\sqrt{2}} \text { and } \frac{\psi_{010}-\psi_{100}}{\sqrt{2}}
$$

It is readily verified these linear combinations are indeed still eigenfunctions with eigenvalue $E_{100}=E_{010}$ : applying the Hamiltonian $H$ to either one will multiply each term by $E_{100}=E_{010}$, hence the entire combination by that amount. How do these alternative eigenfunctions look? Exactly like $\psi_{100}$ and $\psi_{010}$ in figure 4.4, except that they are rotated over 45 degrees. Clearly then, they are just as good as the originals, just seen under a different angle.

Which raises the question, how come the analysis ended up with the ones that it did in the first place? The answer is in the method of separation of variables that was used in subsection 4.1.2. It produced eigenfunctions of the form $h_{n_{x}}(x) h_{n_{y}}(y) h_{n_{z}}(z)$ that were not just eigenfunctions of the full Hamiltonian $H$, but also of the partial Hamiltonians $H_{x}, H_{y}$, and $H_{z}$, being the $x, y$, and $z$ parts of $i t$.

For example, $\psi_{100}=h_{1}(x) h_{0}(y) h_{0}(z)$ is an eigenfunction of $H_{x}$ with eigenvalue $E_{x 1}=\frac{3}{2} \hbar \omega$, of $H_{y}$ with eigenvalue $E_{y 0}=\frac{1}{2} \hbar \omega$, and of $H_{z}$ with eigenvalue $E_{z 0}=\frac{1}{2} \hbar \omega$, as well as of $H$ with eigenvalue $E_{100}^{2}=\frac{5}{2} \hbar \omega$.

The alternative eigenfunctions are still eigenfunctions of $H$, but no longer of the partial Hamiltonians. For example,

$$
\frac{\psi_{100}+\psi_{010}}{\sqrt{2}}=\frac{h_{1}(x) h_{0}(y) h_{0}(z)+h_{0}(x) h_{1}(y) h_{0}(z)}{\sqrt{2}}
$$

is not an eigenfunction of $H_{x}$ : taking $H_{x}$ times this eigenfunction would multiply the first term by $E_{x 1}$ but the second term by $E_{x 0}$.

So, the obtained eigenfunctions were really made determinate by ensuring that they are simultaneously eigenfunctions of $H, H_{x}, H_{y}$, and $H_{z}$. The nice thing about them is that they can answer questions not just about the total energy of the oscillator, but also about how much of that energy is in each of the three directions.

## Key Points

$0-$ Degeneracy occurs when different eigenfunctions produce the same energy.
$0-$ It causes nonuniqueness: alternative eigenfunctions will exist.
$0-$ That can make various analysis a lot more complex.

### 4.1.5 Review Questions

1. Just to check that this book is not lying, (you cannot be too careful), write down the analytical expression for $\psi_{100}$ and $\psi_{010}$ using table 4.1. Next write down $\left(\psi_{100}+\psi_{010}\right) / \sqrt{2}$ and $\left(\psi_{010}-\psi_{100}\right) / \sqrt{2}$. Verify that the latter two are the functions $\psi_{100}$ and $\psi_{010}$ in a coordinate system $(\bar{x}, \bar{y}, z)$ that is rotated 45 degrees counter-clockwise around the $z$-axis compared to the original $(x, y, z)$ coordinate system.

### 4.1.6 Noneigenstates

It should not be thought that the harmonic oscillator only exists in energy eigenstates. The opposite is more like it. Anything that somewhat localizes the particle will produce an uncertainty in energy. This section explores the procedures to deal with states that are not energy eigenstates.

First, even if the wave function is not an energy eigenfunction, it can still always be written as a combination of the eigenfunctions:

$$
\begin{equation*}
\Psi(x, y, z, t)=\sum_{n_{x}=0}^{\infty} \sum_{n_{y}=0}^{\infty} \sum_{n_{z}=0}^{\infty} c_{n_{x} n_{y} n_{z}} \psi_{n_{x} n_{y} n_{z}} \tag{4.16}
\end{equation*}
$$

That this is always possible is a consequence of the completeness of the eigenfunctions of Hermitian operators such as the Hamiltonian. An arbitrary example of such a combination state is shown in figure 4.6.

The coefficients $c_{n_{x} n_{y} n_{z}}$ in the combination are important: according to the orthodox statistical interpretation, their square magnitude gives the probability to find the energy to be the corresponding eigenvalue $E_{n_{x} n_{y} n_{z}}$. For example, $\left|c_{000}\right|^{2}$ gives the probability of finding that the oscillator is in the ground state of lowest energy.

Figure 4.6: Arbitrary wave function (not an energy eigenfunction).

If the wave function $\Psi$ is in a known state, (maybe because the position of the particle was fairly accurately measured), then each coefficient $c_{n_{x} n_{y} n_{z}}$ can be found by computing an inner product:

$$
\begin{equation*}
c_{n_{x} n_{y} n_{z}}=\left\langle\psi_{n_{x} n_{y} n_{z}} \mid \Psi\right\rangle \tag{4.17}
\end{equation*}
$$

The reason this works is orthonormality of the eigenfunctions. As an example, consider the case of coefficient $c_{100}$ :
$c_{100}=\left\langle\psi_{100} \mid \Psi\right\rangle=\left\langle\psi_{100} \mid c_{000} \psi_{000}+c_{100} \psi_{100}+c_{010} \psi_{010}+c_{001} \psi_{001}+c_{200} \psi_{200}+\ldots\right\rangle$
Now proper eigenfunctions of Hermitian operators are orthonormal; the inner product between different eigenfunctions is zero, and between identical eigenfunctions is one:

$$
\left\langle\psi_{100} \mid \psi_{000}\right\rangle=0 \quad\left\langle\psi_{100} \mid \psi_{100}\right\rangle=1 \quad\left\langle\psi_{100} \mid \psi_{010}\right\rangle=0 \quad\left\langle\psi_{100} \mid \psi_{001}\right\rangle=0 \quad \ldots
$$

So, the inner product above must indeed produce $c_{100}$.
Chapter 7.1 will discuss another reason why the coefficients are important: they determine the time evolution of the wave function. It may be recalled that the Hamiltonian, and hence the eigenfunctions derived from it, did not involve time. However, the coefficients do.

Even if the wave function is initially in a state involving many eigenfunctions, such as the one in figure 4.6, the orthodox interpretation says that energy "measurement" will collapse it into a single eigenfunction. For example, assume
that the energies in all three coordinate directions are measured and that they return the values:

$$
E_{x 2}=\frac{5}{2} \hbar \omega \quad E_{y 1}=\frac{3}{2} \hbar \omega \quad E_{z 3}=\frac{7}{2} \hbar \omega
$$

for a total energy $E=\frac{15}{2} \hbar \omega$. Quantum mechanics could not exactly predict that this was going to happen, but it did predict that the energies had to be odd multiples of $\frac{1}{2} \hbar \omega$. Also, quantum mechanics gave the probability of measuring the given values to be whatever $\left|c_{213}\right|^{2}$ was. Or in other words, what $\left|\left\langle\psi_{213} \mid \Psi\right\rangle\right|^{2}$ was.

After the example measurement, the predictions become much more specific, because the wave function is now collapsed into the measured one:

$$
\Psi^{\text {new }}=c_{213}^{\text {new }} \psi_{213}
$$

This eigenfunction was shown earlier in figure 4.5.
If another measurement of the energies is now done, the only values that can come out are $E_{x 2}, E_{y 1}$, and $E_{z 3}$, the same as in the first measurement. There is now certainty of getting those values; the probability $\left|c_{213}^{\text {new }}\right|^{2}=1$. This will continue to be true for energy measurements until the system is disturbed, maybe by a position measurement.

## Key Points

0- The basic ideas of quantum mechanics were illustrated using an example.
$0-$ The energy eigenfunctions are not the only game in town. Their seemingly lowly coefficients are important too.
$0-$ When the wave function is known, the coefficient of any eigenfunction can be found by taking an inner product of the wave function with that eigenfunction.

### 4.2 Angular Momentum

Before a solution can be found for the important electronic structure of the hydrogen atom, the basis for the description of all the other elements and chemical bonds, first angular momentum must be discussed. Like in the classical Newtonian case, angular momentum is essential for the analysis, and in quantum mechanics, angular momentum is also essential for describing the final solution. Moreover, the quantum properties of angular momentum turn out to be quite unexpected and important for practical applications.

### 4.2.1 Definition of angular momentum

The old Newtonian physics defines angular momentum $\vec{L}$ as the vectorial product $\vec{r} \times \vec{p}$, where $\vec{r}$ is the position of the particle in question and $\vec{p}$ is its linear momentum.

Following the Newtonian analogy, quantum mechanics substitutes the gradient operator $\hbar \nabla /$ i for the linear momentum, so the angular momentum operator becomes:

$$
\begin{equation*}
\widehat{\vec{L}}=\frac{\hbar}{\mathrm{i}} \widehat{\vec{r}} \times \nabla \quad \widehat{\vec{r}} \equiv(\widehat{x}, \widehat{y}, \widehat{z}) \quad \nabla \equiv\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right) \tag{4.18}
\end{equation*}
$$

Unlike the Hamiltonian, the angular momentum operator is not specific to a given system. All observations about angular momentum will apply regardless of the physical system being studied.

## Key Points

$0-$ The angular momentum operator (4.18) has been identified.

### 4.2.2 Angular momentum in an arbitrary direction

The intent in this subsection is to find the operator for the angular momentum in an arbitrary direction and its eigenfunctions and eigenvalues.

For convenience, the direction in which the angular momentum is desired will be taken as the $z$-axis of the coordinate system. In fact, much of the mathematics that you do in quantum mechanics requires you to select some arbitrary direction as your $z$-axis, even if the physics itself does not have any preferred direction. It is further conventional in the quantum mechanics of atoms and molecules to draw the chosen $z$-axis horizontal, (though not in [25] or [52]), and that is what will be done here.

Things further simplify greatly if you switch from Cartesian coordinates $x$, $y$, and $z$ to "spherical coordinates" $r, \theta$, and $\phi$, as shown in figure 4.7. The coordinate $r$ is the distance from the chosen origin, $\theta$ is the angular position away from the chosen $z$-axis, and $\phi$ is the angular position around the $z$-axis, measured from the chosen $x$-axis.

In terms of these spherical coordinates, the $z$-component of angular momentum simplifies to:

$$
\begin{equation*}
\widehat{L}_{z} \equiv \frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial \phi} \tag{4.19}
\end{equation*}
$$

This can be verified by looking up the gradient operator $\nabla$ in spherical coordinates in [41, pp. 124-126] and then taking the component of $\vec{r} \times \nabla$ in the $z$ direction.

Figure 4.7: Spherical coordinates of an arbitrary point P.
In any case, with a bit of thought, it clearly makes sense: the $z$-component of linear momentum classically describes the motion in the direction of the $z$ axis, while the $z$-component of angular momentum describes the motion around the $z$-axis. So if in quantum mechanics the $z$ linear momentum is $\hbar / \mathrm{i}$ times the derivative with respect the coordinate $z$ along the $z$-axis, then surely the logical equivalent for $z$ angular momentum is $\hbar / \mathrm{i}$ times the derivative with respect to the angle $\phi$ around the $z$-axis?

Anyway, the eigenfunctions of the operator $\widehat{L}_{z}$ above turn out to be exponentials in $\phi$. More precisely, the eigenfunctions are of the form

$$
\begin{equation*}
C(r, \theta) e^{\mathrm{i} m \phi} \tag{4.20}
\end{equation*}
$$

Here $m$ is a constant and $C(r, \theta)$ can be any arbitrary function of $r$ and $\theta$. For historical reasons, the number $m$ is called the "magnetic quantum number". Historically, physicists have never seen a need to get rid of obsolete and confusing terms. The magnetic quantum number must be an integer, one of $\ldots,-2,-1,0,1,2,3, \ldots$ The reason is that if you increase the angle $\phi$ by $2 \pi$, you make a complete circle around the $z$-axis and return to the same point. Then the eigenfunction (4.20) must again be the same, but that is only the case if $m$ is an integer. To verify this, use the Euler formula (2.5).

Note further that the orbital momentum is associated with a particle whose mass is also indicated by $m$. This book will more specifically indicate the magnetic quantum number as $m_{l}$ if confusion between the two is likely.

The above solution is easily verified directly, and the eigenvalue $L_{z}$ identified, by substitution into the eigenvalue problem $\widehat{L}_{z} C e^{\mathrm{i} m \phi}=L_{z} C e^{\mathrm{i} m \phi}$ using the expression for $\widehat{L}_{z}$ above:

$$
\frac{\hbar}{\mathrm{i}} \frac{\partial C e^{\mathrm{i} m \phi}}{\partial \phi}=L_{z} C e^{\mathrm{i} m \phi} \Longrightarrow \frac{\hbar}{\mathrm{i}} \mathrm{i} C C e^{\mathrm{i} m \phi}=L_{z} C e^{\mathrm{i} m \phi}
$$

It follows that every eigenvalue is of the form:

$$
\begin{equation*}
L_{z}=m_{l} \hbar \text { for } m_{l} \text { an integer } \tag{4.21}
\end{equation*}
$$

So the angular momentum in a given direction cannot just take on any value: it must be a whole multiple $m_{l}$, (possibly negative), of Planck's constant $\hbar$.

Compare that with the linear momentum component $p_{z}$ which can take on any value, within the accuracy that the uncertainty principle allows. $L_{z}$ can only take discrete values, but they will be precise. And since the $z$-axis was arbitrary, this is true in any direction you choose.

It is important to keep in mind that if the surroundings of the particle has no preferred direction, the angular momentum in the arbitrarily chosen $z$-direction is physically irrelevant. For example, for the motion of the electron in an isolated hydrogen atom, no preferred direction of space can be identified. Therefore, the energy of the electron will only depend on its total angular momentum, not on the angular momentum in whatever is completely arbitrarily chosen to be the $z$-direction. In terms of quantum mechanics, that means that the value of $m$ does not affect the energy. (Actually, this is not exactly true, although it is true to very high accuracy. The electron and nucleus have magnetic fields that give them inherent directionality. It remains true that the $z$-component of net angular momentum of the complete atom is not relevant. However, the space in which the electron moves has a preferred direction due to the magnetic field of the nucleus and vice-versa. It affects energy very slightly. Therefore the electron and nucleus must coordinate their angular momentum components, addendum \{A.39\}.)

## Key Points

$0-$ Even if the physics that you want to describe has no preferred direction, you usually need to select some arbitrary $z$-axis to do the mathematics of quantum mechanics.
$0-$ Spherical coordinates based on the chosen $z$-axis are needed in this and subsequent analysis. They are defined in figure 4.7.
$0-$ The operator for the $z$-component of angular momentum is (4.19), where $\phi$ is the angle around the $z$-axis.
$0-$ The eigenvalues, or measurable values, of angular momentum in any arbitrary direction are whole multiples $m$, possibly negative, of $\hbar$.
$0-$ The whole multiple $m$ is called the magnetic quantum number.

### 4.2.2 Review Questions

1. If the angular momentum in a given direction is a multiple of $\hbar=$ $1.0545710^{-34} \mathrm{~J}$ s, then $\hbar$ should have units of angular momentum. Verify that.

Solution angub-a
2. What is the magnetic quantum number of a macroscopic, 1 kg , particle that is encircling the $z$-axis at a distance of 1 m at a speed of $1 \mathrm{~m} / \mathrm{s}$ ? Write out as an integer, and show digits you are not sure about as a question mark.

## Solution angub-b

3. Actually, based on the derived eigenfunction, $C(r, \theta) e^{\mathrm{i} m \phi}$, would any macroscopic particle ever be at a single magnetic quantum number in the first place? In particular, what can you say about where the particle can be found in an eigenstate?

Solution angub-c

### 4.2.3 Square angular momentum

Besides the angular momentum in an arbitrary direction, the other quantity of primary importance is the magnitude of the angular momentum. This is the length of the angular momentum vector, $\sqrt{\vec{L} \cdot \vec{L}}$. The square root is awkward, though; it is easier to work with the square angular momentum:

$$
L^{2} \equiv \vec{L} \cdot \vec{L}
$$

This subsection discusses the $\widehat{L}^{2}$ operator and its eigenvalues.
Like the $\widehat{L}_{z}$ operator of the previous subsection, $\widehat{L}^{2}$ can be written in terms of spherical coordinates. To do so, note first that

$$
\widehat{\vec{L}} \cdot \widehat{\vec{L}}=\frac{\hbar}{\mathrm{i}}(\vec{r} \times \nabla) \cdot \frac{\hbar}{\mathrm{i}}(\vec{r} \times \nabla)=-\hbar^{2} \vec{r} \cdot(\nabla \times(\vec{r} \times \nabla))
$$

(That is the basic vector identity (D.2) with vectors $\vec{r}, \nabla$, and $\vec{r} \times \nabla$.) Next look up the gradient and the curl in [41, pp. 124-126]. The result is:

$$
\begin{equation*}
\widehat{L}^{2} \equiv-\frac{\hbar^{2}}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)-\frac{\hbar^{2}}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}} \tag{4.22}
\end{equation*}
$$

Obviously, this result is not as intuitive as the $\widehat{L}_{z}$ operator of the previous subsection, but once again, it only involves the spherical coordinate angles. The measurable values of square angular momentum will be the eigenvalues of this operator. However, that eigenvalue problem is not easy to solve. In fact the solution is not even unique.

The solution to the problem may be summarized as follows. First, the nonuniqueness is removed by demanding that the eigenfunctions are also eigenfunctions of $\widehat{L}_{z}$, the operator of angular momentum in the $z$-direction. This makes the problem solvable, $\{$ D.14\}, and the resulting eigenfunctions are called the "spherical harmonics" $Y_{l}^{m}(\theta, \phi)$. The first few are given explicitly in table 4.2. In case you need more of them for some reason, there is a generic expression (D.5) in derivation \{D.14\}.

| $Y_{0}^{0}=\sqrt{\frac{1}{4 \pi}}$ | $Y_{1}^{0}=\sqrt{\frac{3}{4 \pi}} \cos (\theta)$ | $Y_{2}^{0}=\sqrt{\frac{5}{16 \pi}}\left(3 \cos ^{2} \theta-1\right)$ |
| :--- | :--- | :--- |
| $Y_{1}^{1}=-\sqrt{\frac{3}{8 \pi}} \sin \theta e^{\mathrm{i} \phi}$ | $Y_{2}^{1}=-\sqrt{\frac{15}{8 \pi}} \sin \theta \cos \theta e^{\mathrm{i} \phi}$ |  |
| $Y_{1}^{-1}=\sqrt{\frac{3}{8 \pi}} \sin \theta e^{-\mathrm{i} \phi}$ | $Y_{2}^{-1}=\sqrt{\frac{15}{8 \pi}} \sin \theta \cos \theta e^{-\mathrm{i} \phi}$ |  |
|  | $Y_{2}^{2}=\sqrt{\frac{15}{32 \pi}} \sin ^{2} \theta e^{2 \mathrm{i} \phi}$ |  |
|  | $Y_{2}^{-2}=\sqrt{\frac{15}{32 \pi}} \sin ^{2} \theta e^{-2 \mathrm{i} \phi}$ |  |

Table 4.2: The first few spherical harmonics.
These eigenfunctions can additionally be multiplied by any arbitrary function of the distance from the origin $r$. They are normalized to be orthonormal integrated over the surface of the unit sphere:

$$
\int_{\theta=0}^{\pi} \int_{\phi=0}^{2 \pi} Y_{l}^{m}(\theta, \phi)^{*} Y_{\underline{l}}^{\underline{m}}(\theta, \phi) \sin \theta \mathrm{d} \theta \mathrm{~d} \phi= \begin{cases}1 & \text { if } l=\underline{l} \text { and } m=\underline{m}  \tag{4.23}\\ 0 & \text { otherwise }\end{cases}
$$

The spherical harmonics $Y_{l}^{m}$ are sometimes symbolically written in "ket notation" as $|l m\rangle$.

What to say about them, except that they are in general a mess? Well, at least every one is proportional to $e^{\mathrm{i} m \phi}$, as an eigenfunction of $\widehat{L}_{z}$ should be. More importantly, the very first one, $Y_{0}^{0}$ is independent of angular position compared to the origin (it is the same for all $\theta$ and $\phi$ angular positions.) This eigenfunction corresponds to the state in which there is no angular momentum around the origin at all. If a particle has no angular momentum around the origin, it can be found at all angular locations relative to it with equal probability.

There is a different way of looking at the angular momentum eigenfunctions. It is shown in table 4.3. It shows that $r^{l} Y_{l}^{m}$ is always a polynomial in the position component of degree $l$. Furthermore, you can check that $\nabla^{2} r^{l} Y_{l}^{m}=$ 0 : the Laplacian of $r^{l} Y_{l}^{m}$ is always zero. This way of looking at the spherical harmonics is often very helpful in understanding more advanced quantum topics. These solutions may be indicated as

$$
\begin{equation*}
\mathcal{Y}_{l}^{m} \equiv r^{l} Y_{l}^{m} \tag{4.24}
\end{equation*}
$$

$$
\begin{array}{|l|l|l|}
\hline \hline Y_{0}^{0}=\sqrt{\frac{1}{4 \pi}} & r Y_{1}^{0}=\sqrt{\frac{3}{4 \pi}} z & r^{2} Y_{2}^{0}=\sqrt{\frac{5}{16 \pi}}\left(2 z^{2}-x^{2}-y^{2}\right) \\
r Y_{1}^{1}=-\sqrt{\frac{3}{8 \pi}}(x+\mathrm{i} y) & r^{2} Y_{2}^{1}=-\sqrt{\frac{15}{8 \pi}} z(x+\mathrm{i} y) \\
r Y_{1}^{-1}=\sqrt{\frac{3}{8 \pi}}(x-\mathrm{i} y) & r^{2} Y_{2}^{-1}=\sqrt{\frac{15}{8 \pi}} z(x-\mathrm{i} y) \\
& r^{2} Y_{2}^{2}=\sqrt{\frac{15}{32 \pi}}(x+\mathrm{i} y)^{2} \\
& r^{2} Y_{2}^{-2}=\sqrt{\frac{15}{32 \pi}}(x-\mathrm{i} y)^{2} \\
\hline \hline
\end{array}
$$

Table 4.3: The first few spherical harmonics rewritten.
and referred to as the "harmonic polynomials." In general the term "harmonic" indicates a function whose Laplacian $\nabla^{2}$ is zero.

Far more important than the details of the eigenfunctions themselves are the eigenvalues that come rolling out of the analysis. A spherical harmonic $Y_{l}^{m}$ has an angular momentum in the $z$-direction

$$
\begin{equation*}
L_{z}=m \hbar \tag{4.25}
\end{equation*}
$$

where the integer $m$ is called the magnetic quantum number, as noted in the previous subsection. That is no surprise, because the analysis demanded that they take that form. The new result is that a spherical harmonic has a square angular momentum

$$
\begin{equation*}
L^{2}=l(l+1) \hbar^{2} \tag{4.26}
\end{equation*}
$$

where $l$ is also an integer, and is called the "azimuthal quantum number" for reasons you do not want to know. It is maybe a weird result, (why not simply $l^{2} \hbar^{2}$ ?) but that is what square angular momentum turns out to be.

The azimuthal quantum number is at least as large as the magnitude of the magnetic quantum number $m$ :

$$
\begin{equation*}
l \geqslant|m| \tag{4.27}
\end{equation*}
$$

The reason is that $\widehat{L}^{2}=\widehat{L}_{x}^{2}+\widehat{L}_{y}^{2}+\widehat{L}_{z}^{2}$ must be at least as large as $\widehat{L}_{z}^{2}$; in terms of eigenvalues, $l(l+1) \hbar^{2}$ must be at least as large as $m^{2} \hbar^{2}$. As it is, with $l \geqslant$ $|m|$, either the angular momentum is completely zero, for $l=m=0$, or $L^{2}$ is always greater than $L_{z}^{2}$.

## Key Points

$0-$ The operator for square angular momentum is (4.22).
$0-$ The eigenfunctions of both square angular momentum and angular momentum in the chosen $z$-direction are called the spherical harmonics $Y_{l}^{m}$.
$0-$ If a particle has no angular momentum around the origin, it can be found at all angular locations relative to it with equal probability.
$0-$ The eigenvalues for square angular momentum take the counter-intuitive form $L^{2}=l(l+1) \hbar^{2}$ where $l$ is a nonnegative integer, one of 0 , $1,2,3, \ldots$, and is called the azimuthal quantum number.
$0-$ The azimuthal quantum number $l$ is always at least as big as the absolute value of the magnetic quantum number $m$.

### 4.2.3 Review Questions

1. The general wave function of a state with azimuthal quantum number $l$ and magnetic quantum number $m$ is $\Psi=R(r) Y_{l}^{m}(\theta, \phi)$, where $R(r)$ is some further arbitrary function of $r$. Show that the condition for this wave function to be normalized, so that the total probability of finding the particle integrated over all possible positions is one, is that

$$
\int_{r=0}^{\infty} R(r)^{*} R(r) r^{2} \mathrm{~d} r=1
$$

Solution anguc-a
2. Can you invert the statement about zero angular momentum and say: if a particle can be found at all angular positions compared to the origin with equal probability, it will have zero angular momentum?
Solution anguc-b
3. What is the minimum amount that the total square angular momentum is larger than just the square angular momentum in the $z$-direction for a given value of $l$ ?
Solution anguc-c

### 4.2.4 Angular momentum uncertainty

Rephrasing the final results of the previous subsection, if there is nonzero angular momentum, the angular momentum in the $z$-direction is always less than the total angular momentum. There is something funny going on here. The $z$ direction can be chosen arbitrarily, and if you choose it in the same direction as the angular momentum vector, then the $z$-component should be the entire vector. So, how can it always be less?

The answer of quantum mechanics is that the looked-for angular momentum vector does not exist. No axis, however arbitrarily chosen, can align with a nonexisting vector.

There is an uncertainty principle here, similar to the one of Heisenberg for position and linear momentum. For angular momentum, it turns out that if the component of angular momentum in a given direction, here taken to be $z$, has a definite value, then the components in both the $x$ and $y$ directions will be uncertain. (Details will be given in chapter 12.2). The wave function will be in a state where $L_{x}$ and $L_{y}$ have a range of possible values $m_{1} \hbar, m_{2} \hbar, \ldots$, each with some probability. Without definite $x$ and $y$ components, there simply is no angular momentum vector.

It is tempting to think of quantities that have not been measured, such as the angular momentum vector in this example, as being merely "hidden." However, the impossibility for the $z$-axis to ever align with any angular momentum vector shows that there is a fundamental difference between "being hidden" and "not existing".

## Key Points

$0-$ According to quantum mechanics, an exact nonzero angular momentum vector will never exist. If one component of angular momentum has a definite value, then the other two components will be uncertain.

### 4.3 The Hydrogen Atom

This section examines the critically important case of the hydrogen atom. The hydrogen atom consists of a nucleus which is just a single proton, and an electron encircling that nucleus. The nucleus, being much heavier than the electron, can be assumed to be at rest, and only the motion of the electron is of concern.

The energy levels of the electron determine the photons that the atom will absorb or emit, allowing the powerful scientific tool of spectral analysis. The electronic structure is also essential for understanding the properties of the other elements and of chemical bonds.

### 4.3.1 The Hamiltonian

The first step is to find the Hamiltonian of the electron. The electron experiences an electrostatic Coulomb attraction to the oppositely charged nucleus. The corresponding potential energy is

$$
\begin{equation*}
V=-\frac{e^{2}}{4 \pi \epsilon_{0} r} \tag{4.28}
\end{equation*}
$$

with $r$ the distance from the nucleus. The constant

$$
\begin{equation*}
e \approx 1.602176610^{-19} \mathrm{C} \tag{4.29}
\end{equation*}
$$

is the magnitude of the electric charges of the electron and proton, and the constant

$$
\begin{equation*}
\epsilon_{0} \approx 8.85418781710^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{~m} \tag{4.30}
\end{equation*}
$$

is called the "permittivity of space."
Unlike for the harmonic oscillator discussed earlier, this potential energy cannot be split into separate parts for Cartesian coordinates $x, y$, and $z$. To do the analysis for the hydrogen atom, you must put the nucleus at the origin of the coordinate system and use spherical coordinates $r$ (the distance from the nucleus), $\theta$ (the angle from an arbitrarily chosen $z$-axis), and $\phi$ (the angle around the $z$-axis); see figure 4.7. In terms of spherical coordinates, the potential energy above depends on just the single coordinate $r$.

To get the Hamiltonian, you need to add to this potential energy the kinetic energy operator $\widehat{T}$. Chapter 3.3 gave this operator as

$$
\widehat{T}=-\frac{\hbar^{2}}{2 m} \nabla^{2}
$$

where $\nabla^{2}$ is the Laplacian. The Laplacian in spherical coordinates is given in the notations, (N.5). Then the Hamiltonian is found to be:

$$
\begin{equation*}
H=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} r^{2}}\left\{\frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r}\right)+\frac{1}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)+\frac{1}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}}\right\}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r} \tag{4.31}
\end{equation*}
$$

where

$$
\begin{equation*}
m_{\mathrm{e}} \approx 9.10910^{-31} \mathrm{~kg} \tag{4.32}
\end{equation*}
$$

is the mass of the electron.
It may be noted that the small proton motion can be corrected for by slightly adjusting the mass of the electron to be an effective $9.104410^{-31} \mathrm{~kg},\{\mathrm{~A} .5\}$. This makes the solution exact, except for extremely small errors due to relativistic effects. (These are discussed in addendum \{A.39\}.)

## Key Points

$0-$ To analyze the hydrogen atom, you must use spherical coordinates.
$0-$ The Hamiltonian in spherical coordinates has been written down. It is (4.31).

### 4.3.2 Solution using separation of variables

This subsection describes in general lines how the eigenvalue problem for the electron of the hydrogen atom is solved. The basic ideas are like those used to solve the particle in a pipe and the harmonic oscillator, but in this case, they are used in spherical coordinates rather than Cartesian ones. Without getting too much caught up in the mathematical details, do not miss the opportunity of learning where the hydrogen energy eigenfunctions and eigenvalues come from. This is the crown jewel of quantum mechanics; brilliant, almost flawless, critically important; one of the greatest works of physical analysis ever.

The eigenvalue problem for the Hamiltonian, as formulated in the previous subsection, can be solved by searching for solutions $\psi$ that take the form of a product of functions of each of the three coordinates: $\psi=R(r) \Theta(\theta) \Phi(\phi)$. More concisely, $\psi=R \Theta \Phi$. The problem now is to find separate equations for the individual functions $R, \Theta$, and $\Phi$ from which they can then be identified. The arguments are similar as for the harmonic oscillator, but messier, since the coordinates are more entangled. First, substituting $\psi=R \Theta \Phi$ into the Hamiltonian eigenvalue problem $H \psi=E \psi$, with the Hamiltonian $H$ as given in the previous subsection and $E$ the energy eigenvalue, produces:

$$
\left[-\frac{\hbar^{2}}{2 m_{\mathrm{e}} r^{2}}\left\{\frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r}\right)+\frac{1}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)+\frac{1}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}}\right\}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r}\right] R \Theta \Phi
$$

$$
=E R \Theta \Phi
$$

To reduce this problem, premultiply by $2 m_{\mathrm{e}} r^{2} / R \Theta \Phi$ and then separate the various terms:

$$
\begin{align*}
-\frac{\hbar^{2}}{R} \frac{\partial}{\partial r}\left(r^{2} \frac{\partial R}{\partial r}\right)+\frac{1}{\Theta \Phi}\left\{-\frac{\hbar^{2}}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)\right. & \left.-\frac{\hbar^{2}}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}}\right\} \Theta \Phi \\
& -\frac{2 m_{\mathrm{e}} r^{2} e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r}=2 m_{\mathrm{e}} r^{2} E \tag{4.33}
\end{align*}
$$

Next identify the terms involving the angular derivatives and name them $E_{\theta \phi}$. They are:

$$
\frac{1}{\Theta \Phi}\left[-\frac{\hbar^{2}}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)-\frac{\hbar^{2}}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}}\right] \Theta \Phi=E_{\theta \phi}
$$

By this definition, $E_{\theta \phi}$ only depends on $\theta$ and $\phi$, not $r$. But it cannot depend on $\theta$ or $\phi$ either, since none of the other terms in the original equation (4.33) depends on them. So $E_{\theta \phi}$ must be a constant, independent of all three coordinates. Then multiplying the angular terms above by $\Theta \Phi$ produces a reduced eigenvalue problem involving $\Theta \Phi$ only, with eigenvalue $E_{\theta \phi}$ :

$$
\begin{equation*}
\left[-\frac{\hbar^{2}}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)-\frac{\hbar^{2}}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \phi^{2}}\right] \Theta \Phi=E_{\theta \phi} \Theta \Phi \tag{4.34}
\end{equation*}
$$

Repeat the game with this reduced eigenvalue problem. Multiply by $\sin ^{2} \theta / \Theta \Phi$, and name the only $\phi$-dependent term $E_{\phi}$. It is:

$$
-\frac{1}{\Phi} \hbar^{2}\left(\frac{\partial^{2}}{\partial \phi^{2}}\right) \Phi=E_{\phi}
$$

By definition $E_{\phi}$ only depends on $\phi$, but since the other two terms in the equation it came from did not depend on $\phi, E_{\phi}$ cannot either, so it must be another constant. What is left is a simple eigenvalue problem just involving $\Phi$ :

$$
-\hbar^{2}\left(\frac{\partial^{2}}{\partial \phi^{2}}\right) \Phi=E_{\phi} \Phi
$$

And that is readily solvable.
In fact, the solution to this final problem has already been given, since the operator involved is just the square of the angular momentum operator $\widehat{L}_{z}$ of section 4.2.2:

$$
-\hbar^{2}\left(\frac{\partial^{2}}{\partial \phi^{2}}\right) \Phi=\left(\frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial \phi}\right)^{2} \Phi=\widehat{L}_{z}^{2} \Phi
$$

So this equation must have the same eigenfunctions as the operator $\widehat{L}_{z}$,

$$
\Phi_{m}=e^{\mathrm{i} m \phi}
$$

and must have the square eigenvalues

$$
E_{\phi}=(m \hbar)^{2}
$$

(each application of $\widehat{L}_{z}$ multiplies the eigenfunction by $m \hbar$ ). It may be recalled that the magnetic quantum number $m$ must be an integer.

The eigenvalue problem (4.34) for $\Theta \Phi$ is even easier; it is exactly the one for the square angular momentum $L^{2}$ of section 4.2.3. (So, no, there was not really a need to solve for $\Phi$ separately.) Its eigenfunctions are therefore the spherical harmonics,

$$
\Theta \Phi=Y_{l}^{m}(\theta, \phi)
$$

and its eigenvalues are

$$
E_{\theta \phi}=l(l+1) \hbar^{2}
$$

It may be recalled that the azimuthal quantum number $l$ must be an integer greater than or equal to $|m|$.

Returning now to the solution of the original eigenvalue problem (4.33), replacement of the angular terms by $E_{\theta \phi}=l(l+1) \hbar^{2}$ turns it into an ordinary differential equation problem for the radial factor $R(r)$ in the energy eigenfunction. As usual, this problem is a pain to solve, so that is again shoved away in a note, $\{$ D.15\}.

It turns out that the solutions of the radial problem can be numbered using a third quantum number, $n$, called the "principal quantum number". It is larger than the azimuthal quantum number $l$, which in turn must be at least as large as the absolute value of the magnetic quantum number:

$$
\begin{equation*}
n>l \geqslant|m| \tag{4.35}
\end{equation*}
$$

so the principal quantum number must be at least 1 . And if $n=1$, then $l=m$ $=0$.

In terms of these three quantum numbers, the final energy eigenfunctions of the hydrogen atom are of the general form:

$$
\begin{equation*}
\psi_{n l m}=R_{n l}(r) Y_{l}^{m}(\theta, \phi) \tag{4.36}
\end{equation*}
$$

where the spherical harmonics $Y_{l}^{m}$ were described in section 4.2.3. The brand new radial wave functions $R_{n l}$ can be found written out in table 4.4 for small values of $n$ and $l$, or in derivation $\{\mathrm{D} .15\}$, (D.8), for any $n$ and $l$. They are usually written in terms of a scaled radial distance from the nucleus $\rho=r / a_{0}$, where the length $a_{0}$ is called the "Bohr radius" and has the value

$$
\begin{equation*}
a_{0}=\frac{4 \pi \epsilon_{0} \hbar^{2}}{m_{\mathrm{e}} e^{2}} \approx 0.52917710^{-10} \mathrm{~m} \tag{4.37}
\end{equation*}
$$

or about half an Ångstrom. The Bohr radius is a really good length scale to describe atoms in terms of. The $\AA$ ngstrom itself is a good choice too, it is $10^{-10}$ m , or one tenth of a nanometer.

$$
\begin{array}{|c|c|c|}
\hline \hline R_{10}=\frac{2}{\sqrt{a_{0}^{3}}} e^{-\rho} & R_{20}=\frac{2-\rho}{2 \sqrt{2 a_{0}^{3}}} e^{-\rho / 2} & R_{30}=\frac{54-36 \rho+4 \rho^{2}}{81 \sqrt{3 a_{0}^{3}}} e^{-\rho / 3} \\
R_{21}=\frac{\rho}{2 \sqrt{6 a_{0}^{3}}} e^{-\rho / 2} & R_{31}=\frac{24 \rho-4 \rho^{2}}{81 \sqrt{6 a_{0}^{3}}} e^{-\rho / 3} \\
\hline R_{32}=\frac{4 \rho^{2}}{81 \sqrt{30 a_{0}^{3}}} e^{-\rho / 3} \\
a_{0}=\frac{4 \pi \epsilon_{0} \hbar^{2}}{m_{\mathrm{e}} e^{2}} \quad \rho=\frac{r}{a_{0}} \\
\hline
\end{array}
$$

Table 4.4: The first few radial wave functions for hydrogen.

The energy eigenvalues are much simpler and more interesting than the eigenfunctions; they are
$E_{n}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} a_{0}^{2}} \frac{1}{n^{2}}=\frac{E_{1}}{n^{2}} \quad n=1,2,3, \ldots \quad E_{1}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} a_{0}^{2}}=-13.6057 \mathrm{eV}$ where eV stands for electron volt, a unit of energy equal to $1.6021810^{-19} \mathrm{~J}$. It is the energy that an electron picks up during a 1 volt change in electric potential.

You may wonder why the energy only depends on the principal quantum number $n$, and not also on the azimuthal quantum number $l$ and the magnetic quantum number $m$. Well, the choice of $z$-axis was arbitrary, so it should not seem that strange that the physics would not depend on the angular momentum in that direction. But that the energy does not depend on $l$ is nontrivial: if you solve the simpler problem of a particle stuck inside an impenetrable spherical container, using procedures from \{A.6\}, the energy values depend on both $n$ and $l$. So, that is just the way it is. (It stops being true anyway if you include relativistic effects in the Hamiltonian.)

Since the lowest possible value of the principal quantum number $n$ is one, the ground state of lowest energy $E_{1}$ is eigenfunction $\psi_{100}$.

## Key Points

$0-$ Skipping a lot of math, energy eigenfunctions $\psi_{n l m}$ and their energy eigenvalues $E_{n}$ have been found.
$0-$ There is one eigenfunction for each set of three integer quantum numbers $n, l$, and $m$ satisfying $n>l \geqslant|m|$. The number $n$ is called the principal quantum number.
$0-$ The typical length scale in the solution is called the Bohr radius $a_{0}$, which is about half an $\AA$ ngstrom.
$0-$ The derived eigenfunctions $\psi_{n l m}$ are eigenfunctions of

- $z$ angular momentum, with eigenvalue $L_{z}=m \hbar$;
- square angular momentum, with eigenvalue $L^{2}=l(l+$ 1) $\hbar^{2}$;
- energy, with eigenvalue $E_{n}=-\hbar^{2} / 2 m_{\mathrm{e}} a_{0}^{2} n^{2}$.
$0-$ The energy values only depend on the principal quantum number $n$.
$0-$ The ground state is $\psi_{100}$.

### 4.3.2 Review Questions

1. Use the tables for the radial wave functions and the spherical harmonics to write down the wave function

$$
\psi_{n l m}=R_{n l}(r) Y_{l}^{m}(\theta, \phi)
$$

for the case of the ground state $\psi_{100}$.
Check that the state is normalized. Note: $\int_{0}^{\infty} e^{-2 u} u^{2} \mathrm{~d} u=\frac{1}{4}$.
Solution hydb-a
2. Use the generic expression

$$
\psi_{n l m}=-\frac{2}{n^{2}} \sqrt{\frac{(n-l-1)!}{\left[(n+l)!a_{0}\right]^{3}}}\left(\frac{2 \rho}{n}\right)^{l} L_{n+l}^{2 l+1}\left(\frac{2 \rho}{n}\right) e^{-\rho / n} Y_{l}^{m}(\theta, \phi)
$$

with $\rho=r / a_{0}$ and $Y_{l}^{m}$ from the spherical harmonics table to find the ground state wave function $\psi_{100}$. Note: the Laguerre polynomial $L_{1}(x)$ $=1-x$ and for any $p, L_{1}^{p}$ is just its $p$-th derivative.
Solution hydb-b
3. Plug numbers into the generic expression for the energy eigenvalues,

$$
E_{n}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} a_{0}^{2}} \frac{1}{n^{2}}
$$

where $a_{0}=4 \pi \epsilon_{0} \hbar^{2} / m_{\mathrm{e}} e^{2}$, to find the ground state energy. Express in eV , where 1 eV equals $1.602210^{-19} \mathrm{~J}$. Values for the physical constants can be found at the start of this section and in the notations section.

Solution hydb-c

### 4.3.3 Discussion of the eigenvalues

The only energy values that the electron in the hydrogen atom can have are the "Bohr energies" derived in the previous subsection:

$$
E_{n}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}} a_{0}^{2}} \frac{1}{n^{2}} \quad n=1,2,3, \ldots
$$

This subsection discusses the physical consequences of this result.
To aid the discussion, the allowed energies are plotted in the form of an energy spectrum in figure 4.8. To the right of the lowest three energy levels the values of the quantum numbers that give rise to those energy levels are listed.

The first thing that the energy spectrum illustrates is that the energy levels are all negative, unlike the ones of the harmonic oscillator, which were all positive. However, that does not mean much; it results from defining the potential energy of the harmonic oscillator to be zero at the nominal position of the particle, while the hydrogen potential is instead defined to be zero at large distance from the nucleus. (It will be shown later, chapter 7.2, that the average potential energy is twice the value of the total energy, and the average kinetic energy is minus the total energy, making the average kinetic energy positive as it should be.)

A more profound difference is that the energy levels of the hydrogen atom have a maximum value, namely zero, while those of the harmonic oscillator

Figure 4.8: Spectrum of the hydrogen atom.
went all the way to infinity. It means physically that while the particle can never escape in a harmonic oscillator, in a hydrogen atom, the electron escapes if its total energy is greater than zero. Such a loss of the electron is called "ionization" of the atom.

There is again a ground state of lowest energy; it has total energy

$$
\begin{equation*}
E_{1}=-13.6 \mathrm{eV} \tag{4.39}
\end{equation*}
$$

(an eV or "electron volt" is $1.610^{-19} \mathrm{~J}$ ). The ground state is the state in which the hydrogen atom will be at absolute zero temperature. In fact, it will still be in the ground state at room temperature, since even then the energy of heat motion is unlikely to raise the energy level of the electron to the next higher one, $E_{2}$.

The ionization energy of the hydrogen atom is 13.6 eV ; this is the minimum amount of energy that must be added to raise the electron from the ground state to the state of a free electron.

If the electron is excited from the ground state to a higher but still bound energy level, (maybe by passing a spark through hydrogen gas), it will in time again transition back to a lower energy level. Discussion of the reasons and the time evolution of this process will have to wait until chapter 7. For now, it can be pointed out that different transitions are possible, as indicated by the arrows in figure 4.8. They are named by their final energy level to be Lyman, Balmer, or Paschen series transitions.

The energy lost by the electron during a transition is emitted as a quantum of electromagnetic radiation called a photon. The most energetic photons, in the ultraviolet range, are emitted by Lyman transitions. Balmer transitions emit visible light and Paschen ones infrared.

The photons emitted by isolated atoms at rest must have an energy very precisely equal to the difference in energy eigenvalues; anything else would violate the requirement of the orthodox interpretation that only the eigenvalues are observable. And according to the "Planck-Einstein relation," the photon's energy equals the angular frequency $\omega$ of its electromagnetic vibration times $\hbar$ :

$$
E_{n_{1}}-E_{n_{2}}=\hbar \omega
$$

Thus the spectrum of the light emitted by hydrogen atoms is very distinctive and can be identified to great accuracy. Different elements have different spectra, and so do molecules. It all allows atoms and molecules to be correctly recognized in a lab or out in space.
(To be sure, the spectral frequencies are not truly mathematically exact numbers. A slight "spectral broadening" is unavoidable because no atom is truly isolated as assumed here; there is always some radiation that perturbs it even in the most ideal empty space. In addition, thermal motion of the atom causes Doppler shifts. In short, only the energy eigenvalues are observable, but exactly what those eigenvalues are for a real-life atom can vary slightly.)

Atoms and molecules may also absorb electromagnetic energy of the same frequencies that they can emit. That allows them to enter an excited state. The excited state will eventually emit the absorbed energy again in a different direction, and possibly at different frequencies by using different transitions. In this way, in astronomy atoms can remove specific frequencies from light that passes them on its way to earth, resulting in an absorption spectrum. Or instead atoms may scatter specific frequencies of light in our direction that was originally not headed to earth, producing an emission spectrum. Doppler shifts can provide information about the thermal and average motion of the atoms. Since hydrogen is so prevalent in the universe, its energy levels as derived here are particularly important in astronomy. Chapter 7 will address the mechanisms of emission and absorption in much greater detail.

## Key Points

$0-$ The energy levels of the electron in a hydrogen atom have a highest value. This energy is by convention taken to be the zero level.
$0-$ The ground state has a energy 13.6 eV below this zero level.
$0-$ If the electron in the ground state is given an additional amount of energy that exceeds the 13.6 eV , it has enough energy to escape from the nucleus. This is called ionization of the atom.

0 - If the electron transitions from a bound energy state with a higher principal quantum number $n_{1}$ to a lower one $n_{2}$, it emits radiation with an angular frequency $\omega$ given by

$$
\hbar \omega=E_{n_{1}}-E_{n_{2}}
$$

0- Similarly, atoms with energy $E_{n_{2}}$ may absorb electromagnetic energy of such a frequency.

### 4.3.3 Review Questions

1. If there are infinitely many energy levels $E_{1}, E_{2}, E_{3}, E_{4}, E_{5}, E_{6}, \ldots$, where did they all go in the energy spectrum?

Solution hydc-a
2. What is the value of energy level $E_{2}$ ? And $E_{3}$ ? Solution hydc-b
3. Based on the results of the previous question, what is the color of the light emitted in a Balmer transition from energy $E_{3}$ to $E_{2}$ ? The PlanckEinstein relation says that the angular frequency $\omega$ of the emitted photon is its energy divided by $\hbar$, and the wave length of light is $2 \pi c / \omega$ where $c$ is the speed of light. Typical wave lengths of visible light are: violet 400 nm , indigo 445 nm , blue 475 nm , green 510 nm , yellow 570 nm , orange 590 nm , red 650 nm .

Solution hydc-c
4. What is the color of the light emitted in a Balmer transition from an energy level $E_{n}$ with a high value of $n$ to $E_{2}$ ?

Solution hydc-d

### 4.3.4 Discussion of the eigenfunctions

The appearance of the energy eigenstates will be of great interest in understanding the heavier elements and chemical bonds. This subsection describes the most important of them.

It may be recalled from subsection 4.3 .2 that there is one eigenfunction $\psi_{n l m}$ for each set of three integer quantum numbers. They are the principal quantum number $n$ (determining the energy of the state), the azimuthal quantum number $l$ (determining the square angular momentum), and the magnetic quantum number $m$ (determining the angular momentum in the chosen $z$-direction.) They must satisfy the requirements that

$$
n>l \geqslant|m|
$$

For the ground state, with the lowest energy $E_{1}, n=1$ and hence according to the conditions above both $l$ and $m$ must be zero. So the ground state eigenfunction is $\psi_{100}$; it is unique.

The expression for the wave function of the ground state is (from the results of subsection 4.3.2):

$$
\begin{equation*}
\psi_{100}(r)=\frac{1}{\sqrt{\pi a_{0}^{3}}} e^{-r / a_{0}} \tag{4.40}
\end{equation*}
$$

where $a_{0}$ is called the "Bohr radius",

$$
\begin{equation*}
a_{0}=\frac{4 \pi \epsilon_{0} \hbar^{2}}{m_{\mathrm{e}} e^{2}} \approx 0.529177210710^{-10} \mathrm{~m} \tag{4.41}
\end{equation*}
$$

The square magnitude of the energy states will again be displayed as grey tones, darker regions corresponding to regions where the electron is more likely to be found. The ground state is shown this way in figure 4.9; the electron may be found within a blob size that is about three times the Bohr radius, or roughly an $\AA$ ngstrom, $\left(10^{-10} \mathrm{~m}\right)$, in diameter.

Figure 4.9: Ground state wave function of the hydrogen atom.
It is the quantum mechanical refusal of electrons to restrict themselves to a single location that gives atoms their size. If Planck's constant $\hbar$ would have been zero, so would have been the Bohr radius, and the electron would have been in the nucleus. It would have been a very different world.

The ground state probability distribution is spherically symmetric: the probability of finding the electron at a point depends on the distance from the nucleus, but not on the angular orientation relative to it.

The excited energy levels $E_{2}, E_{3}, \ldots$ are all degenerate; as the spectrum figure 4.8 indicated, there is more than one eigenstate producing each level. Let's have a look at the states at energy level $E_{2}$ now.

Figure 4.10 shows energy eigenfunction $\psi_{200}$. Like $\psi_{100}$, it is spherically symmetric. In fact, all eigenfunctions $\psi_{n 00}$ are spherically symmetric. However, the wave function has blown up a lot, and now separates into a small, more or less spherical region in the center, surrounded by a second region that forms a spherical shell. Separating the two is a radius at which there is zero probability of finding the electron.

The state $\psi_{200}$ is commonly referred to as the " 2 s " state. The 2 indicates that it is a state with energy $E_{2}$. The "s" indicates that the azimuthal quantum number is zero; just think "spherically symmetric." Similarly, the ground state $\psi_{100}$ is commonly indicated as " 1 s ", having the lowest energy $E_{1}$.

## Figure 4.10: Eigenfunction $\psi_{200}$.

States which have azimuthal quantum number $l=1$ are called "p" states, for some historical reason. Historically, physicists have always loved confusing and inconsistent notations. In particular, the $\psi_{21 m}$ states are called " 2 p " states. As first example of such a state, figure 4.11 shows $\psi_{210}$. This wave function squeezes itself close to the $z$-axis, which is plotted horizontally by convention. There is zero probability of finding the electron at the vertical $x, y$ symmetry plane, and maximum probability at two symmetric points on the $z$-axis. Since the wave

Figure 4.11: Eigenfunction $\psi_{210}$, or $2 \mathrm{p}_{z}$.
function squeezes close to the $z$-axis, this state is often more specifically referred to as the " $2 \mathrm{p}_{z}$ " state. Think "points along the $z$-axis."

Figure 4.12 shows the other two " 2 p " states, $\psi_{211}$ and $\psi_{21-1}$. These two states look exactly the same as far as the probability density is concerned. It is somewhat hard to see in the figure, but they really take the shape of a torus around the left-to-right $z$-axis.

Eigenfunctions $\psi_{200}, \psi_{210}, \psi_{211}$, and $\psi_{21-1}$ are degenerate: they all four have the same energy $E_{2}=-3.4 \mathrm{eV}$. The consequence is that they are not unique. Combinations of them can be formed that have the same energy. These combination states may be more important physically than the original eigenfunctions.

Figure 4.12: Eigenfunction $\psi_{211}$ (and $\psi_{21-1}$ ).
In particular, the torus-shaped eigenfunctions $\psi_{211}$ and $\psi_{21-1}$ are often not very useful for descriptions of heavier elements and chemical bonds. Two states that are more likely to be relevant here are called $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$; they are the combination states:

$$
\begin{equation*}
2 \mathrm{p}_{x}: \frac{1}{\sqrt{2}}\left(-\psi_{211}+\psi_{21-1}\right) \quad 2 \mathrm{p}_{y}: \frac{\mathrm{i}}{\sqrt{2}}\left(\psi_{211}+\psi_{21-1}\right) \tag{4.42}
\end{equation*}
$$

These two states are shown in figure 4.13; they look exactly like the "pointer" state $2 \mathrm{p}_{z}$ of figure 4.11, except that they squeeze along the $x$-axis, respectively the $y$-axis, instead of along the $z$-axis. (Since the $y$-axis is pointing towards you, $2 \mathrm{p}_{y}$ looks rotationally symmetric. Seen from the side, it would look like $\mathrm{p}_{z}$ in figure 4.11.)

Figure 4.13: Eigenfunctions $2 \mathrm{p}_{x}$, left, and $2 \mathrm{p}_{y}$, right.
Note that unlike the two original states $\psi_{211}$ and $\psi_{21-1}$, the states $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ do not have a definite value of the $z$-component of angular momentum; the $z$-component has a $50 / 50$ uncertainty of being either $+\hbar$ or $-\hbar$. But that is
not important in most circumstances. What is important is that when multiple electrons occupy the p states, mutual repulsion effects tend to push them into the $\mathrm{p}_{x}, \mathrm{p}_{y}$, and $\mathrm{p}_{z}$ states.

So, the four independent eigenfunctions at energy level $E_{2}$ are best thought of as consisting of one spherically symmetrical 2 s state, and three directional states, $2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}$, and $2 \mathrm{p}_{z}$, pointing along the three coordinate axes.

But even that is not always ideal; as discussed in chapter 5.11.4, for many chemical bonds, especially those involving the important element carbon, still different combination states called "hybrids" show up. They involve combinations of the 2 s and the 2 p states and therefore have uncertain square angular momentum as well.

## Key Points

$0-$ The typical size of eigenstates is given by the Bohr radius, making the size of the atom of the order of an $\AA$.
$0-$ The ground state $\psi_{100}$, or 1 s state, is nondegenerate: no other set of quantum numbers $n, l, m$ produces energy $E_{1}$.
$0-$ All higher energy levels are degenerate, there is more than one eigenstate producing that energy.
$0-$ All states of the form $\psi_{n 00}$, including the ground state, are spherically symmetric, and are called s states. The ground state $\psi_{100}$ is the 1 s state, $\psi_{200}$ is the 2 s state, etcetera.
$0-$ States of the form $\psi_{n 1 m}$ are called p states. The basic 2p states are $\psi_{21-1}, \psi_{210}$, and $\psi_{211}$.
$0-$ The state $\psi_{210}$ is also called the $2 \mathrm{p}_{z}$ state, since it squeezes itself around the $z$-axis.
$0=$ There are similar $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ states that squeeze around the $x$ and $y$ axes. Each is a combination of $\psi_{21-1}$ and $\psi_{211}$.
$0-$ The four spatial states at the $E_{2}$ energy level can therefore be thought of as one spherically symmetric 2 s state and three 2 p pointer states along the axes.
$0-$ However, since the $E_{2}$ energy level is degenerate, eigenstates of still different shapes are likely to show up in applications.

### 4.3.4 Review Questions

1. At what distance $r$ from the nucleus does the square of the ground state wave function become less than one percent of its value at the nucleus? Express it both as a multiple of the Bohr radius $a_{0}$ and in $\AA$.

Solution hydd-a
2. Check from the conditions

$$
n>l \geqslant|m|
$$

that $\psi_{200}, \psi_{211}, \psi_{210}$, and $\psi_{21-1}$ are the only states of the form $\psi_{n l m}$ that have energy $E_{2}$. (Of course, all their combinations, like $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$, have energy $E_{2}$ too, but they are not simply of the form $\psi_{n l m}$, but combinations of the "basic" solutions $\psi_{200}, \psi_{211}, \psi_{210}$, and $\psi_{21-1}$.)
Solution hydd-b
3. Check that the states

2 \mathrm{p}_{x}=\frac{1}{\sqrt{2}}\left(-\psi_{211}+\psi_{21-1}\right) \quad 2 \mathrm{p}_{y}=\frac{\mathrm{i}}{\sqrt{2}}\left(\psi_{211}+\psi_{21-1}\right)
$$

are properly normalized.
Solution hydd-c

### 4.4 Expectation Value and Standard Deviation

It is a striking consequence of quantum mechanics that physical quantities may not have a value. This occurs whenever the wave function is not an eigenfunction of the quantity of interest. For example, the ground state of the hydrogen atom is not an eigenfunction of the position operator $\widehat{x}$, so the $x$-position of the electron does not have a value. According to the orthodox interpretation, it cannot be predicted with certainty what a measurement of such a quantity will produce.

However, it is possible to say something if the same measurement is done on a large number of systems that are all the same before the measurement. An example would be $x$-position measurements on a large number of hydrogen atoms that are all in the ground state before the measurement. In that case, it is relatively straightforward to predict what the average, or "expectation value," of all the measurements will be.

The expectation value is certainly not a replacement for the classical value of physical quantities. For example, for the hydrogen atom in the ground state, the expectation position of the electron is in the nucleus by symmetry. Yet because the nucleus is so small, measurements will never find it there! (The typical measurement will find it a distance comparable to the Bohr radius away.) Actually, that is good news, because if the electron would be in the nucleus as a classical particle, its potential energy would be almost minus infinity instead of the correct value of about -27 eV . It would be a very different universe. Still, having an expectation value is of course better than having no information at all.

The average discrepancy between the expectation value and the actual measurements is called the "standard deviation." In the hydrogen atom example, where typically the electron is found a distance comparable to the Bohr radius
away from the nucleus, the standard deviation in the $x$-position turns out to be exactly one Bohr radius. (The same of course for the standard deviations in the $y$ and $z$ positions away from the nucleus.)

In general, the standard deviation is the quantitative measure for how much uncertainty there is in a physical value. If the standard deviation is very small compared to what you are interested in, it is probably OK to use the expectation value as a classical value. It is perfectly fine to say that the electron of the hydrogen atom that you are measuring is in your lab but it is not OK to say that it has countless electron volts of negative potential energy because it is in the nucleus.

This section discusses how to find expectation values and standard deviations after a brief introduction to the underlying ideas of statistics.

## Key Points

$0-$ The expectation value is the average value obtained when doing measurements on a large number of initially identical systems. It is as close as quantum mechanics can come to having classical values for uncertain physical quantities.
$0-$ The standard deviation is how far the individual measurements on average deviate from the expectation value. It is the quantitative measure of uncertainty in quantum mechanics.

### 4.4.1 Statistics of a die

Since it seems to us humans as if, in Einstein's words, God is playing dice with the universe, it may be a worthwhile idea to examine the statistics of a die first.

For a fair die, each of the six numbers will, on average, show up a fraction $1 / 6$ of the number of throws. In other words, each face has a probability of $1 / 6$.

The average value of a large number of throws is called the expectation value. For a fair die, the expectation value is 3.5. After all, number 1 will show up in about $1 / 6$ of the throws, as will numbers 2 through 6 , so the average is

$$
\frac{(\text { number of throws }) \times\left(\frac{1}{6} 1+\frac{1}{6} 2+\frac{1}{6} 3+\frac{1}{6} 4+\frac{1}{6} 5+\frac{1}{6} 6\right)}{\text { number of throws }}=3.5
$$

The general rule to get the expectation value is to sum the probability for each value times the value. In this example:

$$
\frac{1}{6} 1+\frac{1}{6} 2+\frac{1}{6} 3+\frac{1}{6} 4+\frac{1}{6} 5+\frac{1}{6} 6=3.5
$$

Note that the name "expectation value" is very poorly chosen. Even though the average value of a lot of throws will be 3.5, you would surely not expect to throw 3.5. But it is probably too late to change the name now.

The maximum possible deviation from the expectation value does of course occur when you throw a 1 or a 6 ; the absolute deviation is then $|1-3.5|=$ $|6-3.5|=2.5$. It means that the possible values produced by a throw can deviate as much as 2.5 from the expectation value.

However, the maximum possible deviation from the average is not a useful concept for quantities like position, or for the energy levels of the harmonic oscillator, where the possible values extend all the way to infinity. So, instead of the maximum deviation from the expectation value, some average deviation is better. The most useful of those is called the "standard deviation", denoted by $\sigma$. It is found in two steps: first the average square deviation from the expectation value is computed, and then a square root is taken of that. For the die that works out to be:

$$
\begin{aligned}
\sigma= & {\left[\frac{1}{6}(1-3.5)^{2}+\frac{1}{6}(2-3.5)^{2}+\frac{1}{6}(3-3.5)^{2}+\right.} \\
& \left.\frac{1}{6}(4-3.5)^{2}+\frac{1}{6}(5-3.5)^{2}+\frac{1}{6}(6-3.5)^{2}\right]^{1 / 2} \\
= & 1.71
\end{aligned}
$$

On average then, the throws are 1.71 points off from 3.5.

## Key Points

$0-$ The expectation value is obtained by summing the possible values times their probabilities.
$0-$ To get the standard deviation, first find the average square deviation from the expectation value, then take a square root of that.

### 4.4.2 Statistics of quantum operators

The expectation values of the operators of quantum mechanics are defined in the same way as those for the die.

Consider an arbitrary physical quantity, call it $a$, and assume it has an associated operator $A$. For example, if the physical quantity $a$ is the total energy $E, A$ will be the Hamiltonian $H$.

The equivalent of the face values of the die are the values that the quantity $a$ can take, and according to the orthodox interpretation, that are the eigenvalues

$$
a_{1}, a_{2}, a_{3}, \ldots
$$

of the operator $A$.
Next, the probabilities of getting those values are according to quantum mechanics the square magnitudes of the coefficients when the wave function is written in terms of the eigenfunctions of $A$. In other words, if $\alpha_{1}, \alpha_{2}, \alpha_{3}, \ldots$ are the eigenfunctions of operator $A$, and the wave function is

$$
\Psi=c_{1} \alpha_{1}+c_{2} \alpha_{2}+c_{3} \alpha_{3}+\ldots
$$

then $\left|c_{1}\right|^{2}$ is the probability of value $a_{1},\left|c_{2}\right|^{2}$ the probability of value $a_{2}$, etcetera.
The expectation value is written as $\langle a\rangle$, or as $\langle A\rangle$, whatever is more appealing. Like for the die, it is found as the sum of the probability of each value times the value:

$$
\langle a\rangle=\left|c_{1}\right|^{2} a_{1}+\left|c_{2}\right|^{2} a_{2}+\left|c_{3}\right|^{2} a_{3}+\ldots
$$

Of course, the eigenfunctions might be numbered using multiple indices; that does not really make a difference. For example, the eigenfunctions $\psi_{n l m}$ of the hydrogen atom are numbered with three indices. In that case, if the wave function of the hydrogen atom is

$$
\Psi=c_{100} \psi_{100}+c_{200} \psi_{200}+c_{210} \psi_{210}+c_{211} \psi_{211}+c_{21-1} \psi_{21-1}+c_{300} \psi_{300}+\ldots
$$

then the expectation value for energy will be, noting that $E_{1}=-13.6 \mathrm{eV}, E_{2}$ $=-3.4 \mathrm{eV}, \ldots$ :

$$
\langle E\rangle=-\left|c_{100}\right|^{2} 13.6 \mathrm{eV}-\left|c_{200}\right|^{2} 3.4 \mathrm{eV}-\left|c_{210}\right|^{2} 3.4 \mathrm{eV}-\left|c_{211}\right|^{2} 3.4 \mathrm{eV}-\ldots
$$

Also, the expectation value of the square angular momentum will be, recalling that its eigenvalues are $l(l+1) \hbar^{2}$,

$$
\left\langle L^{2}\right\rangle=\left|c_{100}\right|^{2} 0+\left|c_{200}\right|^{2} 0+\left|c_{210}\right|^{2} 2 \hbar^{2}+\left|c_{211}\right|^{2} 2 \hbar^{2}+\left|c_{21-1}\right|^{2} 2 \hbar^{2}+\left|c_{300}\right|^{2} 0+\ldots
$$

Also, the expectation value of the $z$-component of angular momentum will be, recalling that its eigenvalues are $m \hbar$,

$$
\left\langle L_{z}\right\rangle=\left|c_{100}\right|^{2} 0+\left|c_{200}\right|^{2} 0+\left|c_{210}\right|^{2} 0+\left|c_{211}\right|^{2} \hbar-\left|c_{21-1}\right|^{2} \hbar+\left|c_{300}\right|^{2} 0+\ldots
$$

## Key Points

$0=$ The expectation value of a physical quantity is found by summing its eigenvalues times the probability of measuring that eigenvalue.
$0-$ To find the probabilities of the eigenvalues, the wave function $\Psi$ can be written in terms of the eigenfunctions of the physical quantity. The probabilities will be the square magnitudes of the coefficients of the eigenfunctions.

### 4.4.3 Simplified expressions

The procedure described in the previous section to find the expectation value of a quantity is unwieldy: it requires that first the eigenfunctions of the quantity are found, and next that the wave function is written in terms of those eigenfunctions. There is a quicker way.

Assume that you want to find the expectation value, $\langle a\rangle$ or $\langle A\rangle$, of some quantity $a$ with associated operator $A$. The simpler way to do it is as an inner product:

$$
\begin{equation*}
\langle A\rangle=\langle\Psi| A|\Psi\rangle . \tag{4.43}
\end{equation*}
$$

(Recall that $\langle\Psi| A|\Psi\rangle$ is just the inner product $\langle\Psi \mid A \Psi\rangle$; the additional separating bar is often visually convenient, though.) This formula for the expectation value is easily remembered as "leaving out $\Psi$ " from the inner product bracket. The reason that $\langle\Psi| A|\Psi\rangle$ works for getting the expectation value is given in derivation $\{$ D. 17$\}$.

The simplified expression for the expectation value can also be used to find the standard deviation, $\sigma_{A}$ or $\sigma_{a}$ :

$$
\begin{equation*}
\sigma_{A}=\sqrt{\left\langle(A-\langle A\rangle)^{2}\right\rangle} \tag{4.44}
\end{equation*}
$$

where $\left\langle(A-\langle A\rangle)^{2}\right\rangle$ is the inner product $\left\langle\Psi \mid(A-\langle A\rangle)^{2} \Psi\right\rangle$.

## Key Points

$0-$ The expectation value of a quantity $a$ with operator $A$ can be found as $\langle A\rangle=\langle\Psi \mid A \Psi\rangle$.

- Similarly, the standard deviation can be found using the expression $\sigma_{A}=\sqrt{\left\langle(A-\langle A\rangle)^{2}\right\rangle}$.

### 4.4.3 Review Questions

1. The $2 \mathrm{p}_{x}$ pointer state of the hydrogen atom was defined as

$$
\frac{1}{\sqrt{2}}\left(-\psi_{211}+\psi_{21-1}\right)
$$

where both $\psi_{211}$ and $\psi_{21-1}$ are eigenfunctions of the total energy Hamiltonian $H$ with eigenvalue $E_{2}$ and of square angular momentum $\widehat{L}^{2}$ with eigenvalue $2 \hbar^{2}$; however, $\psi_{211}$ is an eigenfunction of $z$ angular momentum $\widehat{L}_{z}$ with eigenvalue $\hbar$, while $\psi_{21-1}$ is one with eigenvalue $-\hbar$. Evaluate the expectation values of energy, square angular momentum, and $z$ angular momentum in the $2 \mathrm{p}_{x}$ state using inner products. (Of course, since $2 \mathrm{p}_{x}$ is already written out in terms of the eigenfunctions, there is no simplification in this case.)

## Solution esdb2-a

2. Continuing the previous question, evaluate the standard deviations in energy, square angular momentum, and $z$ angular momentum in the $2 \mathrm{p}_{x}$ state using inner products.
Solution esdb2-b

### 4.4.4 Some examples

This section gives some examples of expectation values and standard deviations for known wave functions.

First consider the expectation value of the energy of the hydrogen atom in its ground state $\psi_{100}$. The ground state is an energy eigenfunction with the lowest possible energy level $E_{1}=-13.6 \mathrm{eV}$ as eigenvalue. So, according to the orthodox interpretation, energy measurements of the ground state can only return the value $E_{1}$, with $100 \%$ certainty.

Clearly, if all measurements return the value $E_{1}$, then the average value must be that value too. So the expectation value $\langle E\rangle$ should be $E_{1}$. In addition, the measurements will never deviate from the value $E_{1}$, so the standard deviation $\sigma_{E}$ should be zero.

It is instructive to check those conclusions using the simplified expressions for expectation values and standard deviations from the previous subsection. The expectation value can be found as:

$$
\langle E\rangle=\langle H\rangle=\langle\Psi| H|\Psi\rangle
$$

In the ground state

$$
\Psi=c_{100} \psi_{100}
$$

where $c_{100}$ is a constant of magnitude one, and $\psi_{100}$ is the ground state eigenfunction of the Hamiltonian $H$ with the lowest eigenvalue $E_{1}$. Substituting this $\Psi$, the expectation value of the energy becomes

$$
\langle E\rangle=\left\langle c_{100} \psi_{100} \mid H c_{100} \psi_{100}\right\rangle=c_{100}^{*} c_{100}\left\langle\psi_{100} \mid E_{1} \psi_{100}\right\rangle=c_{100}^{*} c_{100} E_{1}\left\langle\psi_{100} \mid \psi_{100}\right\rangle
$$

since $H \psi_{100}=E_{1} \psi_{100}$ by the definition of eigenfunction. Note that constants come out of the inner product bra as their complex conjugate, but unchanged out of the ket. The final expression shows that $\langle E\rangle=E_{1}$ as it should, since $c_{100}$ has magnitude one, while $\left\langle\psi_{100} \mid \psi_{100}\right\rangle=1$ because proper eigenfunctions are normalized to one. So the expectation value checks out OK.

The standard deviation

$$
\sigma_{E}=\sqrt{\left\langle(H-\langle E\rangle)^{2}\right\rangle}
$$

checks out OK too:

$$
\sigma_{E}=\sqrt{\left\langle\psi_{100} \mid\left(H-E_{1}\right)^{2} \psi_{100}\right\rangle}
$$

and since $H \psi_{100}=E_{1} \psi_{100}$, you have that $\left(H-E_{1}\right) \psi_{100}$ is zero, so $\sigma_{E}$ is zero as it should be.

In general,
If the wave function is an eigenfunction of the measured variable, the expectation value will be the eigenvalue, and the standard deviation will be zero.
To get uncertainty, in other words, a nonzero standard deviation, the wave function should not be an eigenfunction of the quantity being measured.

For example, the ground state of the hydrogen atom is an energy eigenfunction, but not an eigenfunction of the position operators. The expectation value for the position coordinate $x$ can still be found as an inner product:

$$
\langle x\rangle=\left\langle\psi_{100} \mid \widehat{x} \psi_{100}\right\rangle=\iiint x\left|\psi_{100}\right|^{2} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z
$$

This integral is zero. The reason is that $\left|\psi_{100}\right|^{2}$, shown as grey scale in figure 4.9, is symmetric around $x=0$; it has the same value at a negative value of $x$ as at the corresponding positive value. Since the factor $x$ in the integrand changes sign, integration values at negative $x$ cancel out against those at positive $x$. So $\langle x\rangle=0$.

The position coordinates $y$ and $z$ go the same way, and it follows that the expectation value of position is at $(x, y, z)=(0,0,0)$; the expectation position of the electron is in nucleus.

In fact, all basic energy eigenfunctions $\psi_{n l m}$ of the hydrogen atom, like figures 4.9, 4.10, 4.11, 4.12, as well as the combination states $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ of figure 4.13, have a symmetric probability distribution, and all have the expectation value of
position in the nucleus. (For the hybrid states discussed later, that is no longer true.)

But don't really expect to ever find the electron in the negligible small nucleus! You will find it at locations that are on average one standard deviation away from it. For example, in the ground state

$$
\sigma_{x}=\sqrt{\left\langle(x-\langle x\rangle)^{2}\right\rangle}=\sqrt{\left\langle x^{2}\right\rangle}=\sqrt{\iiint x^{2}\left|\psi_{100}(x, y, z)\right|^{2} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z}
$$

which is positive since the integrand is everywhere positive. So, the results of $x$-position measurements are uncertain, even though they average out to the nominal position $x=0$. The negative experimental results for $x$ average away against the positive ones. The same is true in the $y$ and $z$ directions. Thus the expectation position becomes the nucleus even though the electron will really never be found there.

If you actually do the integral above, (it is not difficult in spherical coordinates,) you find that the standard deviation in $x$ equals the Bohr radius. So on average, the electron will be found at an $x$-distance equal to the Bohr radius away from the nucleus. Similar deviations will occur in the $y$ and $z$ directions.

The expectation value of linear momentum in the ground state can be found from the linear momentum operator $\widehat{p}_{x}=\hbar \partial / \mathrm{i} \partial x$ :

$$
\left\langle p_{x}\right\rangle=\left\langle\psi_{100} \mid \widehat{p}_{x} \psi_{100}\right\rangle=\iiint \psi_{100} \frac{\hbar}{\mathrm{i}} \frac{\partial \psi_{100}}{\partial x} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z=\frac{\hbar}{\mathrm{i}} \iiint \frac{\partial \frac{1}{2} \psi_{100}^{2}}{\partial x} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z
$$

This is again zero, since differentiation turns a symmetric function into an antisymmetric one, one which changes sign between negative and corresponding positive positions. Alternatively, just perform integration with respect to x , noting that the wave function is zero at infinity.

More generally, the expectation value for linear momentum is zero for all the energy eigenfunctions; that is a consequence of Ehrenfest's theorem covered in chapter 7.2.1. The standard deviations are again nonzero, so that linear momentum is uncertain like position is.

All these observations carry over in the same way to the eigenfunctions $\psi_{n_{x} n_{y} n_{z}}$ of the harmonic oscillator. They too all have the expectation values of position at the origin, in other words in the nucleus, and the expectation linear momenta equal to zero.

If combinations of energy eigenfunctions are considered, it changes. Such combinations may have nontrivial expectation positions and linear momenta. A discussion will have to wait until chapter 7 .

## Key Points

$0=$ Examples of definite and uncertain quantities were given for example wave functions.
$0-$ A quantity has a definite value when the wave function is an eigenfunction of the operator corresponding to that quantity.

### 4.5 The Commutator

As the previous section discussed, the standard deviation $\sigma$ is a measure of the uncertainty of a property of a quantum system. The larger the standard deviation, the farther typical measurements stray from the expected average value. Quantum mechanics often requires a minimum amount of uncertainty when more than one quantity is involved, like position and linear momentum in Heisenberg's uncertainty principle. In general, this amount of uncertainty is related to an important mathematical object called the "commutator", to be discussed in this section.

### 4.5.1 Commuting operators

First, note that there is no fundamental reason why several quantities cannot have a definite value at the same time. For example, if the electron of the hydrogen atom is in a $\psi_{n l m}$ eigenstate, its total energy, square angular momentum, and $z$-component of angular momentum all have definite values, with zero uncertainty.

More generally, two different quantities with operators $A$ and $B$ have definite values if the wave function is an eigenfunction of both $A$ and $B$. So, the question whether two quantities can be definite at the same time is really whether their operators $A$ and $B$ have common eigenfunctions. And it turns out that the answer has to do with whether these operators "commute", in other words, on whether their order can be reversed as in $A B=B A$.

In particular, $\{D .18\}$ :
Iff two Hermitian operators commute, there is a complete set of eigenfunctions that is common to them both.
(For more than two operators, each operator has to commute with all others.)
For example, the operators $H_{x}$ and $H_{y}$ of the harmonic oscillator of chapter 4.1.2 commute:

$$
\begin{aligned}
H_{x} H_{y} \Psi & =\left[-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial x^{2}}+\frac{1}{2} c x^{2}\right]\left[-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial y^{2}}+\frac{1}{2} c y^{2}\right] \Psi \\
& =\left(\frac{\hbar^{2}}{2 m}\right)^{2} \frac{\partial^{4} \Psi}{\partial x^{2} \partial y^{2}}-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \frac{1}{2} c y^{2} \Psi}{\partial x^{2}}-\frac{1}{2} c x^{2} \frac{\hbar^{2}}{2 m} \frac{\partial^{2} \Psi}{\partial y^{2}}+\frac{1}{2} c x^{2} \frac{1}{2} c y^{2} \Psi \\
& =H_{y} H_{x} \Psi
\end{aligned}
$$

This is true since it makes no difference whether you differentiate $\Psi$ first with respect to $x$ and then with respect to $y$ or vice versa, and since the $\frac{1}{2} c y^{2}$ can be pulled in front of the $x$-differentiations and the $\frac{1}{2} c x^{2}$ can be pushed inside the $y$-differentiations, and since multiplications can always be done in any order.

The same way, $H_{z}$ commutes with $H_{x}$ and $H_{y}$, and that means that $H$ commutes with them all, since $H$ is just their sum. So, these four operators should have a common set of eigenfunctions, and they do: it is the set of eigenfunctions $\psi_{n_{x} n_{y} n_{z}}$ derived in chapter 4.1.2.

Similarly, for the hydrogen atom, the total energy Hamiltonian $H$, the square angular momentum operator $\widehat{L}^{2}$ and the $z$-component of angular momentum $\widehat{L}_{z}$ all commute, and they have the common set of eigenfunctions $\psi_{n l m}$.

Note that such eigenfunctions are not necessarily the only game in town. As a counter-example, for the hydrogen atom $H, \widehat{L}^{2}$, and the $x$-component of angular momentum $\widehat{L}_{x}$ also all commute, and they too have a common set of eigenfunctions. But that will not be the $\psi_{n l m}$, since $\widehat{L}_{x}$ and $\widehat{L}_{z}$ do not commute (It will however be the $\psi_{n l m}$ after you rotate them all 90 degrees around the $y$ axis.) It would certainly be simpler mathematically if each operator had just one unique set of eigenfunctions, but nature does not cooperate.

## Key Points

$0=$ Operators commute if you can change their order, as in $A B=B A$.
$0=$ For commuting operators, a common set of eigenfunctions exists.
$0-$ For those eigenfunctions, the physical quantities corresponding to the commuting operators all have definite values at the same time.

### 4.5.1 Review Questions

1. The pointer state

$$
2 \mathrm{p}_{x}=\frac{1}{\sqrt{2}}\left(-\psi_{211}+\psi_{21-1}\right)
$$

is one of the eigenstates that $H, \widehat{L}^{2}$, and $\widehat{L}_{x}$ have in common. Check that it is not an eigenstate that $H, \widehat{L}^{2}$, and $\widehat{L}_{z}$ have in common.

Solution commutea-a

### 4.5.2 Noncommuting operators and their commutator

Two quantities with operators that do not commute cannot in general have definite values at the same time. If one has a definite value, the other is in general uncertain.

The qualification "in general" is needed because there may be exceptions. The angular momentum operators do not commute, but it is still possible for the angular momentum to be zero in all three directions. But as soon as the
angular momentum in any direction is nonzero, only one component of angular momentum can have a definite value.

A measure for the amount to which two operators $A$ and $B$ do not commute is the difference between $A B$ and $B A$; this difference is called their "commutator" $[A, B]$ :

$$
\begin{equation*}
[A, B] \equiv A B-B A \tag{4.45}
\end{equation*}
$$

A nonzero commutator $[A, B]$ demands a minimum amount of uncertainty in the corresponding quantities $a$ and $b$. It can be shown, \{D.19\}, that the uncertainties, or standard deviations, $\sigma_{a}$ in $a$ and $\sigma_{b}$ in $b$ are at least so large that:

$$
\begin{equation*}
\sigma_{a} \sigma_{b} \geqslant \frac{1}{2}|\langle[A, B]\rangle| \tag{4.46}
\end{equation*}
$$

This equation is called the "generalized uncertainty relationship".

## Key Points

$0-$ The commutator of two operators $A$ and $B$ equals $A B-B A$ and is written as $[A, B]$.
$0-$ The product of the uncertainties in two quantities is at least one half the magnitude of the expectation value of their commutator.

### 4.5.3 The Heisenberg uncertainty relationship

This section will work out the uncertainty relationship (4.46) of the previous subsection for the position and linear momentum in an arbitrary direction. The result will be a precise mathematical statement of the Heisenberg uncertainty principle.

To be specific, the arbitrary direction will be taken as the $x$-axis, so the position operator will be $\widehat{x}$, and the linear momentum operator $\widehat{p}_{x}=\hbar \partial / \mathrm{i} \partial x$. These two operators do not commute, $\widehat{p}_{x} \widehat{x} \Psi$ is simply not the same as $\widehat{x} \widehat{p}_{x} \Psi$ : $\widehat{p}_{x} \widehat{x} \Psi$ means multiply function $\Psi$ by $x$ to get the product function $x \Psi$ and then apply $\widehat{p}_{x}$ on that product, while $\widehat{x} \widehat{p}_{x} \Psi$ means apply $\widehat{p}_{x}$ on $\Psi$ and then multiply the resulting function by $x$. The difference is found from writing it out:

$$
\widehat{p}_{x} \widehat{x} \Psi=\frac{\hbar}{\mathrm{i}} \frac{\partial x \Psi}{\partial x}=\frac{\hbar}{\mathrm{i}} \Psi+\frac{\hbar}{\mathrm{i}} x \frac{\partial \Psi}{\partial x}=-\mathrm{i} \hbar \Psi+\widehat{x} \widehat{p}_{x} \Psi
$$

the second equality resulting from differentiating out the product.
Comparing start and end shows that the difference between $\widehat{x} \widehat{p}_{x}$ and $\widehat{p}_{x} \widehat{x}$ is not zero, but i$\hbar$. By definition, this difference is their commutator:

$$
\begin{equation*}
\left[\widehat{x}, \widehat{p}_{x}\right]=\mathrm{i} \hbar \tag{4.47}
\end{equation*}
$$

This important result is called the "canonical commutation relation." The commutator of position and linear momentum in the same direction is the nonzero constant i $\hbar$.

Because the commutator is nonzero, there must be nonzero uncertainty involved. Indeed, the generalized uncertainty relationship of the previous subsection becomes in this case:

$$
\begin{equation*}
\sigma_{x} \sigma_{p_{x}} \geqslant \frac{1}{2} \hbar \tag{4.48}
\end{equation*}
$$

This is the uncertainty relationship as first formulated by Heisenberg.
It implies that when the uncertainty in position $\sigma_{x}$ is narrowed down to zero, the uncertainty in momentum $\sigma_{p_{x}}$ must become infinite to keep their product nonzero, and vice versa. More generally, you can narrow down the position of a particle and you can narrow down its momentum. But you can never reduce the product of the uncertainties $\sigma_{x}$ and $\sigma_{p_{x}}$ below $\frac{1}{2} \hbar$, whatever you do.

It should be noted that the uncertainty relationship is often written as $\Delta p_{x} \Delta x \geqslant \frac{1}{2} \hbar$ or even as $\Delta p_{x} \Delta x \approx \hbar$ where $\Delta p$ and $\Delta x$ are taken to be vaguely described "uncertainties" in momentum and position, rather than rigorously defined standard deviations. And people write a corresponding uncertainty relationship for time, $\Delta E \Delta t \geqslant \frac{1}{2} \hbar$, because relativity suggests that time should be treated just like space. But note that unlike the linear momentum operator, the Hamiltonian is not at all universal. So, you might guess that the definition of the "uncertainty" $\Delta t$ in time would not be universal either, and you would be right, chapter 7.2.2.

## Key Points

$0-$ The canonical commutator $\left[\widehat{x}, \widehat{p}_{x}\right]$ equals $\mathrm{i} \hbar$.
$0-$ If either the uncertainty in position in a given direction or the uncertainty in linear momentum in that direction is narrowed down to zero, the other uncertainty blows up.
$0=$ The product of the two uncertainties is at least the constant $\frac{1}{2} \hbar$.

### 4.5.4 Commutator reference

It is a fact of life in quantum mechanics that commutators pop up all over the place. Not just in uncertainty relations, but also in the time evolution of expectation values, in angular momentum, and in quantum field theory, the advanced
theory of quantum mechanics used in solids and relativistic applications. This section can make your life easier dealing with them. Browse through it to see what is there. Then come back when you need it.

Recall the definition of the commutator $[A, B]$ of any two operators $A$ and B:

$$
\begin{equation*}
[A, B]=A B-B A \tag{4.49}
\end{equation*}
$$

By this very definition, the commutator is zero for any two operators $A_{1}$ and $A_{2}$ that commute, (whose order can be interchanged):

$$
\begin{equation*}
\left[A_{1}, A_{2}\right]=0 \quad \text { if } A_{1} \text { and } A_{2} \text { commute; } A_{1} A_{2}=A_{2} A_{1} \tag{4.50}
\end{equation*}
$$

If operators all commute, all their products commute too:

$$
\begin{equation*}
\left[A_{1} A_{2} \ldots A_{k}, A_{k+1} \ldots A_{n}\right]=0 \quad \text { if } A_{1}, A_{2}, \ldots, A_{k}, A_{k+1}, \ldots, A_{n} \text { all commute. } \tag{4.51}
\end{equation*}
$$

Everything commutes with itself, of course:

$$
\begin{equation*}
[A, A]=0 \tag{4.52}
\end{equation*}
$$

and everything commutes with a numerical constant; if $A$ is an operator and $a$ is some number, then:

$$
\begin{equation*}
[A, a]=[a, A]=0 \tag{4.53}
\end{equation*}
$$

The commutator is "antisymmetric"; or in simpler words, if you interchange the sides; it will change the sign, $\{$ D. 20$\}$ :

$$
\begin{equation*}
[B, A]=-[A, B] \tag{4.54}
\end{equation*}
$$

For the rest however, linear combinations multiply out just like you would expect:

$$
\begin{equation*}
[a A+b B, c C+d D]=a c[A, C]+a d[A, D]+b c[B, C]+b d[B, D] \tag{4.55}
\end{equation*}
$$

(in which it is assumed that $A, B, C$, and $D$ are operators, and $a, b, c$, and $d$ numerical constants.)

To deal with commutators that involve products of operators, the rule to remember is: "the first factor comes out at the front of the commutator, the second at the back". More precisely:

$$
\begin{equation*}
[A \underbrace{B, \ldots]}=A[B, \ldots]+[A, \ldots] B, \quad \xrightarrow{[\ldots, A B]}=A[\ldots, B]+[\ldots, A] B . \tag{4.56}
\end{equation*}
$$

So, if $A$ or $B$ commutes with the other side of the operator, it can simply be taken out at at its side; (the second commutator will be zero.) For example,

$$
\left[A_{1} B, A_{2}\right]=A_{1}\left[B, A_{2}\right], \quad\left[B A_{1}, A_{2}\right]=\left[B, A_{2}\right] A_{1}
$$

if $A_{1}$ and $A_{2}$ commute.
Now from the general to the specific. Because changing sides in a commutator merely changes its sign, from here on only one of the two possibilities will be shown. First the position operators all mutually commute:

$$
\begin{equation*}
[\widehat{x}, \widehat{y}]=[\widehat{y}, \widehat{z}]=[\widehat{z}, \widehat{x}]=0 \tag{4.57}
\end{equation*}
$$

as do position-dependent operators such as a potential energy $V(x, y, z)$ :

$$
\begin{equation*}
[\widehat{x}, V(x, y, z)]=[\widehat{y}, V(x, y, z)]=[\widehat{z}, V(x, y, z)]=0 \tag{4.58}
\end{equation*}
$$

This illustrates that if a set of operators all commute, then all combinations of those operators commute too.

The linear momentum operators all mutually commute:

$$
\begin{equation*}
\left[\widehat{p}_{x}, \widehat{p}_{y}\right]=\left[\widehat{p}_{y}, \widehat{p}_{z}\right]=\left[\widehat{p}_{z}, \widehat{p}_{x}\right]=0 \tag{4.59}
\end{equation*}
$$

However, position operators and linear momentum operators in the same direction do not commute; instead:

$$
\begin{equation*}
\left[\widehat{x}, \widehat{p}_{x}\right]=\left[\widehat{y}, \widehat{p}_{y}\right]=\left[\widehat{z}, \widehat{p}_{z}\right]=\mathrm{i} \hbar \tag{4.60}
\end{equation*}
$$

As seen in the previous subsection, this lack of commutation causes the Heisenberg uncertainty principle. Position and linear momentum operators in different directions do commute:

$$
\begin{equation*}
\left[\widehat{x}, \widehat{p}_{y}\right]=\left[\widehat{x}, \widehat{p}_{z}\right]=\left[\widehat{y}, \widehat{p}_{z}\right]=\left[\widehat{y}, \widehat{p}_{x}\right]=\left[\widehat{z}, \widehat{p}_{x}\right]=\left[\widehat{z}, \widehat{p}_{y}\right]=0 \tag{4.61}
\end{equation*}
$$

A generalization that is frequently very helpful is:

$$
\begin{equation*}
\left[f, \widehat{p}_{x}\right]=\mathrm{i} \hbar \frac{\partial f}{\partial x} \quad\left[f, \widehat{p}_{y}\right]=\mathrm{i} \hbar \frac{\partial f}{\partial y} \quad\left[f, \widehat{p}_{z}\right]=\mathrm{i} \hbar \frac{\partial f}{\partial z} \tag{4.62}
\end{equation*}
$$

where $f$ is any function of $x, y$, and $z$.
Unlike linear momentum operators, angular momentum operators do not mutually commute. The commutators are given by the so-called "fundamental commutation relations:"

$$
\begin{equation*}
\left[\widehat{L}_{x}, \widehat{L}_{y}\right]=\mathrm{i} \hbar \widehat{L}_{z} \quad\left[\widehat{L}_{y}, \widehat{L}_{z}\right]=\mathrm{i} \hbar \widehat{L}_{x} \quad\left[\widehat{L}_{z}, \widehat{L}_{x}\right]=\mathrm{i} \hbar \widehat{L}_{y} \tag{4.63}
\end{equation*}
$$

Note the $\ldots x y z x y z \ldots$ order of the indices that produces positive signs; a reversed $\ldots z y x z y \ldots$ order adds a minus sign. For example $\left[\widehat{L}_{z}, \widehat{L}_{y}\right]=-\mathrm{i} \hbar \widehat{L}_{x}$ because $y$ following $z$ is in reversed order.

The angular momentum components do all commute with the square angular momentum operator:

$$
\begin{equation*}
\left[\widehat{L}_{x}, \widehat{L}^{2}\right]=\left[\widehat{L}_{y}, \widehat{L}^{2}\right]=\left[\widehat{L}_{z}, \widehat{L}^{2}\right]=0 \quad \text { where } \widehat{L}^{2}=\widehat{L}_{x}^{2}+\widehat{L}_{y}^{2}+\widehat{L}_{z}^{2} \tag{4.64}
\end{equation*}
$$

Just the opposite of the situation for linear momentum, position and angular momentum operators in the same direction commute,

$$
\begin{equation*}
\left[\widehat{x}, \widehat{L}_{x}\right]=\left[\widehat{y}, \widehat{L}_{y}\right]=\left[\widehat{z}, \widehat{L}_{z}\right]=0 \tag{4.65}
\end{equation*}
$$

but those in different directions do not:

$$
\begin{equation*}
\left[\widehat{x}, \widehat{L}_{y}\right]=\left[\widehat{L}_{x}, \widehat{y}\right]=\mathrm{i} \hbar \widehat{z} \quad\left[\widehat{y}, \widehat{L}_{z}\right]=\left[\widehat{L}_{y}, \widehat{z}\right]=\mathrm{i} \hbar \widehat{x} \quad\left[\widehat{z}, \widehat{L}_{x}\right]=\left[\widehat{L}_{z}, \widehat{x}\right]=\mathrm{i} \hbar \widehat{y} \tag{4.66}
\end{equation*}
$$

Square position commutes with all components of angular momentum,

$$
\begin{equation*}
\left[\widehat{r}^{2}, \widehat{L}_{x}\right]=\left[\widehat{r}^{2}, \widehat{L}_{y}\right]=\left[\widehat{r}^{2}, \widehat{L}_{z}\right]=\left[\widehat{r}^{2}, \widehat{L}^{2}\right]=0 \tag{4.67}
\end{equation*}
$$

The commutator between position and square angular momentum is, using vector notation for conciseness,

$$
\begin{equation*}
\left[\widehat{\vec{r}}, \widehat{L}^{2}\right]=-2 \hbar^{2} \widehat{\vec{r}}-2 \mathrm{i} \hbar \widehat{\vec{r}} \times \widehat{\vec{L}}=-2 \hbar^{2} \widehat{\vec{r}}+2 \mathrm{i} \hbar(\widehat{\vec{r}} \cdot \widehat{\vec{r}}) \widehat{\vec{p}}-2 \mathrm{i} \hbar \widehat{\vec{r}}(\widehat{\vec{r}} \cdot \widehat{\vec{p}}) \tag{4.68}
\end{equation*}
$$

The commutators between linear and angular momentum are very similar to the ones between position and angular momentum:

$$
\begin{equation*}
\left[\widehat{p}_{x}, \widehat{L}_{x}\right]=\left[\widehat{p}_{y}, \widehat{L}_{y}\right]=\left[\widehat{p}_{z}, \widehat{L}_{z}\right]=0 \tag{4.69}
\end{equation*}
$$

$$
\begin{gather*}
{\left[\widehat{p}_{x}, \widehat{L}_{y}\right]=\left[\begin{array}{ll}
\left.\widehat{L}_{x}, \widehat{p}_{y}\right]=\mathrm{i} \hbar \widehat{p}_{z} \quad\left[\widehat{p}_{y}, \widehat{L}_{z}\right]=\left[\widehat{L}_{y}, \widehat{p}_{z}\right]=\mathrm{i} \hbar \widehat{p}_{x} \quad\left[\widehat{p}_{z}, \widehat{L}_{x}\right]=\left[\widehat{L}_{z}, \widehat{p}_{x}\right]=\mathrm{i} \hbar \widehat{p}_{y} \\
{\left[\widehat{p}^{2}, \widehat{L}_{x}\right]=\left[\widehat{p}^{2}, \widehat{L}_{y}\right]=\left[\widehat{p}^{2}, \widehat{L}_{z}\right]=\left[\widehat{p}^{2}, \widehat{L}^{2}\right]=0} \\
{\left[\widehat{\vec{p}}, \widehat{L}^{2}\right]=-2 \hbar^{2} \widehat{\vec{p}}-2 \mathrm{i} \hbar \widehat{\vec{p}} \times \widehat{\vec{L}}=2 \hbar^{2} \widehat{\vec{p}}+2 \mathrm{i} \hbar(\widehat{\vec{r}} \cdot \widehat{\vec{p}} \widehat{\vec{p}}-2 \mathrm{i} \hbar \widehat{\vec{r}}(\widehat{\vec{p}} \cdot \widehat{\vec{p}})}
\end{array}, ~(4.72)\right.} \tag{4.70}
\end{gather*}
$$

The following commutators are also useful:

$$
\begin{equation*}
\left[\vec{r} \times \widehat{\vec{L}}, \widehat{L}^{2}\right]=2 \mathrm{i} \hbar \vec{r} \widehat{L}^{2} \quad\left[\left[\vec{r}, \widehat{L}^{2}\right], \widehat{L}^{2}\right]=2 \hbar^{2}\left(\vec{r} \widehat{L}^{2}+\widehat{L}^{2} \vec{r}\right) \tag{4.73}
\end{equation*}
$$

Commutators involving spin are discussed in a later chapter, 5.5.3.

### 4.6 The Hydrogen Molecular Ion

The hydrogen atom studied earlier is where full theoretical analysis stops. Larger systems are just too difficult to solve analytically. Yet, it is often quite possible to understand the solution of such systems using approximate arguments. As an example, this section considers the $\mathrm{H}_{2}^{+}$-ion. This ion consists of two protons and a single electron circling them. It will be shown that a chemical bond forms that holds the ion together. The bond is a "covalent" one, in which the protons share the electron.

The general approach will be to compute the energy of the ion, and to show that the energy is less when the protons are sharing the electron as a molecule than when they are far apart. This must mean that the molecule is stable: energy must be expended to take the protons apart.

The approximate technique to be used to find the state of lowest energy is a basic example of what is called a "variational method."

### 4.6.1 The Hamiltonian

First the Hamiltonian is needed. Since the protons are so much heavier than the electron, to good approximation they can be considered fixed points in the energy computation. That is called the "Born-Oppenheimer approximation". In this approximation, only the Hamiltonian of the electron is needed. It makes things a lot simpler, which is why the Born-Oppenheimer approximation is a common assumption in applications of quantum mechanics.

Compared to the Hamiltonian of the hydrogen atom of section 4.3.1, there are now two terms to the potential energy, the electron experiencing attraction to both protons:

$$
\begin{equation*}
H=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla^{2}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{1}}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{\mathrm{r}}} \tag{4.74}
\end{equation*}
$$

where $r_{1}$ and $r_{\mathrm{r}}$ are the distances from the electron to the left and right protons,

$$
\begin{equation*}
r_{1} \equiv\left|\vec{r}-\vec{r}_{\mathrm{lp}}\right| \quad r_{\mathrm{r}} \equiv\left|\vec{r}-\vec{r}_{\mathrm{rp}}\right| \tag{4.75}
\end{equation*}
$$

with $\vec{r}_{\mathrm{lp}}$ the position of the left proton and $\vec{r}_{\mathrm{rp}}$ that of the right one.
The hydrogen ion in the Born-Oppenheimer approximation can be solved analytically using "prolate spheroidal coordinates." However, approximations will be used here. For one thing, you learn more about the physics that way.

## Key Points

$0-$ The Hamiltonian in the Born-Oppenheimer approximation has been found. It is above.

### 4.6.2 Energy when fully dissociated

The fully dissociated state is when the protons are very far apart and there is no coherent molecule, as in figure 4.14. The best the electron can do under those circumstances is to combine with either proton, say the left one, and form a hydrogen atom in the ground state of lowest energy. In that case the right proton will be alone. According to the solution for the hydrogen atom, the

Figure 4.14: Hydrogen atom plus free proton far apart.
electron loses 13.6 eV of energy by going in the ground state around the left proton. Of course, it would lose the same energy going into the ground state around the right proton, but for now, assume that it is around the left proton.

The wave function describing this state is just the ground state $\psi_{100}$ derived for the hydrogen atom, equation (4.40), but the distance should be measured from the position $\vec{r}_{\text {lp }}$ of the left proton instead of from the origin:

$$
\psi=\psi_{100}\left(\left|\vec{r}-\vec{r}_{\mathrm{lp}}\right|\right)
$$

To shorten the notations, this wave function will be denoted by $\psi_{1}$ :

$$
\begin{equation*}
\psi_{1}(\vec{r}) \equiv \psi_{100}\left(\left|\vec{r}-\vec{r}_{\mathrm{lp}}\right|\right) \tag{4.76}
\end{equation*}
$$

Similarly the wave function that would describe the electron as being in the ground state around the right proton will be denoted as $\psi_{\mathrm{r}}$, with

$$
\begin{equation*}
\psi_{\mathrm{r}}(\vec{r}) \equiv \psi_{100}\left(\left|\vec{r}-\vec{r}_{\mathrm{rp}}\right|\right) \tag{4.77}
\end{equation*}
$$

## Key Points

0- When the protons are far apart, there are two lowest energy states, $\psi_{1}$ and $\psi_{\mathrm{r}}$, in which the electron is in the ground state around the left, respectively right, proton. In either case there is an hydrogen atom plus a free proton.

Figure 4.15: Hydrogen atom plus free proton closer together.

### 4.6.3 Energy when closer together

When the protons get a bit closer to each other, but still well apart, the distance $r_{\mathrm{r}}$ between the electron orbiting the left proton and the right proton decreases, as sketched in figure 4.15. The potential that the electron sees is now not just that of the left proton; the distance $r_{\mathrm{r}}$ is no longer so large that the $-e^{2} / 4 \pi \epsilon_{0} r_{\mathrm{r}}$ potential can be completely neglected.

However, assuming that the right proton stays sufficiently clear of the electron wave function, the distance $r_{\mathrm{r}}$ between electron and right proton can still be averaged out as being the same as the distance $d$ between the two protons. Within that approximation, it simply adds the constant $-e^{2} / 4 \pi \epsilon_{0} d$ to the Hamiltonian of the electron. And adding a constant to a Hamiltonian does not change the eigenfunction; it only changes the eigenvalue, the energy, by that constant. So the ground state $\psi_{1}$ of the left proton remains a good approximation to the lowest energy wave function.

Moreover, the decrease in energy due to the electron/right proton attraction is balanced by an increase in energy of the protons by their mutual repulsion, so the total energy of the ion remains the same. In other words, the right proton is to first approximation neither attracted nor repelled by the neutral hydrogen atom on the left. To second approximation the right proton does change the wave function of the electron a bit, resulting in some attraction, but this effect will be ignored.

So far, it has been assumed that the electron is circling the left proton. But the case that the electron is circling the right proton is of course physically equivalent. In particular the energy must be exactly the same by symmetry.

## Key Points

[^0]
### 4.6.4 States that share the electron

The approximate energy eigenfunction $\psi_{1}$ that describes the electron as being around the left proton has the same energy as the eigenfunction $\psi_{\mathrm{r}}$ that describes the electron as being around the right one. Therefore any linear combination of the two,

$$
\begin{equation*}
\psi=a \psi_{1}+b \psi_{\mathrm{r}} \tag{4.78}
\end{equation*}
$$

is also an eigenfunction with the same energy. In such combinations, the electron is shared by the protons, in ways that depend on the chosen values of $a$ and $b$.

Note that the constants $a$ and $b$ are not independent: the wave function should be normalized, $\langle\psi \mid \psi\rangle=1$. Since $\psi_{1}$ and $\psi_{\mathrm{r}}$ are already normalized, and assuming that $a$ and $b$ are real, this works out to

$$
\begin{equation*}
\left\langle a \psi_{1}+b \psi_{\mathrm{r}} \mid a \psi_{1}+b \psi_{\mathrm{r}}\right\rangle=a^{2}+b^{2}+2 a b\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle=1 \tag{4.79}
\end{equation*}
$$

As a consequence, only the ratio the coefficients $a / b$ can be chosen freely.
A particularly interesting case is the "antisymmetric" one, $b=-a$. As figure 4.16 shows, in this state there is zero probability of finding the electron at the symmetry plane midway in between the protons. The reason is that $\psi_{1}$ and $\psi_{\mathrm{r}}$

Figure 4.16: The electron being antisymmetrically shared.
are equal at the symmetry plane, making their difference zero.
This is actually a quite weird result. You combine two states, in both of which the electron has some probability of being at the symmetry plane, and in the combination the electron has zero probability of being there. The probability of finding the electron at any position, including the symmetry plane, in the first state is given by $\left|\psi_{1}\right|^{2}$. Similarly, the probability of finding the electron in the second state is given by $\left|\psi_{\mathrm{r}}\right|^{2}$. But for the combined state nature does not do the logical thing of adding the two probabilities together to come up with $\frac{1}{2}\left|\psi_{1}\right|^{2}+\frac{1}{2}\left|\psi_{\mathrm{r}}\right|^{2}$.

Instead of adding physically observable probabilities, nature squares the unobservable wave function $a \psi_{1}-a \psi_{\mathrm{r}}$ to find the new probability distribution. The squaring adds a cross term, $-2 a^{2} \psi_{1} \psi_{\mathrm{r}}$, that simply adding probabilities does not have. This term has the physical effect of preventing the electron to be at the symmetry plane, but it does not have a normal physical explanation. There is
no force repelling the electrons from the symmetry plane or anything like that. Yet it looks as if there is one in this state.

The most important combination of $\psi_{1}$ and $\psi_{\mathrm{r}}$ is the "symmetric" one, $b=$ $a$. The approximate wave function then takes the form $a\left(\psi_{1}+\psi_{\mathrm{r}}\right)$. That can be written out fully in terms of the hydrogen ground state wave function as:

$$
\begin{equation*}
\Psi \approx a\left[\psi_{100}\left(\left|\vec{r}-\vec{r}_{\mathrm{lp}}\right|\right)+\psi_{100}\left(\left|\vec{r}-\vec{r}_{\mathrm{rp}}\right|\right)\right] \quad \psi_{100}(r) \equiv \frac{1}{\sqrt{\pi a_{0}^{3}}} e^{-r / a_{0}} \tag{4.80}
\end{equation*}
$$

where $a_{0}=0.53 \AA$ is the Bohr radius and $\vec{r}, \vec{r}_{\mathrm{lp}}$, and $\vec{r}_{\mathrm{rp}}$ are again the position vectors of electron and protons. In this case, there is increased probability for the electron to be at the symmetry plane, as shown in figure 4.17.

Figure 4.17: The electron being symmetrically shared.
A state in which the electron is shared is truly a case of the electron being in two different places at the same time. For if instead of sharing the electron, each proton would be given its own half electron, the expression for the Bohr radius, $a_{0}=4 \pi \epsilon_{0} \hbar^{2} / m_{\mathrm{e}} e^{2}$, shows that the eigenfunctions $\psi_{1}$ and $\psi_{\mathrm{r}}$ would have to blow up in radius by a factor four. (Because of $m_{\mathrm{e}}$ and $e$; the second factor $e$ is the proton charge.) The energy would then reduce by the same factor four. That is simply not what happens. You get the physics of a complete electron being present around each proton with $50 \%$ probability, not the physics of half an electron being present for sure.

## Key Points

$0-$ This subsection brought home the physical weirdness arising from the mathematics of the unobservable wave function.
$0-$ In particular, within the approximations made, there exist states that all have the same ground state energy, but whose physical properties are dramatically different.
0- The protons may "share the electron." In such states there is a probability of finding the electron around either proton.
$0-$ Even if the protons share the electron equally as far as the probability distribution is concerned, different physical states are still possible.

In the symmetric case that the wave functions around the protons have the same sign, there is increased probability of the electron being found in between the protons. In the antisymmetric case of opposite sign, there is decreased probability of the electron being found in between the protons.

### 4.6.5 Comparative energies of the states

The previous two subsections described states of the hydrogen molecular ion in which the electron is around a single proton, as well as states in which it is shared between protons. To the approximations made, all these states have the same energy. Yet, if the expectation energy of the states is more accurately examined, it turns out that increasingly large differences show up when the protons get closer together. The symmetric state has the least energy, the antisymmetric state the highest, and the states where the electron is around a single proton have something in between.

It is not that easy to see physically why the symmetric state has the lowest energy. An argument is often made that in the symmetric case, the electron has increased probability of being in between the protons, where it is most effective in pulling them together. However, actually the potential energy of the symmetric state is higher than for the other states: putting the electron midway in between the two protons means having to pull it away from one of them.

The Feynman lectures on physics, [22], argue instead that in the symmetric case, the electron is somewhat less constrained in position. According to the Heisenberg uncertainty relationship, that allows it to have less variation in momentum, hence less kinetic energy. Indeed the symmetric state does have less kinetic energy, but this is almost totally achieved at the cost of a corresponding increase in potential energy, rather than due to a larger area to move in at the same potential energy. And the kinetic energy is not really directly related to available area in any case. The argument is not incorrect, but in what sense it explains, rather than just summarizes, the answer is debatable.

## Key Points

$0-$ The energies of the discussed states are not the same when examined more closely.
$0-$ The symmetric state has the lowest energy, the antisymmetric one the highest.

### 4.6.6 Variational approximation of the ground state

The objective of this subsection is to use the rough approximations of the previous subsections to get some very concrete data on the hydrogen molecular ion.

The idea is simple but powerful: since the true ground state is the state of lowest energy among all wave functions, the best among approximate wave functions is the one with the lowest energy. In the previous subsections, approximations to the ground state were discussed that took the form $a \psi_{1}+b \psi_{\mathrm{r}}$, where $\psi_{1}$ described the state where the electron was in the ground state around the left proton, and $\psi_{\mathrm{r}}$ where it was around the right proton. The wave function of this type with the lowest energy will produce the best possible data on the true ground state, $\{\mathrm{N} .6\}$.

Note that all that can be changed in the approximation $a \psi_{1}+b \psi_{\mathrm{r}}$ to the wave function is the ratio of the coefficients $a / b$, and the distance between the protons $d$. If the ratio $a / b$ is fixed, $a$ and $b$ can be computed from it using the normalization condition (4.79), so there is no freedom to chose them individually. The basic idea is now to search through all possible values of $a / b$ and $d$ until you find the values that give the lowest energy.

This sort of method is called a "variational method" because at the minimum of energy, the derivatives of the energy must be zero. That in turn means that the energy does not vary with infinitesimally small changes in the parameters $a / b$ and $d$.

To find the minimum energy is nothing that an engineering graduate student could not do, but it does take some effort. You cannot find the best values of $a / b$ and $d$ analytically; you have to have a computer find the energy at a lot of values of $d$ and $a / b$ and search through them to find the lowest energy. Or actually, simply having a computer print out a table of values of energy versus $d$ for a few typical values of $a / b$, including $a / b=1$ and $a / b=-1$, and looking at the print-out to see where the energy is most negative works fine too. That is what the numbers below came from.

You do want to evaluate the energy of the approximate states accurately as the expectation value. If you do not find the energy as the expectation value, the results may be less dependable. Fortunately, finding the expectation energy for the given approximate wave functions can be done exactly; the details are in derivation $\{\mathrm{D} .21\}$.

If you actually go through the steps, your print-out should show that the minimum energy occurs when $a=b$, the symmetric state, and at a separation distance between the protons equal to about $1.3 \AA$. This separation distance is called the "bond length". The minimum energy is found to be about 1.8 eV below the energy of -13.6 eV when the protons are far apart. So it will take at least 1.8 eV to take the ground state with the protons at a distance of 1.3 $\AA$ completely apart into well separated protons. For that reason, the 1.8 eV is
called the "binding energy".

## Key Points

$0-$ The best approximation to the ground state using approximate wave functions is the one with the lowest energy.
$0-$ Making such an approximation is called a variational method.
0- The energy should be evaluated as the expectation value of the Hamiltonian.
$0-$ Using combinations of $\psi_{1}$ and $\psi_{\mathrm{r}}$ as approximate wave functions, the approximate ground state turns out to be the one in which the electron is symmetrically shared between the protons.
$0-$ The binding energy is the energy required to take the molecule apart.
$0-$ The bond length is the distance between the nuclei.

### 4.6.6 Review Questions

1. The solution for the hydrogen molecular ion requires elaborate evaluations of inner product integrals and a computer evaluation of the state of lowest energy. As a much simpler example, you can try out the variational method on the one-dimensional case of a particle stuck inside a pipe, as discussed in chapter 3.5. Take the approximate wave function to be:

$$
\psi=a x(\ell-x)
$$

Find $a$ from the normalization requirement that the total probability of finding the particle integrated over all possible $x$ positions is one. Then evaluate the energy $\langle E\rangle$ as $\langle\psi| H|\psi\rangle$, where according to chapter 3.5.3, the Hamiltonian is

$$
H=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial x^{2}}
$$

Compare the ground state energy with the exact value,

$$
E_{1}=\hbar^{2} \pi^{2} / 2 m \ell^{2}
$$

(Hints: $\int_{0}^{\ell} x(\ell-x) \mathrm{d} x=\ell^{3} / 6$ and $\left.\int_{0}^{\ell} x^{2}(\ell-x)^{2} \mathrm{~d} x=\ell^{5} / 30\right)$
Solution hione-a

### 4.6.7 Comparison with the exact ground state

The variational solution derived in the previous subsection is only a crude approximation of the true ground state of the hydrogen molecular ion. In particular, the assumption that the molecular wave function can be approximated using the individual atom ground states is only valid when the protons are far apart, and is inaccurate if they are $1.3 \AA$ apart, as the solution says they are.

Yet, for such a poor wave function, the main results are surprisingly good. For one thing, it leaves no doubt that a bound state really exists. The reason is that the true ground state must always have a lower energy than any approximate one. So, the binding energy must be at least the 1.8 eV predicted by the approximation.

In fact, the experimental binding energy is 2.8 eV . The found approximate value is only a third less, pretty good for such a simplistic assumption for the wave function. It is really even better than that, since a fair comparison requires the absolute energies to be compared, rather than just the binding energy; the approximate solution has -15.4 eV , rather than -16.4 . This high accuracy for the energy using only marginal wave functions is one of the advantages of variational methods $\{\mathrm{A} .7\}$.

The estimated bond length is not too bad either; experimentally the protons are $1.06 \AA$ apart instead of $1.3 \AA$. (The analytical solution using spheroidal coordinates mentioned earlier gives 2.79 eV and $1.06 \AA$, in good agreement with the experimental values. But even that solution is not really exact: the electron does not bind the nuclei together rigidly, but more like a spring force. As a result, the nuclei behave like a harmonic oscillator around their common center of gravity. Even in the ground state, they will retain some uncertainty around the $1.06 \AA$ position of minimal energy, and a corresponding small amount of additional molecular kinetic and potential energy. The improved Born-Oppenheimer approximation of chapter 9.2.3 can be used to compute such effects.)

The qualitative properties of the approximate wave function are correct. For example, it can be seen that the exact ground state wave function must be real and positive $\{$ A. 8$\}$; the approximate wave function is real and positive too.

It can also be seen that the exact ground state must be symmetric around the symmetry plane midway between the protons, and rotationally symmetric around the line connecting the protons, $\{\mathrm{A} .9\}$. The approximate wave function has both those properties too.

Incidentally, the fact that the ground state wave function must be real and positive is a much more solid reason that the protons must share the electron symmetrically than the physical arguments given in subsection 4.6.5, even though it is more mathematical.

## Key Points

$0=$ The obtained approximate ground state is pretty good.
$0-$ The protons really share the electron symmetrically in the ground state.

## Multiple-Particle Systems

#### Abstract

\section*{Abstract}

So far, only wave functions for single particles have been discussed. This chapter explains how the ideas generalize to more particles. The basic idea is simple: you just keep adding more and more arguments to your wave function. That simple idea will immediately be used to derive a solution for the hydrogen molecule. The chemical bond that keeps the molecule together is a two-electron one. It involves sharing the two electrons in a very weird way that can only be described in quantum terms. Now it turns out that usually chemical bonds involve the sharing of two electrons like in the hydrogen molecule, not just one as in the hydrogen molecular ion. To understand the reason, simple approximate systems will be examined that have no more than two different states. It will then be seen that sharing lowers the energy due to "twilight" terms. These are usually more effective for two-electron bonds than for single electron-ones.

Before systems with more than two electrons can be discussed, a different issue must be addressed first. Electrons, as well as most other quantum particles, have intrinsic angular momentum called "spin". It is quantized much like orbital angular momentum. Electrons can either have spin angular momentum $\frac{1}{2} \hbar$ or $-\frac{1}{2} \hbar$ in a given direction. It is said that the electron has spin $1 / 2$. Photons can have angular momentum $\hbar, 0$, or $-\hbar$ in a given direction and have spin 1. Particles with half-integer spin like electrons are called fermions. Particles with integer spin like photons are called bosons. For quantum mechanics there are two consequences. First, it means that spin must be added to the wave function as an uncertain quantity in addition to position. That can be done in various equivalent ways. Second, it turns out that there are requirements on the wave function depending on whether particles are bosons or fermions. In particular, wave func-

tions must stay the same if two identical bosons, say two photons, are interchanged. Wave functions must change sign when any two electrons, or any other two identical fermions, are interchanged.
This so-called antisymmetrization requirement is usually not such a big deal for two electron systems. Two electrons can satisfy the requirement by assuming a suitable combined spin state. However, for more than two electrons, the effects of the antisymmetrization requirement are dramatic. They determine the very nature of the chemical elements beyond helium. Without the antisymmetrization requirements on the electrons, chemistry would be something completely different. And therefore, so would all of nature be. Before that can be properly understood, first a better look is needed at the ways in which the symmetrization requirements can be satisfied. It is then seen that the requirement for fermions can be formulated as the so-called Pauli exclusion principle. The principle says that any number $I$ of identical fermions must occupy $I$ different quantum states. Fermions are excluded from entering the same quantum state.
At that point, the atoms heavier than hydrogen can be properly discussed. It can also be explained why atoms prevent each other from coming too close. Finally, the derived quantum properties of the atoms are used to describe the various types of chemical bonds.

### 5.1 Wave Function for Multiple Particles

While a single particle is described by a wave function $\Psi(\vec{r} ; t)$, a system of two particles, call them 1 and 2 , is described by a wave function

$$
\begin{equation*}
\Psi\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) \tag{5.1}
\end{equation*}
$$

depending on both particle positions. The value of $\left|\Psi\left(\vec{r}_{1}, \vec{r}_{2} ; t\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}$ gives the probability of simultaneously finding particle 1 within a vicinity $\mathrm{d}^{3} \vec{r}_{1}$ of $\vec{r}_{1}$ and particle 2 within a vicinity $\mathrm{d}^{3} \vec{r}_{2}$ of $\vec{r}_{2}$.

The wave function must be normalized to express that the electrons must be somewhere:

$$
\begin{equation*}
\langle\Psi \mid \Psi\rangle_{6}=\iint\left|\Psi\left(\vec{r}_{1}, \vec{r}_{2} ; t\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}=1 \tag{5.2}
\end{equation*}
$$

where the subscript 6 of the inner product is just a reminder that the integration is over all six scalar position coordinates of $\Psi$.

The underlying idea of increasing system size is "every possible combination:" allow for every possible combination of state for particle 1 and state for particle 2. For example, in one dimension, all possible $x$ positions of particle 1 geometrically form an $x_{1}$-axis. Similarly all possible $x$ positions of particle 2 form an $x_{2}$-axis. If every possible position $x_{1}$ is separately combined with every
possible position $x_{2}$, the result is an $x_{1}, x_{2}$-plane of possible positions of the combined system.

Similarly, in three dimensions the three-dimensional space of positions $\vec{r}_{1}$ combines with the three-dimensional space of positions $\vec{r}_{2}$ into a six-dimensional space having all possible combinations of values for $\vec{r}_{1}$ with all possible values for $\vec{r}_{2}$.

The increase in the number of dimensions when the system size increases is a major practical problem for quantum mechanics. For example, a single arsenic atom has 33 electrons, and each electron has 3 position coordinates. It follows that the wave function is a function of 99 scalar variables. (Not even counting the nucleus, spin, etcetera.) In a brute-force numerical solution of the wave function, maybe you could restrict each position coordinate to only ten computational values, if no very high accuracy is desired. Even then, $\Psi$ values at $10^{99}$ different combined positions must be stored, requiring maybe $10^{91}$ Gigabytes of storage. To do a single multiplication on each of those those numbers within a few years would require a computer with a speed of $10^{82}$ gigaflops. No need to take any of that arsenic to be long dead before an answer is obtained. (Imagine what it would take to compute a microgram of arsenic instead of an atom.) Obviously, more clever numerical procedures are needed.

Sometimes the problem size can be reduced. In particular, the problem for a two-particle system like the proton-electron hydrogen atom can be reduced to that of a single particle using the concept of reduced mass. That is shown in addendum $\{$ A. 5$\}$.

## Key Points

0- To describe multiple-particle systems, just keep adding more independent variables to the wave function.
$0-$ Unfortunately, this makes many-particle problems impossible to solve by brute force.

### 5.1 Review Questions

1. A simple form that a six-dimensional wave function can take is a product of two three-dimensional ones, as in $\psi\left(\vec{r}_{1}, \vec{r}_{2}\right)=\psi_{1}\left(\vec{r}_{1}\right) \psi_{2}\left(\vec{r}_{2}\right)$. Show that if $\psi_{1}$ and $\psi_{2}$ are normalized, then so is $\psi$.

Solution complex-a
2. Show that for a simple product wave function as in the previous question, the relative probabilities of finding particle 1 near a position $\vec{r}_{a}$ versus finding it near another position $\vec{r}_{b}$ is the same regardless where particle 2 is. (Or rather, where particle 2 is likely to be found.)
Note: This is the reason that a simple product wave function is called "uncorrelated." For particles that interact with each other, an uncorrelated wave function is often not a good approximation. For example, two
electrons repel each other. All else being the same, the electrons would rather be at positions where the other electron is nowhere close. As a result, it really makes a difference for electron 1 where electron 2 is likely to be and vice-versa. To handle such situations, usually sums of product wave functions are used. However, for some cases, like for the helium atom, a single product wave function is a perfectly acceptable first approximation. Real-life electrons are crowded together around attracting nuclei and learn to live with each other.
Solution complex-b

### 5.2 The Hydrogen Molecule

This section uses similar approximations as for the hydrogen molecular ion of chapter 4.6 to examine the neutral $\mathrm{H}_{2}$ hydrogen molecule. This molecule has two electrons circling two protons. It will turn out that in the ground state, the protons share the two electrons, rather than each being assigned one. This is typical of covalent bonds.

Of course, "share" is a vague term, but the discussion will show what it really means in terms of the six-dimensional electron wave function.

### 5.2.1 The Hamiltonian

Just like for the hydrogen molecular ion of chapter 4.6, for the neutral molecule the Born-Oppenheimer approximation will be made that the protons are at given fixed points. So the problem simplifies to just finding the wave function of the two electrons, $\Psi\left(\vec{r}_{1}, \vec{r}_{2}\right)$, where $\vec{r}_{1}$ and $\vec{r}_{2}$ are the positions of the two electrons 1 and 2. In terms of scalar arguments, the wave function can be written out further as $\Psi\left(x_{1}, y_{1}, z_{1}, x_{2}, y_{2}, z_{2}\right)$.

In the Hamiltonian, following the Newtonian analogy the kinetic and potential energy operators simply add:

$$
\begin{equation*}
H=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}}\left(\nabla_{1}^{2}+\nabla_{2}^{2}\right)-\frac{e^{2}}{4 \pi \epsilon_{0}}\left(\frac{1}{r_{11}}+\frac{1}{r_{1 \mathrm{r}}}+\frac{1}{r_{21}}+\frac{1}{r_{2 \mathrm{r}}}-\frac{1}{\left|\vec{r}_{1}-\vec{r}_{2}\right|}\right) \tag{5.3}
\end{equation*}
$$

In this expression, the Laplacians of the first two, kinetic energy, terms are with respect to the position coordinates of the two electrons:

$$
\nabla_{1}^{2}=\frac{\partial^{2}}{\partial x_{1}^{2}}+\frac{\partial^{2}}{\partial y_{1}^{2}}+\frac{\partial^{2}}{\partial z_{1}^{2}} \quad \nabla_{2}^{2}=\frac{\partial^{2}}{\partial x_{2}^{2}}+\frac{\partial^{2}}{\partial y_{2}^{2}}+\frac{\partial^{2}}{\partial z_{z}^{2}}
$$

The next four terms in the Hamiltonian (5.3) are the attractive potentials between the electrons and the protons, with $r_{11}, r_{21}, r_{1 \mathrm{r}}$, and $r_{2 \mathrm{r}}$ being the distances between electrons 1 and 2 and the left, respectively right proton. The final term represents the repulsive potential between the two electrons.

## Key Points

$0-$ The Hamiltonian for the 6 -dimensional electron wave function has been written down.

### 5.2.1 Review Questions

1. Verify that the repulsive potential between the electrons is infinitely large when the electrons are at the same position.
Note: You might therefore think that the wave function needs to be zero at the locations in six-dimensional space where $\vec{r}_{1}=\vec{r}_{2}$. Some authors refer to that as a "Coulomb hole." But the truth is that in quantum mechanics, electrons are smeared out due to uncertainty. That causes electron 1 to "see electron 2 at all sides", and vice-versa, and they do therefore not encounter any unusually large potential when the wave function is nonzero at $\vec{r}_{1}=\vec{r}_{2}$. In general, it is just not worth the trouble for the electrons to stay away from the same position: that would reduce their uncertainty in position, increasing their uncertainty-demanded kinetic energy.
Solution hmola-a
2. Note that the total kinetic energy term is simply a multiple of the six-dimensional Laplacian operator. It treats all Cartesian position coordinates exactly the same, regardless of which direction or which electron it is. Is this still the case if other particles are involved?

Solution hmola-b

### 5.2.2 Initial approximation to the lowest energy state

The next step is to identify an approximate ground state for the hydrogen molecule. Following the same approach as in chapter 4.6, it will first be assumed that the protons are relatively far apart. One obvious approximate solution is then that of two neutral atoms, say the one in which electron 1 is around the left proton in its ground state and electron 2 is around the right one.

To formulate the wave function for that, the shorthand notation $\psi_{1}$ will again be used for the wave function of a single electron that in the ground state around the left proton and $\psi_{\mathrm{r}}$ for one that is in the ground state around the right hand one:

$$
\psi_{1}(\vec{r}) \equiv \psi_{100}\left(\left|\vec{r}-\vec{r}_{\mathrm{lp}}\right|\right) \quad \psi_{\mathrm{r}}(\vec{r}) \equiv \psi_{100}\left(\left|\vec{r}-\vec{r}_{\mathrm{rp}}\right|\right)
$$

where $\psi_{100}$ is the hydrogen atom ground state (4.40), and $\vec{r}_{\mathrm{lp}}$ and $\vec{r}_{\mathrm{rp}}$ are the positions of the left and right protons.

The wave function that describes that electron 1 is in the ground state around the left proton and electron 2 around the right one will be approximated to be the product of the single electron states:

$$
\psi\left(\vec{r}_{1}, \vec{r}_{2}\right)=\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)
$$

Taking the combined wave function as a product of single electron states is really equivalent to an assumption that the two electrons are independent. Indeed, for the product state, the probability of finding electron 1 at position $\vec{r}_{1}$ and electron 2 at $\vec{r}_{2}$ is:

$$
\left|\psi_{1}\left(\vec{r}_{1}\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{1} \times\left|\psi_{\mathrm{r}}\left(\vec{r}_{2}\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{2}
$$

or in words:
[probability of finding 1 at $\vec{r}_{1}$ unaffected by where 2 is] $\times$ [probability of finding 2 at $\vec{r}_{2}$ unaffected by where 1 is]

Such product probabilities are characteristic of statistically independent quantities. As a simple example, the chances of getting a three in the first throw of a die and a five in the second throw are $\frac{1}{6} \times \frac{1}{6}$ or 1 in 36 . Throwing the three does not affect the chances of getting a five in the second throw.

## Key Points

$0-$ When the protons are well apart, an approximate ground state is that of two neutral atoms.
$0-$ Single electron wave functions for that case are $\psi_{1}$ and $\psi_{\mathrm{r}}$.
$0-$ The complete wave function for that case is $\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)$, assuming that electron 1 is around the left proton and electron 2 around the right one.

### 5.2.2 Review Questions

1. If electron 2 does not affect where electron 1 is likely to be, how would a grey-scale picture of the probability of finding electron 1 look? Solution hmolb-a
2. When the protons are close to each other, the electrons do affect each other, and the wave function above is no longer valid. But suppose you were given the true wave function, and you were once again asked to draw the blob showing the probability of finding electron 1 (using a plotting package, say). What would the big problem be?

Solution hmolb-b

### 5.2.3 The probability density

For multiple-particle systems like the electrons of the hydrogen molecule, showing the magnitude of the wave function as grey tones no longer works since it is a function in six-dimensional space. You cannot visualize six-dimensional space. However, at every spatial position $\vec{r}$ in normal space, you can instead show the
"probability density" $n(\vec{r})$, which is the probability per unit volume of finding either electron in a vicinity $\mathrm{d}^{3} \vec{r}$ of the point. This probability is found as

$$
\begin{equation*}
n(\vec{r})=\int\left|\Psi\left(\vec{r}, \vec{r}_{2}\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{2}+\int\left|\Psi\left(\vec{r}_{1}, \vec{r}\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{1} \tag{5.4}
\end{equation*}
$$

since the first integral gives the probability of finding electron 1 at $\vec{r}$ regardless of where electron 2 is, (i.e. integrated over all possible positions for electron 2), and the second gives the probability of finding 2 at $\vec{r}$ regardless of where 1 is. Since $d^{3} \vec{r}$ is vanishingly small, the chances of finding both particles in it at the same time are zero.

The probability density $n(\vec{r})$ for state $\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)$ with electron 1 around the left proton and electron 2 around the right one is shown in figure 5.1. Of course the probability density for the state $\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)$ with the electrons exchanged would look exactly the same.

Figure 5.1: State with two neutral atoms.

## Key Points

$0=$ The probability density is the probability per unit volume of finding an electron, whichever one, near a given point.

### 5.2.3 Review Questions

1. Suppose, given the wave function $\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)$, that you found an electron near the left proton. What electron would it probably be? Suppose you found an electron at the point halfway in between the protons. What electron would that likely be?
Solution hmolc-a

### 5.2.4 States that share the electrons

This section will examine the states where the protons share the two electrons.
The first thing is to shorten the notations a bit. So, the state $\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)$ which describes that electron 1 is around the left proton and electron 2 around the right one will be indicated by $\psi_{1} \psi_{\mathrm{r}}$, using the convention that the first factor
refers to electron 1 and the second to electron 2. In this convention, the state where electron 1 is around the right proton and electron 2 around the left one is $\psi_{\mathrm{r}} \psi_{1}$, shorthand for $\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)$. It is of course physically the same thing as $\psi_{1} \psi_{\mathrm{r}}$; the two electrons are identical.

The "every possible combination" idea of combining every possible state for electron 1 with every possible state for electron 2 would suggest that the states $\psi_{1} \psi_{1}$ and $\psi_{\mathrm{r}} \psi_{\mathrm{r}}$ should also be included. But these states have the electrons around the same proton, and that is not going to be energetically favorable due to the mutual repulsion of the electrons. So they are not useful for finding a simple approximate ground state of lowest energy.

States where the electrons are no longer assigned to a particular proton can be found as linear combinations of $\psi_{1} \psi_{\mathrm{r}}$ and $\psi_{\mathrm{r}} \psi_{1}$ :

$$
\begin{equation*}
\psi=a \psi_{1} \psi_{\mathrm{r}}+b \psi_{\mathrm{r}} \psi_{\mathrm{l}} \tag{5.5}
\end{equation*}
$$

In such a combination each electron has a probability of being found about either proton, but wherever it is found, the other electron will be around the other proton.

The eigenfunction must be normalized, which noting that $\psi_{1}$ and $\psi_{\mathrm{r}}$ are real and normalized produces

$$
\begin{equation*}
\langle\psi \mid \psi\rangle_{6}=\left\langle a \psi_{1} \psi_{\mathrm{r}}+b \psi_{\mathrm{r}} \psi_{1} \mid a \psi_{1} \psi_{\mathrm{r}}+b \psi_{\mathrm{r}} \psi_{1}\right\rangle=a^{2}+b^{2}+2 a b\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle^{2}=1 \tag{5.6}
\end{equation*}
$$

assuming that $a$ and $b$ are real. As a result, only the ratio $a / b$ can be chosen freely. The probability density of the combination can be found to be:

$$
\begin{equation*}
n=\psi_{1}^{2}+\psi_{\mathrm{r}}^{2}+2 a b\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle\left\{2 \psi_{1} \psi_{\mathrm{r}}-\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle\left(\psi_{1}^{2}+\psi_{\mathrm{r}}^{2}\right)\right\} \tag{5.7}
\end{equation*}
$$

The most important combination state is the one with $b=a$ :

$$
\begin{equation*}
\psi\left(\vec{r}_{1}, \vec{r}_{2}\right)=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right] \tag{5.8}
\end{equation*}
$$

This state is called "symmetric with respect to exchanging electron 1 with electron 2," or more precisely, with respect to replacing $\vec{r}_{1}$ by $\vec{r}_{2}$ and vice-versa. Such an exchange does not change this wave function at all. If you change $\vec{r}_{1}$ into $\vec{r}_{2}$ and vice-versa, you still end up with the same wave function. In terms of the hydrogen ground state wave function, it may be written out fully as

$$
\begin{equation*}
\Psi \approx a\left[\psi_{100}\left(\left|\vec{r}_{1}-\vec{r}_{1 \mathrm{p}}\right|\right) \psi_{100}\left(\left|\vec{r}_{2}-\vec{r}_{\mathrm{rp}}\right|\right)+\psi_{100}\left(\left|\vec{r}_{1}-\vec{r}_{\mathrm{rp}}\right|\right) \psi_{100}\left(\left|\vec{r}_{2}-\vec{r}_{1 \mathrm{p}}\right|\right)\right] \tag{5.9}
\end{equation*}
$$

with $\psi_{100}(r) \equiv e^{-r / a_{0}} / \sqrt{\pi a_{0}^{3}}$, where $a_{0}=0.53 \AA$ is the Bohr radius, and $\vec{r}_{1}, \vec{r}_{2}$, $\vec{r}_{\mathrm{lp}}$, and $\vec{r}_{\mathrm{rp}}$ are again the position vectors of the electrons and protons.

The probability density of this wave function looks like figure 5.2. It has increased likelihood for electrons to be found in between the protons, compared to figure 5.1 in which each proton had its own electron.

Figure 5.2: Symmetric sharing of the electrons.

The state with $b=-a$,

$$
\begin{equation*}
\psi\left(\vec{r}_{1}, \vec{r}_{2}\right)=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathbf{r}}\left(\vec{r}_{2}\right)-\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right] \tag{5.10}
\end{equation*}
$$

is called "antisymmetric" with respect to exchanging electron 1 with electron 2 : swapping $\vec{r}_{1}$ and $\vec{r}_{2}$ changes the sign of wave function, but leaves it further unchanged. As seen in figure 5.3, the antisymmetric state has decreased likelihood for electrons to be found in between the protons.

Figure 5.3: Antisymmetric sharing of the electrons.

## Key Points

$0-$ In state $\psi_{1} \psi_{\mathrm{r}}$, the electron numbered 1 is around the left proton and 2 around the right one.
$0-$ In state $\psi_{\mathrm{r}} \psi_{1}$, the electron numbered 1 is around the right proton and 2 around the left one.
$0-$ In the symmetric state $a\left(\psi_{1} \psi_{\mathrm{r}}+\psi_{\mathrm{r}} \psi_{1}\right)$ the protons share the electrons equally; each electron has an equal chance of being found around either proton. In this state there is increased probability of finding an electron somewhere in between the protons.
$0-$ In the antisymmetric state $a\left(\psi_{1} \psi_{\mathrm{r}}-\psi_{\mathrm{r}} \psi_{1}\right)$ the protons also share the electrons equally; each electron has again an equal chance of being found around either proton. But in this state there is decreased probability of finding an electron somewhere in between the protons.
$0-$ So, like for the molecular ion, at large proton separations the weird trick of shuffling unobservable wave functions around does again produce different physical states with pretty much the same energy.

### 5.2.4 Review Questions

1. Obviously, the visual difference between the various states is minor. It may even seem counter-intuitive that there is any difference at all: the states $\psi_{1} \psi_{\mathrm{r}}$ and $\psi_{\mathrm{r}} \psi_{1}$ are exactly the same physically, with one electron around each proton. So why would their combinations be any different?
The quantum difference would be much more clear if you could see the full six-dimensional wave function, but visualizing six-dimensional space just does not work. However, if you restrict yourself to only looking on the $z$-axis through the nuclei, you get a drawable $z_{1}, z_{2}$-plane describing near what axial combinations of positions you are most likely to find the two electrons. In other words: what would be the chances of finding electron 1 near some axial position $z_{1}$ and electron 2 at the same time near some other axial position $z_{2}$ ?
Try to guess these probabilities in the $z_{1}, z_{2}$-plane as grey tones, (darker if more likely), and then compare with the answer.

Solution hmold-a
2. Based on the previous question, how would you think the probability density $n(z)$ would look on the axis through the nuclei, again ignoring the existence of positions beyond the axis?
Solution hmold-b

### 5.2.5 Variational approximation of the ground state

The purpose of this section is to find an approximation to the ground state of the hydrogen molecule using the rough approximation of the wave function described in the previous subsections.

Like for the hydrogen molecular ion of chapter 4.6.6, the idea is that since the true ground state is the state of lowest energy among all wave functions, the best among approximate wave functions is the one with the lowest energy. The approximate wave functions are here of the form $a \psi_{1} \psi_{\mathrm{r}}+b \psi_{\mathrm{r}} \psi_{1}$; in these the protons share the electrons, but in such a way that when one electron is around the left proton, the other is around the right one, and vice-versa.

A computer program is again needed to print out the expectation value of the energy for various values of the ratio of coefficients $a / b$ and proton-proton distance $d$. And worse, the expectation value of energy for given $a / b$ and $d$ is a six-dimensional integral, and parts of it cannot be done analytically; numerical integration must be used. That makes it a much more messy problem, \{D.23\}.

You might just want to take it on faith that the binding energy, at the state of lowest energy found, turns out to be 3.2 eV , at a proton to proton spacing of $0.87 \AA$, and that it occurs for the symmetric state $a=b$.

## Key Points

$0-$ An approximate ground state can be found for the hydrogen molecule using a variational method much like that for the molecular ion.

### 5.2.6 Comparison with the exact ground state

The solution for the ground state of the hydrogen molecule obtained in the previous subsection is, like the one for the molecular ion, pretty good. The approximate binding energy, 3.2 eV , is not too much different from the experimental value of 4.52 eV . Similarly, the bond length of $0.87 \AA$ is not too far from the experimental value of $0.74 \AA$.

Qualitatively, the exact ground state wave function is real, positive and symmetric with respect to reflection around the symmetry plane and to rotations around the line connecting the protons, and so is the approximate one. The reasons for these properties are similar as for the molecular ion; \{A.8,A.9\}.

One very important new symmetry for the neutral molecule is the effect of exchanging the electrons, replacing $\vec{r}_{1}$ by $\vec{r}_{2}$ and vice-versa. The approximate wave function is symmetric (unchanged) under such an exchange, and so is the exact wave function. To understand why, note that the operation of exchanging the electrons commutes with the Hamiltonian, (exchanging identical electrons physically does not do anything). So energy eigenfunctions can be taken to be also eigenfunctions of the "exchange operator." Furthermore, the exchange operator is a Hermitian one, (taking it to the other side in inner products is equivalent to a simple name change of integration variables,) so it has real eigenvalues. And more specifically, the eigenvalues can only be plus or minus one, since swapping electrons does not change the magnitude of the wave function. So the energy eigenfunctions, including the ground state, must be symmetric under electron exchange (eigenvalue one), or antisymmetric (eigenvalue minus one.) Since the ground state must be everywhere positive, (or more precisely, of a single sign), a sign change due to swapping electrons is not possible. So only the symmetric possibility exists for the ground state.

One issue that does not occur for the molecular ion, but only for the neutral molecule is the mutual repulsion between the two electrons. This repulsion is reduced when the electron clouds start to merge, compared to what it would be if the clouds were more compact. (A similar effect is that the gravity force of the earth decreases when you go down below the surface. To be sure, the potential energy keeps going down, or up for electron clouds, but not as much as it would otherwise. Compare figure 13.7.) Since the nuclei are compact, it gives an advantage to nucleus-electron attraction over electron-electron repulsion. This increases the binding energy significantly; in the approximate model from about 1.8 eV to 3.2 eV . It also allows the protons to approach more closely; $\{\mathrm{D} .23\}$.

The question has been asked whether there should not be an "activation energy" involved in creating the hydrogen molecule from the hydrogen atoms. The answer is no, hydrogen atoms are radicals, not stable molecules that need to be taken apart before recombining. In fact, the hydrogen atoms attract each other even at large distances due to Van der Waals attraction, chapter 10.1, an effect lost in the approximate wave functions used in this section. But hydrogen atoms that fly into each other also have enough energy to fly apart again; some of the excess energy must be absorbed elsewhere to form a stable molecule. According to web sources, hydrogen molecule formation in the universe is believed to typically occur on dust specks.

## Key Points

0 - The approximate ground state is pretty good, considering its simplicity.

### 5.3 Two-State Systems

Two-state systems are systems in which only two quantum states are of importance. That makes such systems the simplest nontrivial quantum systems. A lot of qualitative understanding can be obtained from them. Among others, this section will shed some light on the reason why chemical bonds tend to involve pairs of electrons.

As seen in chapter 4.6, the protons in the $\mathrm{H}_{2}^{+}$hydrogen molecular ion are held together by a single shared electron. However, in the $\mathrm{H}_{2}$ neutral hydrogen molecule of the previous section, they are held together by a shared pair of electrons. In both cases a stable bond was formed. So why are chemical bonds involving a single electron relatively rare, while bonds involving pairs of shared electrons are common?

The unifying concept relating the two bonds is that of two-state systems. Such systems involve two intuitive basic states $\psi_{1}$ and $\psi_{2}$.

For the hydrogen molecular ion, one state, $\psi_{1}=\psi_{1}$, described that the electron was in the ground state around the left proton. A physically equivalent state, $\psi_{2}=\psi_{\mathrm{r}}$, had the electron in the ground state around the right proton. For the hydrogen molecule, $\psi_{1}=\psi_{1} \psi_{\mathrm{r}}$ had electron 1 around the left proton and electron 2 around the right one. The other state $\psi_{2}=\psi_{\mathrm{r}} \psi_{1}$ was physically the same, but it had the electrons reversed.

There are many other physical situations that may be described as two state systems. Covalent chemical bonds involving atoms other than hydrogen would be an obvious example. Just substitute a positive ion for one or both protons.

As another example of a two-state system, consider the $\mathrm{C}_{6} \mathrm{H}_{6}$ "benzene molecular ring." This molecule consists of a hexagon of 6 carbon atoms that
are held together by 9 covalent bonds. The logical way that 9 bonds can be arranged between the atoms of a 6 atom ring is to make every second bond a double one. However, that still leaves two possibilities; the locations of the single and double bonds can be swapped. So there are once again two different but equivalent states $\psi_{1}$ and $\psi_{2}$.

The $\mathrm{NH}_{3}$ "ammonia molecule" consists of an nitrogen atom bonded to three hydrogen atoms. By symmetry, the logical place for the nitrogen atom to sit would surely be in the center of the triangle formed by the three hydrogen atoms. But it does not sit there. If it was in the center of the triangle, the angles between the hydrogen atoms, measured from the nitrogen nucleus, should be $120^{\circ}$ each. However, as discussed later in chapter 5.11.3, valence bond theory requires that the angles should be about $90^{\circ}$, not $120^{\circ}$. (The actual angles are about $108^{\circ}$ because of reasons similar to those for water as discussed in chapter 5.11.3.) The key point here is that the nitrogen must sit to the side of the triangle, and there are two sides, producing once again two different but equivalent physical states $\psi_{1}$ and $\psi_{2}$.

In each case described above, there are two intuitive physical states $\psi_{1}$ and $\psi_{2}$. The peculiarities of the quantum mechanics of two-state systems arise from states that are combinations of these two states, as in

$$
\psi=c_{1} \psi_{1}+c_{2} \psi_{2}
$$

Note that according to the ideas of quantum mechanics, the square magnitude of the first coefficient of the combined state, $\left|c_{1}\right|^{2}$, represents the probability of being in state $\psi_{1}$ and $\left|c_{2}\right|^{2}$ the probability of being in state $\psi_{2}$. Of course, the total probability of being in one of the states should be one:

$$
\left|c_{1}\right|^{2}+\left|c_{2}\right|^{2}=1
$$

(This is only true if the $\psi_{1}$ and $\psi_{2}$ states are orthonormal. In the hydrogen molecule cases, orthonormalizing the basic states would change them a bit, but their physical nature would remain much the same, especially if the protons are not too close.)

The key question is now what combination of states has the lowest energy. That will be the ground state $\psi_{\mathrm{gs}}$ of the two-state system. The expectation value of energy is

$$
\langle E\rangle=\left\langle c_{1} \psi_{1}+c_{2} \psi_{2}\right| H\left|c_{1} \psi_{1}+c_{2} \psi_{2}\right\rangle
$$

This can be multiplied out, taking into account that numerical factors come out of the left of an inner product as complex conjugates. The result is

$$
\langle E\rangle=\left|c_{1}\right|^{2}\left\langle E_{1}\right\rangle+c_{1}^{*} c_{2} H_{12}+c_{2}^{*} c_{1} H_{21}+\left|c_{2}\right|^{2}\left\langle E_{2}\right\rangle
$$

using the shorthand notation

$$
\left\langle E_{1}\right\rangle=\left\langle\psi_{1} \mid H \psi_{1}\right\rangle, \quad H_{12}=\left\langle\psi_{1} \mid H \psi_{2}\right\rangle, \quad H_{21}=\left\langle\psi_{2} \mid H \psi_{1}\right\rangle, \quad\left\langle E_{2}\right\rangle=\left\langle\psi_{2} \mid H \psi_{2}\right\rangle
$$

Note that $\left\langle E_{1}\right\rangle$ and $\left\langle E_{2}\right\rangle$ are real, (2.16). They are the expectation energies of the states $\psi_{1}$ and $\psi_{2}$. The states will be ordered so that $\left\langle E_{1}\right\rangle$ is less or equal to $\left\langle E_{2}\right\rangle$. (In all the examples mentioned so far, $\left\langle E_{1}\right\rangle$ and $\left\langle E_{2}\right\rangle$ are equal because the two states are physically equivalent.) Normally, $H_{12}$ and $H_{21}$ are not real but complex conjugates, (2.16). However, you can always change the definition of, say, $\psi_{1}$ by a complex factor of magnitude one to make $H_{12}$ equal to a real and negative number, and then $H_{21}$ will be that same negative number.

The above expression for the expectation energy consists of two kinds of terms, which will be called:

$$
\begin{align*}
\text { the averaged energy: } & \left|c_{1}\right|^{2}\left\langle E_{1}\right\rangle+\left|c_{2}\right|^{2}\left\langle E_{2}\right\rangle  \tag{5.11}\\
\text { the twilight terms: } & \left(c_{1}^{*} c_{2}+c_{2}^{*} c_{1}\right) H_{12} \tag{5.12}
\end{align*}
$$

Each of those contributions will be discussed in turn.
The averaged energy is the energy that you would intuitively expect the combined wave function to have. It is a straightforward sum of the expectation energies of the two component states $\psi_{1}$ and $\psi_{2}$ times the probabilities of being in those states. In particular, in the important case that the two states have the same energy, the averaged energy is that energy. What is more logical than that any mixture of two states with the same energy would have that energy too?

But the twilight terms throw a monkey wrench in this simplistic thinking. It can be seen that they will always make the ground state energy $E_{\text {gs }}$ lower than the lowest energy of the component states $\left\langle E_{1}\right\rangle$. (To see that, just take $c_{1}$ and $c_{2}$ positive real numbers and $c_{2}$ small enough that $c_{2}^{2}$ can be neglected.) This lowering of the energy below the lowest component state comes out of the mathematics of combining states; absolutely no new physical forces are added to produce it. But if you try to describe it in terms of classical physics, it really looks like a mysterious new "twilight force" is in operation here. It is no new force; it is the weird mathematics of quantum mechanics.

So, what are these twilight terms physically? If you mean, what are they in terms of classical physics, there is simply no answer. But if you mean, what are they in terms of normal language, rather than formulae, it is easy. Just have another look at the definition of the twilight terms; they are a measure of the inner product $\left\langle\psi_{1} \mid H \psi_{2}\right\rangle$. That is the energy you would get if nature was in state $\psi_{1}$ if nature was in state $\psi_{2}$. On quantum scales, nature can get really, really ethereal, where it moves beyond being describable by classical physics, and the result is very concrete, but weird, interactions. For, at these scales twilight is real, and classical physics is not.

For the twilight terms to be nonzero, there must be a region where the two states overlap, i.e. there must be a region where both $\psi_{1}$ and $\psi_{2}$ are nonzero. In the simplest case of the hydrogen molecular ion, if the atoms are far apart, the left and right wave functions do not overlap and the twilight terms will be
zero. For the hydrogen molecule, it gets a bit less intuitive, since the overlap should really be visualized in the six-dimensional space of those functions. But still, the terms are zero when the atoms are far apart.

The twilight terms are customarily referred to as "exchange terms," but everybody seems to have a different idea of what that is supposed to mean. The reason may be that these terms pop up all over the place, in all sorts of very different settings. This book prefers to call them twilight terms, since that most clearly expresses what they really are. Nature is in a twilight zone of ambiguity.

The lowering of the energy by the twilight terms produces more stable chemical bonds than you would expect. Typically, the effect of the terms is greatest if the two basic states $\psi_{1}$ and $\psi_{2}$ are physically equivalent, like for the mentioned examples. Then the two states have the same expectation energy, call it $\langle E\rangle_{1,2}$. For such symmetric systems, the ground state will occur for an equal mixture of the two states, $c_{1}=c_{2}=\sqrt{\frac{1}{2}}$, because then the twilight terms are most negative. (Complex coefficients do not really make a physical difference, so $c_{1}$ and $c_{2}$ can be assumed to be real numbers for convenience.) In the ground state, the lowest energy is then an amount $\left|H_{12}\right|$ below the energy of the component states:

$$
\begin{equation*}
\text { Symmetric 2-state systems: } \quad \psi_{\mathrm{gs}}=\frac{\psi_{1}+\psi_{2}}{\sqrt{2}} \quad E_{\mathrm{gs}}=\langle E\rangle_{1,2}-\left|H_{12}\right| \tag{5.13}
\end{equation*}
$$

On the other hand, if the lower energy state $\psi_{1}$ has significantly less energy than state $\psi_{2}$, then the minimum energy will occur near the lower energy state. That means that $\left|c_{1}\right| \approx 1$ and $\left|c_{2}\right| \approx 0$. (This assumes that the twilight terms are not big enough to dominate the energy.) In that case $c_{1} c_{2} \approx 0$ in the twilight terms (5.12), which pretty much takes the terms out of the picture completely.

This happens for the single-electron bond of the hydrogen molecular ion if the second proton is replaced by another ion, say a lithium ion. The energy in state $\psi_{1}$, where the electron is around the proton, will now be significantly less than that of state $\psi_{2}$, where it is around the lithium ion. For such asymmetrical single-electron bonds, the twilight terms are not likely to help much in forging a strong bond. While it turns out that the $\mathrm{LiH}^{+}$ion is stable, the binding energy is only 0.14 eV or so, compared to 2.8 eV for the $\mathrm{H}_{2}^{+}$ion. Also, the $\mathrm{LiH}^{+}$bond seems to be best described as a Van der Waals attraction, rather than a true chemical bond.

In contrast, for the two-electron bond of the neutral hydrogen molecule, if the second proton is replaced by a lithium ion, states $\psi_{1}$ and $\psi_{2}$ will still be the same: both states will have one electron around the proton and one around the lithium ion. The two states do have the electrons reversed, but the electrons are identical. Thus the twilight terms are still likely to be effective. Indeed neutral

LiH lithium hydride exists as a stable molecule with a binding energy of about 2.5 eV at low pressures.
(It should be noted that the LiH bond is very ionic, with the "shared" electrons mostly at the hydrogen side, so the actual ground state is quite different from the covalent hydrogen model. But the model should be better when the nuclei are farther apart, so the analysis can at least justify the existence of a significant bond.)

For the ammonia molecule, the two states $\psi_{1}$ and $\psi_{2}$ differ only in the side of the hydrogen triangle that the nitrogen atom is at. Since these two states are physically equivalent, there is again a significant lowering of the energy $E_{\mathrm{gs}}$ for the symmetric combination $c_{1}=c_{2}$. Similarly, there is a significant raising of the energy $E_{\text {as }}$ for the antisymmetric combination $c_{1}=-c_{2}$. Transitions between these two energy states produce photons of a single energy in the microwave range. It allows a maser (microwave-range laser) to be constructed. The first maser was in fact an ammonia one. It gave rise to the subsequent development of optical-range versions. These were initially called "optical masers," but are now known as "lasers." Masers are important for providing a single frequency reference, like in some atomic clocks. See chapter 7.7 for the operating principle of masers and lasers.

The ammonia molecule may well be the best example of how weird these twilight effects are. Consider, there are two common-sense states in which the nitrogen is at one side of the hydrogen triangle. What physical reason could there possibly be that there is a state of lower energy in which the atom is at both sides at the same time with a $50 / 50$ probability? Before you answer that, recall that it only works if you do the 50/50 case right. If you do it wrong, you end up raising the energy. And the only way to figure out whether you do it right is to look at the behavior of the sign of a physically unobservable wave function.

It may finally be noted that in the context of chemical bonds, the raisedenergy antisymmetric state is often called an "antibonding" state.

## Key Points

$0-$ In quantum mechanics, the energy of different but physically equivalent states can be lowered by mixing them together.
$0-$ This lowering of energy does not come from new physical forces, but from the weird mathematics of the wave function.
$0-$ The effect tends to be much less when the original states are physically very different.
$0-$ One important place where states are indeed physically the same is in chemical bonds involving pairs of electrons. Here the equivalent states merely have the identical electrons interchanged.

### 5.3 Review Questions

1. The effectiveness of mixing states was already shown by the hydrogen molecule and molecular ion examples. But the generalized story above restricts the "basis" states to be orthogonal, and the states used in the hydrogen examples were not.
Show that if $\psi_{1}$ and $\psi_{2}$ are not orthogonal states, but are normalized and produce a real and positive value for $\left\langle\psi_{1} \mid \psi_{2}\right\rangle$, like in the hydrogen examples, then orthogonal states can be found in the form

$$
\bar{\psi}_{1}=\alpha\left(\psi_{1}-\varepsilon \psi_{2}\right) \quad \bar{\psi}_{2}=\alpha\left(\psi_{2}-\varepsilon \psi_{1}\right)
$$

For normalized $\psi_{1}$ and $\psi_{2}$ the Cauchy-Schwartz inequality implies that $\left\langle\psi_{1} \mid \psi_{2}\right\rangle$ will be less than one. If the states do not overlap much, it will be much less than one and $\varepsilon$ will be small.
(If $\psi_{1}$ and $\psi_{2}$ do not meet the stated requirements, you can always redefine them by factors $a e^{i c}$ and $b e^{-\mathrm{i} c}$, with $a, b$, and $c$ real, to get states that do.)
Solution 2state-a
2. Show that it does not have an effect on the solution whether or not the basic states $\psi_{1}$ and $\psi_{2}$ are normalized, like in the previous question, before the state of lowest energy is found.
This requires no detailed analysis; just check that the same solution can be described using the nonorthogonal and orthogonal basis states. It is however an important observation for various numerical solution procedures: your set of basis functions can be cleaned up and simplified without affecting the solution you get.
Solution 2state-b

### 5.4 Spin

At this stage, it becomes necessary to look somewhat closer at the various particles involved in quantum mechanics themselves. The analysis so far already used the fact that particles have a property called mass, a quantity that special relativity has identified as being an internal amount of energy. It turns out that in addition particles have a fixed amount of "build-in" angular momentum, called "spin." Spin reflects itself, for example, in how a charged particle such as an electron interacts with a magnetic field.

To keep it apart from spin, from now on the angular momentum of a particle due to its motion will on be referred to as "orbital" angular momentum. As was discussed in chapter 4.2, the square orbital angular momentum of a particle is given by

$$
L^{2}=l(l+1) \hbar^{2}
$$

where the azimuthal quantum number $l$ is a nonnegative integer.

The square spin angular momentum of a particle is given by a similar expression:

$$
\begin{equation*}
S^{2}=s(s+1) \hbar^{2} \tag{5.14}
\end{equation*}
$$

but the "spin $s$ " is a fixed number for a given type of particle. And while $l$ can only be an integer, the spin $s$ can be any multiple of one half.

Particles with half integer spin are called "fermions." For example, electrons, protons, and neutrons all three have spin $s=\frac{1}{2}$ and are fermions.

Particles with integer spin are called "bosons." For example, photons have $\operatorname{spin} s=1$. The $\pi$-mesons have spin $s=0$ and gravitons, unobserved at the time of writing, should have spin $s=2$.

The spin angular momentum in an arbitrarily chosen $z$-direction is

$$
\begin{equation*}
S_{z}=m \hbar \tag{5.15}
\end{equation*}
$$

the same formula as for orbital angular momentum, and the values of $m$ range again from $-s$ to $+s$ in integer steps. For example, photons can have spin in a given direction that is $\hbar, 0$, or $-\hbar$. (The photon, a relativistic particle with zero rest mass, has only two spin states along the direction of propagation; the zero value does not occur in this case. But photons radiated by atoms can still come off with zero angular momentum in a direction normal to the direction of propagation. A derivation is in addendum $\{\mathrm{A} .21 .6\}$ and $\{\mathrm{A} .21 .7\}$.)

The common particles, (electrons, protons, neutrons), can only have spin angular momentum $\frac{1}{2} \hbar$ or $-\frac{1}{2} \hbar$ in any given direction. The positive sign state is called "spin up", the negative one "spin down".

It may be noted that the proton and neutron are not elementary particles, but are baryons, consisting of three quarks. Similarly, mesons consist of a quark and an anti-quark. Quarks have spin $1 / 2$, which allows baryons to have spin $3 / 2$ or $1 / 2$. (It is not self-evident, but spin values can be additive or subtractive within the confines of their discrete allowable values; see chapter 12.) The same way, mesons can have spin 1 or 0 .

Spin states are commonly shown in "ket notation" as $|s m\rangle$. For example, the spin-up state for an electron is indicated by $\left|\frac{1}{2} \frac{1}{2}\right\rangle$ and the spin-down state as $|1 / 2-1 / 2\rangle$. More informally, $\uparrow$ and $\downarrow$ are often used.

## Key Points

$0-$ Most particles have internal angular momentum called spin.
$0-$ The square spin angular momentum and its quantum number $s$ are always the same for a given particle.
$0-$ Electrons, protons and neutrons all have spin $1 / 2$. Their spin angular momentum in a given direction is either $\frac{1}{2} \hbar$ or $-\frac{1}{2} \hbar$.
$0-$ Photons have spin one. Possible values for their angular momentum in a given direction are $\hbar$, zero, or $-\hbar$, though zero does not occur in the direction of propagation.

- Particles with integer spin, like photons, are called bosons. Particles with half-integer spin, like electrons, protons, and neutrons, are called fermions.
$0-$ The spin-up state of a spin one-half particle like an electron is usually indicated by $|1 / 21 / 2\rangle$ or $\uparrow$. Similarly, the spin-down state is indicated by $|1 / 2-1 / 2\rangle$ or $\downarrow$.

### 5.5 Multiple-Particle Systems Including Spin

Spin will turn out to have a major effect on how quantum particles behave Therefore, quantum mechanics as discussed so far must be generalized to include spin. Just like there is a probability that a particle is at some position $\vec{r}$, there is the additional probability that it has spin angular momentum $S_{z}$ in an arbitrarily chosen $z$-direction and this must be included in the wave function. This section discusses how.

### 5.5.1 Wave function for a single particle with spin

The first question is how spin should be included in the wave function of a single particle. If spin is ignored, a single particle has a wave function $\Psi(\vec{r} ; t)$, depending on position $\vec{r}$ and on time $t$. Now, the spin $S_{z}$ is just some other scalar variable that describes the particle, in that respect no different from say the $x$-position of the particle. The "every possible combination" idea of allowing every possible combination of states to have its own probability indicates that $S_{z}$ needs to be added to the list of variables. So the complete wave function $\Psi$ of the particle can be written out fully as:

$$
\begin{equation*}
\Psi \equiv \Psi\left(\vec{r}, S_{z} ; t\right) \tag{5.16}
\end{equation*}
$$

The value of $\left|\Psi\left(\vec{r}, S_{z} ; t\right)\right|^{2} \mathrm{~d}^{3} \vec{r}$ gives the probability of finding the particle within a vicinity $\mathrm{d}^{3} \vec{r}$ of $\vec{r}$ and with spin angular momentum in the $z$-direction $S_{z}$.

But note that there is a big difference between the spin "coordinate" and the position coordinates: while the position variables can take on any value, the values of $S_{z}$ are highly limited. In particular, for the electron, proton, and
neutron, $S_{z}$ can only be $\frac{1}{2} \hbar$ or $-\frac{1}{2} \hbar$, nothing else. You do not really have a full $S_{z}$ "axis", just two points.

As a result, there are other meaningful ways of writing the wave function. The full wave function $\Psi\left(\vec{r}, S_{z} ; t\right)$ can be thought of as consisting of two parts $\Psi_{+}$and $\Psi_{-}$that only depend on position:

$$
\begin{equation*}
\Psi_{+}(\vec{r} ; t) \equiv \Psi\left(\vec{r}, \frac{1}{2} \hbar ; t\right) \quad \text { and } \quad \Psi_{-}(\vec{r} ; t) \equiv \Psi\left(\vec{r},-\frac{1}{2} \hbar ; t\right) \tag{5.17}
\end{equation*}
$$

These two parts can in turn be thought of as being the components of a twodimensional vector that only depends on position:

$$
\vec{\Psi}(\vec{r} ; t) \equiv\binom{\Psi_{+}(\vec{r} ; t)}{\Psi_{-}(\vec{r} ; t)}
$$

Remarkably, Dirac found that the wave function for particles like electrons has to be a vector, if it is assumed that the relativistic equations take a guessed simple and beautiful form, like the Schrödinger and all other basic equations of physics are simple and beautiful. Just like relativity reveals that particles should have build-in energy, it also reveals that particles like electrons have build-in angular momentum. A description of the Dirac equation is in chapter 12.12 if you are curious.

The two-dimensional vector is called a "spinor" to indicate that its components do not change like those of ordinary physical vectors when the coordinate system is rotated. (How they do change is of no importance here, but will eventually be described in derivation \{D.68\}.) The spinor can also be written in terms of a magnitude times a unit vector:

$$
\vec{\Psi}(\vec{r} ; t)=\Psi_{m}(\vec{r} ; t)\binom{\chi_{1}(\vec{r} ; t)}{\chi_{2}(\vec{r} ; t)}
$$

This book will just use the scalar wave function $\Psi\left(\vec{r}, S_{z} ; t\right)$; not a vector one. But it is often convenient to write the scalar wave function in a form equivalent to the vector one:

$$
\begin{equation*}
\Psi\left(\vec{r}, S_{z} ; t\right)=\Psi_{+}(\vec{r} ; t) \uparrow\left(S_{z}\right)+\Psi_{-}(\vec{r} ; t) \downarrow\left(S_{z}\right) \tag{5.18}
\end{equation*}
$$

The square magnitude of function $\Psi_{+}$gives the probability of finding the particle near a position with spin-up. That of $\Psi_{-}$gives the probability of finding it with spin-down. The "spin-up" function $\uparrow\left(S_{z}\right)$ and the "spin-down" function $\downarrow\left(S_{z}\right)$ are in some sense the equivalent of the unit vectors $\hat{\imath}$ and $\hat{\jmath}$ in normal vector analysis; they have by definition the following values:

$$
\begin{array}{|lll}
\hline \uparrow\left(\frac{1}{2} \hbar\right)=1 & \uparrow\left(-\frac{1}{2} \hbar\right)=0 & \downarrow\left(\frac{1}{2} \hbar\right)=0
\end{array} \quad \downarrow\left(-\frac{1}{2} \hbar\right)=1 .
$$

The function arguments will usually be left away for conciseness, so that

$$
\Psi=\Psi_{+} \uparrow+\Psi_{-\downarrow}
$$

is the way the wave function of, say, an electron will normally be written out.

## Key Points

$0-$ Spin must be included as an independent variable in the wave function of a particle with spin.
$0-$ Usually, the wave function $\Psi\left(\vec{r}, S_{z} ; t\right)$ of a single particle with spin $1 / 2$ will be written as

$$
\Psi=\Psi_{+} \uparrow+\Psi_{-\downarrow}
$$

where $\Psi_{+}(\vec{r} ; t)$ determines the probability of finding the particle near a given location $\vec{r}$ with spin up, and $\Psi_{-}(\vec{r} ; t)$ the one for finding it spin down.
$0-$ The functions $\uparrow\left(S_{z}\right)$ and $\downarrow\left(S_{z}\right)$ have the values

$$
\uparrow\left(\frac{1}{2} \hbar\right)=1 \quad \uparrow\left(-\frac{1}{2} \hbar\right)=0 \quad \downarrow\left(\frac{1}{2} \hbar\right)=0 \quad \downarrow\left(-\frac{1}{2} \hbar\right)=1
$$

and represent the pure spin-up, respectively spin-down states.

### 5.5.1 Review Questions

1. What is the normalization requirement of the wave function of a spin $1 / 2$ particle in terms of $\Psi_{+}$and $\Psi_{-}$?

Solution complexsa-a

### 5.5.2 Inner products including spin

Inner products are important: they are needed for finding normalization factors, expectation values, uncertainty, approximate ground states, etcetera. The additional spin coordinates add a new twist, since there is no way to integrate over the few discrete points on the spin "axis". Instead, you must sum over these points.

As an example, the inner product of two arbitrary electron wave functions $\Psi_{1}\left(\vec{r}, S_{z} ; t\right)$ and $\Psi_{2}\left(\vec{r}, S_{z} ; t\right)$ is

$$
\left\langle\Psi_{1} \mid \Psi_{2}\right\rangle=\sum_{S_{z}= \pm \frac{1}{2} \hbar} \int_{\text {all } \vec{r}} \Psi_{1}^{*}\left(\vec{r}, S_{z} ; t\right) \Psi_{2}\left(\vec{r}, S_{z} ; t\right) \mathrm{d}^{3} \vec{r}
$$

or writing out the two-term sum,
$\left\langle\Psi_{1} \mid \Psi_{2}\right\rangle=\int_{\text {all } \vec{r}} \Psi_{1}^{*}\left(\vec{r}, \frac{1}{2} \hbar ; t\right) \Psi_{2}\left(\vec{r}, \frac{1}{2} \hbar ; t\right) \mathrm{d}^{3} \vec{r}+\int_{\text {all } \vec{r}} \Psi_{1}^{*}\left(\vec{r},-\frac{1}{2} \hbar ; t\right) \Psi_{2}\left(\vec{r},-\frac{1}{2} \hbar ; t\right) \mathrm{d}^{3} \vec{r}$ The individual factors in the integrals are by definition the spin-up components $\Psi_{1+}$ and $\Psi_{2+}$ and the spin down components $\Psi_{1-}$ and $\Psi_{2-}$ of the wave functions, so:

$$
\left\langle\Psi_{1} \mid \Psi_{2}\right\rangle=\int_{\text {all } \vec{r}} \Psi_{1+}^{*}(\vec{r} ; t) \Psi_{2+}(\vec{r} ; t) \mathrm{d}^{3} \vec{r}+\int_{\text {all } \vec{r}} \Psi_{1-}^{*}(\vec{r} ; t) \Psi_{2-}(\vec{r} ; t) \mathrm{d}^{3} \vec{r}
$$

In other words, the inner product with spin evaluates as

$$
\begin{equation*}
\left\langle\Psi_{1+} \uparrow+\Psi_{1-\downarrow} \mid \Psi_{2+} \uparrow+\Psi_{2-\downarrow}\right\rangle=\left\langle\Psi_{1+} \mid \Psi_{2+}\right\rangle+\left\langle\Psi_{1-} \mid \Psi_{2-}\right\rangle \tag{5.19}
\end{equation*}
$$

It is spin-up components together and spin-down components together.
Another way of looking at this, or maybe remembering it, is to note that the spin states are an orthonormal pair,

$$
\begin{equation*}
\langle\uparrow \mid \uparrow\rangle=1 \quad\langle\uparrow \mid \downarrow\rangle=\langle\downarrow \mid \uparrow\rangle=0 \quad\langle\downarrow \mid \downarrow\rangle=1 \tag{5.20}
\end{equation*}
$$

as can be verified directly from the definitions of those functions as given in the previous subsection. Then you can think of an inner product with spin as multiplying out as:

$$
\begin{aligned}
\left\langle\Psi_{1+} \uparrow\right. & +\Psi_{1-\downarrow}\left|\Psi_{2+} \uparrow+\Psi_{2-} \downarrow\right\rangle \\
& =\left\langle\Psi_{1+} \mid \Psi_{2+}\right\rangle\langle\uparrow \mid \uparrow\rangle+\left\langle\Psi_{1+} \mid \Psi_{2-}\right\rangle\langle\uparrow \mid \downarrow\rangle+\left\langle\Psi_{1-} \mid \Psi_{2+}\right\rangle\langle\downarrow \mid \uparrow\rangle+\left\langle\Psi_{1-} \mid \Psi_{2-}\right\rangle\langle\downarrow \mid \downarrow\rangle \\
& =\left\langle\Psi_{1+} \mid \Psi_{2+}\right\rangle+\left\langle\Psi_{1-} \mid \Psi_{2-}\right\rangle
\end{aligned}
$$

## Key Points

$0-$ In inner products, you must sum over the spin states. $0-$ For spin $1 / 2$ particles:

$$
\left\langle\Psi_{1+} \uparrow+\Psi_{1-\downarrow} \mid \Psi_{2+} \uparrow+\Psi_{2-\downarrow}\right\rangle=\left\langle\Psi_{1+} \mid \Psi_{2+}\right\rangle+\left\langle\Psi_{1-} \mid \Psi_{2-}\right\rangle
$$

which is spin-up components together plus spin-down components together.
0- The spin-up and spin-down states $\uparrow$ and $\downarrow$ are an orthonormal pair.

### 5.5.2 Review Questions

1. Show that the normalization requirement for the wave function of a spin $1 / 2$ particle in terms of $\Psi_{+}$and $\Psi_{-}$requires its norm $\sqrt{\langle\Psi \mid \Psi\rangle}$ to be one. Solution complexsai-a
2. Assume that $\psi_{1}$ and $\psi_{\mathrm{r}}$ are normalized spatial wave functions. Now show that a combination of the two like $\left(\psi_{1} \uparrow+\psi_{\mathrm{r}} \downarrow\right) / \sqrt{2}$ is a normalized wave function with spin.

### 5.5.3 Commutators including spin

There is no known "internal physical mechanism" that gives rise to spin like there is for orbital angular momentum. Fortunately, this lack of detailed information about spin is to a considerable amount made less of an issue by knowledge about its commutators.

In particular, physicists have concluded that spin components satisfy the same commutation relations as the components of orbital angular momentum:

$$
\begin{equation*}
\left[\widehat{S}_{x}, \widehat{S}_{y}\right]=\mathrm{i} \hbar \widehat{S}_{z} \quad\left[\widehat{S}_{y}, \widehat{S}_{z}\right]=\mathrm{i} \hbar \widehat{S}_{x} \quad\left[\widehat{S}_{z}, \widehat{S}_{x}\right]=\mathrm{i} \hbar \widehat{S}_{y} \tag{5.21}
\end{equation*}
$$

These equations are called the "fundamental commutation relations." As will be shown in chapter 12, a large amount of information about spin can be teased from them.

Further, spin operators commute with all functions of the spatial coordinates and with all spatial operators, including position, linear momentum, and orbital angular momentum. The reason why can be understood from the given description of the wave function with spin. First of all, the square spin operator $\widehat{S}^{2}$ just multiplies the entire wave function by the constant $\hbar^{2} s(s+1)$, and everything commutes with a constant. And the operator $\widehat{S}_{z}$ of spin in an arbitrary $z$-direction commutes with spatial functions and operators in much the same way that an operator like $\partial / \partial x$ commutes with functions depending on $y$ and with $\partial / \partial y$. The $z$-component of spin corresponds to an additional "axis" separate from the $x, y$, and $z$ ones, and $\widehat{S}_{z}$ only affects the variation in this additional direction. For example, for a particle with spin one half, $\widehat{S}_{z}$ multiplies the spin-up part of the wave function $\Psi_{+}$by the constant $\frac{1}{2} \hbar$ and $\Psi_{-}$by $-\frac{1}{2} \hbar$. Spatial functions and operators commute with these constants for both $\Psi_{+}$and $\Psi_{-}$hence commute with $\widehat{S}_{z}$ for the entire wave function. Since the $z$-direction is arbitrary, this commutation applies for any spin component.

## Key Points

0- While a detailed mechanism of spin is missing, commutators with spin can be evaluated.
$0-$ The components of spin satisfy the same mutual commutation relations as the components of orbital angular momentum.
$0=$ Spin commutes with spatial functions and operators.

### 5.5.4 Wave function for multiple particles with spin

The extension of the ideas of the previous subsections towards multiple particles is straightforward. For two particles, such as the two electrons of the hydrogen
molecule, the full wave function follows from the "every possible combination" idea as

$$
\begin{equation*}
\Psi=\Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right) \tag{5.22}
\end{equation*}
$$

The value of $\left|\Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}$ gives the probability of simultaneously finding particle 1 within a vicinity $\mathrm{d}^{3} \vec{r}_{1}$ of $\vec{r}_{1}$ with spin angular momentum in the $z$-direction $S_{z 1}$, and particle 2 within a vicinity $\mathrm{d}^{3} \vec{r}_{2}$ of $\vec{r}_{2}$ with spin angular momentum in the $z$-direction $S_{z 2}$.

Restricting the attention again to spin $1 / 2$ particles like electrons, protons and neutrons, there are now four possible spin states at any given point, with corresponding spatial wave functions

$$
\begin{align*}
\Psi_{++}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) & \equiv \Psi\left(\vec{r}_{1},+\frac{1}{2} \hbar, \vec{r}_{2},+\frac{1}{2} \hbar ; t\right) \\
\Psi_{+-}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) & \equiv \Psi\left(\vec{r}_{1},+\frac{1}{2} \hbar, \vec{r}_{2},-\frac{1}{2} \hbar ; t\right)  \tag{5.23}\\
\Psi_{-+}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) & \equiv \Psi\left(\vec{r}_{1},-\frac{1}{2} \hbar, \vec{r}_{2},+\frac{1}{2} \hbar ; t\right) \\
\Psi_{--}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) & \equiv \Psi\left(\vec{r}_{1},-\frac{1}{2} \hbar, \vec{r}_{2},-\frac{1}{2} \hbar ; t\right)
\end{align*}
$$

For example, $\left|\Psi_{+-}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}$ gives the probability of finding particle 1 within a vicinity $\mathrm{d}^{3} \vec{r}_{1}$ of $\vec{r}_{1}$ with spin up, and particle 2 within a vicinity $\mathrm{d}^{3} \vec{r}_{2}$ of $\vec{r}_{2}$ with spin down.

The wave function can be written using purely spatial functions and purely spin functions as

$$
\begin{aligned}
\Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right) & =\Psi_{++}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) \uparrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)+\Psi_{+-}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) \uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right) \\
& +\Psi_{-+}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) \downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)+\Psi_{--}\left(\vec{r}_{1}, \vec{r}_{2} ; t\right) \downarrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)
\end{aligned}
$$

As you might guess from this multi-line display, usually this will be written more concisely as

$$
\Psi=\Psi_{++} \uparrow \uparrow+\Psi_{+-} \uparrow \downarrow+\Psi_{-+\downarrow} \downarrow \uparrow+\Psi_{--\downarrow \downarrow}
$$

by leaving out the arguments of the spatial and spin functions. The understanding is that the first of each pair of arrows refers to particle 1 and the second to particle 2.

The inner product now evaluates as

$$
\begin{aligned}
& \left\langle\Psi_{1} \mid \Psi_{2}\right\rangle= \\
& \quad \sum_{S_{z 1}= \pm \frac{1}{2} \hbar} \sum_{S_{z 2}= \pm \frac{1}{2} \hbar} \int_{\text {all }} \int_{\vec{r}_{1}} \Psi_{\text {all } \vec{r}_{2}} \Psi_{1}^{*}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right) \Psi_{2}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right) \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}
\end{aligned}
$$

This can be written in terms of the purely spatial components as

$$
\left\langle\Psi_{1} \mid \Psi_{2}\right\rangle=\left\langle\Psi_{1++} \mid \Psi_{2++}\right\rangle+\left\langle\Psi_{1+-} \mid \Psi_{2+-}\right\rangle+\left\langle\Psi_{1-+} \mid \Psi_{2-+}\right\rangle+\left\langle\Psi_{1--} \mid \Psi_{2--}\right\rangle
$$

It reflects the fact that the four spin basis states $\uparrow \uparrow, \uparrow \downarrow, \downarrow \uparrow$, and $\downarrow \downarrow$ are an orthonormal quartet.

## Key Points

o- The wave function of a single particle with spin generalizes in a straightforward way to multiple particles with spin.
$0-$ The wave function of two spin $1 / 2$ particles can be written in terms of spatial components multiplying pure spin states as

$$
\Psi=\Psi_{++} \uparrow \uparrow+\Psi_{+-\uparrow \downarrow}+\Psi_{-+\downarrow} \downarrow \uparrow+\Psi_{--\downarrow \downarrow}
$$

where the first arrow of each pair refers to particle 1 and the second to particle 2.
$0-$ In terms of spatial components, the inner product $\left\langle\Psi_{1} \mid \Psi_{2}\right\rangle$ evaluates as inner products of matching spin components:

$$
\left\langle\Psi_{1++} \mid \Psi_{2++}\right\rangle+\left\langle\Psi_{1+-} \mid \Psi_{2+-}\right\rangle+\left\langle\Psi_{1-+} \mid \Psi_{2-+}\right\rangle+\left\langle\Psi_{1--} \mid \Psi_{2--}\right\rangle
$$

$0-$ The four spin basis states $\uparrow \uparrow, \uparrow \downarrow, \downarrow \uparrow$, and $\downarrow \downarrow$ are an orthonormal quartet.

### 5.5.4 Review Questions

1. As an example of the orthonormality of the two-particle spin states, verify that $\langle\uparrow \uparrow \mid \downarrow \uparrow\rangle$ is zero, so that $\uparrow \uparrow$ and $\downarrow \uparrow$ are indeed orthogonal. Do so by explicitly writing out the sums over $S_{z 1}$ and $S_{z 2}$.
Solution complexsb-a
2. A more concise way of understanding the orthonormality of the twoparticle spin states is to note that an inner product like $\langle\uparrow \uparrow \mid \downarrow \uparrow\rangle$ equals $\langle\uparrow \mid \downarrow\rangle\langle\uparrow \mid \uparrow\rangle$, where the first inner product refers to the spin states of particle 1 and the second to those of particle 2 . The first inner product is zero because of the orthogonality of $\uparrow$ and $\downarrow$, making $\langle\uparrow \uparrow \mid \downarrow \uparrow\rangle$ zero too.
To check this argument, write out the sums over $S_{z 1}$ and $S_{z 2}$ for $\langle\uparrow \mid \downarrow\rangle\langle\uparrow \mid \uparrow\rangle$ and verify that it is indeed the same as the written out sum for $\langle\uparrow \uparrow \mid \downarrow \uparrow\rangle$ given in the answer for the previous question.
The underlying mathematical principle is that sums of products can be factored into separate sums as in:

$$
\sum_{\text {all } S_{z 1} \text { all } S_{z 2}} f\left(S_{z 1}\right) g\left(S_{z 2}\right)=\left[\sum_{\text {all } S_{z 1}} f\left(S_{z 1}\right)\right]\left[\sum_{\text {all } S_{z 2}} g\left(S_{z 2}\right)\right]
$$

This is similar to the observation in calculus that integrals of products can be factored into separate integrals:

$$
\begin{aligned}
& \int_{\text {all } \vec{r}_{1}} \int_{\text {all } \vec{r}_{2}} f\left(\vec{r}_{1}\right) g\left(\vec{r}_{2}\right) \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}= \\
& \quad\left[\int_{\text {all } \vec{r}_{1}} f\left(\vec{r}_{1}\right) \mathrm{d}^{3} \vec{r}_{1}\right]\left[\int_{\text {all } \vec{r}_{2}} g\left(\vec{r}_{2}\right) \mathrm{d}^{3} \vec{r}_{2}\right]
\end{aligned}
$$

## Solution complexsb-b

### 5.5.5 Example: the hydrogen molecule

As an example, this section considers the ground state of the hydrogen molecule. It was found in section 5.2 that the ground state electron wave function must be of the approximate form

$$
\psi_{\mathrm{gs}, 0}=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{\mathrm{l}}\left(\vec{r}_{2}\right)\right]
$$

where $\psi_{1}$ was the electron ground state of the left hydrogen atom, and $\psi_{\mathrm{r}}$ the one of the right one; $a$ was just a normalization constant. This solution excluded all consideration of spin.

Including spin, the ground state wave function must be of the general form

$$
\psi_{\mathrm{gs}}=\psi_{++} \uparrow \uparrow+\psi_{+-} \uparrow \downarrow+\psi_{-+\downarrow} \downarrow \uparrow+\psi_{--} \downarrow \downarrow
$$

As you might guess, in the ground state, each of the four spatial functions $\psi_{++}$, $\psi_{+-}, \psi_{-+}$, and $\psi_{--}$must be proportional to the no-spin solution $\psi_{\mathrm{gs}, 0}$ above. Anything else would have more than the lowest possible energy, $\{\mathrm{D} .24\}$.

So the approximate ground state including spin must take the form

$$
\begin{equation*}
\psi_{\mathrm{gs}}=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right]\left[a_{++} \uparrow \uparrow+a_{+-} \uparrow \downarrow+a_{-+\downarrow} \uparrow+a_{--\downarrow \downarrow} \downarrow\right. \tag{5.25}
\end{equation*}
$$

where $a_{++}, a_{+-}, a_{-+}$, and $a_{--}$are constants.

## Key Points

0 - The electron wave function $\psi_{\mathrm{gs}, 0}$ for the hydrogen molecule derived previously ignored spin.
$0-$ In the full electron wave function, each spatial component must separately be proportional to $a\left(\psi_{1} \psi_{\mathrm{r}}+\psi_{\mathrm{r}} \psi_{\mathrm{l}}\right)$.

### 5.5.5 Review Questions

1. Show that the normalization requirement for $\psi_{\mathrm{gs}}$ means that

$$
\left|a_{++}\right|^{2}+\left|a_{+-}\right|^{2}+\left|a_{-+}\right|^{2}+\left|a_{--}\right|^{2}=1
$$

Solution complexsc-a

### 5.5.6 Triplet and singlet states

In the case of two particles with spin $1 / 2$, it is often more convenient to use slightly different basis states to describe the spin states than the four arrow
combinations $\uparrow \uparrow, \uparrow \downarrow, ~ \downarrow \uparrow$, and $\downarrow \downarrow$. The more convenient basis states can be written in $|s m\rangle$ ket notation, and they are:

$$
\underbrace{|11\rangle=\uparrow \uparrow \quad|10\rangle=\frac{1}{\sqrt{2}}(\uparrow \downarrow+\downarrow \uparrow) \quad|1-1\rangle=\downarrow \downarrow}_{\text {the triplet states }} \quad \underbrace{|00\rangle=\frac{1}{\sqrt{2}}(\uparrow \downarrow-\downarrow \uparrow)}_{\text {the singlet state }}
$$

A state $|s m\rangle$ has net spin $s$, giving a net square angular momentum $s(s+1) \hbar^{2}$, and has net angular momentum in the $z$-direction $m \hbar$. For example, if the two particles are in the state $|11\rangle$, the net square angular momentum is $2 \hbar^{2}$, and their net angular momentum in the $z$-direction is $\hbar$.

The $\uparrow \downarrow$ and $\downarrow \uparrow$ states can be written as

$$
\uparrow \downarrow=\frac{1}{\sqrt{2}}(|10\rangle+|00\rangle) \quad \downarrow \uparrow=\frac{1}{\sqrt{2}}(|10\rangle-|00\rangle)
$$

This shows that while they have zero angular momentum in the $z$-direction; they do not have a value for the net spin: they have a $50 / 50$ probability of net spin 1 and net spin 0 . A consequence is that $\uparrow \downarrow$ and $\downarrow \uparrow$ cannot be written in $|s m\rangle$ ket notation; there is no value for $s$. (Related to that, these states also do not have a definite value for the dot product of the two spins, $\{$ A.10 .

Incidentally, note that $z$ components of angular momentum simply add up, as the Newtonian analogy suggests. For example, for $\uparrow \downarrow$, the $\frac{1}{2} \hbar$ spin angular momentum of the first electron adds to the $-\frac{1}{2} \hbar$ of the second electron to produce zero. But Newtonian analysis does not allow square angular momenta to be added together, and neither does quantum mechanics. In fact, it is quite a messy exercise to actually prove that the triplet and singlet states have the net spin values claimed above. (See chapter 12 if you want to see how it is done.)

The spin states $\uparrow=|1 / 21 / 2\rangle$ and $\downarrow=|1 / 2-1 / 2\rangle$ that apply for a single spin- $\frac{1}{2}$ particle are often referred to as the "doublet" states, since there are two of them.

## Key Points

$0=$ The set of spin states $\uparrow \uparrow, \uparrow \downarrow, \downarrow \uparrow$, and $\downarrow \downarrow$ are often better replaced by the triplet and singlet states $|11\rangle,|10\rangle,|1-1\rangle$, and $|00\rangle$.
$0=$ The triplet and singlet states have definite values for the net square spin.

### 5.5.6 Review Questions

1. Like the states $\uparrow \uparrow, \uparrow \downarrow, \downarrow \uparrow$, and $\downarrow \downarrow$; the triplet and singlet states are an orthonormal quartet. For example, check that the inner product of $|10\rangle$ and $|00\rangle$ is zero.

### 5.6 Identical Particles

A number of the counter-intuitive features of quantum mechanics have already been discussed: Electrons being neither on Mars or on Venus until they pop up at either place. Superluminal interactions. The fundamental impossibility of improving the accuracy of both position and momentum beyond a given limit. Collapse of the wave function. A hidden random number generator. Quantized energies and angular momenta. Nonexisting angular momentum vectors. Intrinsic angular momentum. But nature has one more trick on its sleeve, and it is a big one.

Nature entangles all identical particles with each other. Specifically, it requires that the wave function remains unchanged if any two identical bosons are exchanged. If particles $i$ and $j$ are identical bosons, then:

$$
\begin{equation*}
\Psi\left(\vec{r}_{1}, S_{z 1}, \ldots, \vec{r}_{i}, S_{z i}, \ldots, \vec{r}_{j}, S_{z j}, \ldots\right)=\Psi\left(\vec{r}_{1}, S_{z 1}, \ldots, \vec{r}_{j}, S_{z j}, \ldots, \vec{r}_{i}, S_{z i}, \ldots\right) \tag{5.27}
\end{equation*}
$$

On the other hand, nature requires that the wave function changes sign if any two identical fermions are exchanged. If particles $i$ and $j$ are identical fermions, (say, both electrons), then:

$$
\begin{equation*}
\Psi\left(\vec{r}_{1}, S_{z 1}, \ldots, \vec{r}_{i}, S_{z i}, \ldots, \vec{r}_{j}, S_{z j}, \ldots\right)=-\Psi\left(\vec{r}_{1}, S_{z 1}, \ldots, \vec{r}_{j}, S_{z j}, \ldots, \vec{r}_{i}, S_{z i}, \ldots\right) \tag{5.28}
\end{equation*}
$$

In other words, the wave function must be symmetric with respect to exchange of identical bosons, and antisymmetric with respect to exchange of identical fermions. This greatly restricts what wave functions can be.

For example, consider what this means for the electron structure of the hydrogen molecule. The approximate ground state of lowest energy was in the previous section found to be

$$
\psi_{\mathrm{gs}}=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{\mathrm{l}}\left(\vec{r}_{2}\right)\right]\left[a_{++} \uparrow \uparrow+a_{+-} \uparrow \downarrow+a_{-+\downarrow} \downarrow+a_{--\downarrow \downarrow]}\right. \text { (5.29) }
$$

were $\psi_{1}$ was the ground state of the left hydrogen atom, $\psi_{\mathrm{r}}$ the one of the right one, first arrows indicate the spin of electron 1 and second arrows the one of electron 2, and $a$ and the $a_{ \pm \pm}$are constants.

But since the two electrons are identical fermions, this wave function must turn into its negative under exchange of the two electrons. Exchanging the two electrons produces

$$
-\psi_{\mathrm{gs}}=a\left[\psi_{1}\left(\vec{r}_{2}\right) \psi_{\mathrm{r}}\left(\vec{r}_{1}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{2}\right) \psi_{1}\left(\vec{r}_{1}\right)\right]\left[a_{++} \uparrow \uparrow+a_{+-\downarrow \uparrow}+a_{-+} \uparrow \downarrow+a_{--\downarrow \downarrow} \downarrow\right] ;
$$

note in particular that since the first arrow of each pair is taken to refer to electron 1 , exchanging the electrons means that the order of each pair of arrows must be inverted. To compare the above wave function with the nonexchanged version (5.29), reorder the terms back to the same order:

$$
-\psi_{\mathrm{gs}}=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathbf{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right]\left[a_{++} \uparrow \uparrow+a_{-+} \uparrow \downarrow+a_{+-} \downarrow \uparrow+a_{--\downarrow \downarrow}\right]
$$

The spatial factor is seen to be the same as the nonexchanged version in (5.29); the spatial part is symmetric under particle exchange. The sign change will have to come from the spin part.

Since each of the four spin states is independent from the others, the coefficient of each of these states will have to be the negative of the one of the nonexchanged version. For example, the coefficient $a_{++}$of $\uparrow \uparrow$ must be the negative of the coefficient $a_{++}$of $\uparrow \uparrow$ in the nonexchanged version, otherwise there is a conflict at $S_{z 1}=\frac{1}{2} \hbar$ and $S_{z 2}=\frac{1}{2} \hbar$, where only the spin state $\uparrow \uparrow$ is nonzero. Something can only be the negative of itself if it is zero, so $a_{++}$must be zero to satisfy the antisymmetry requirement. The same way, $a_{--}=-a_{--}$, requiring $a_{--}$to be zero too. The remaining two spin states both require that $a_{+-}=$ $-a_{-+}$, but this can be nonzero.

So, due to the antisymmetrization requirement, the full wave function of the ground state must be,

$$
\psi_{\mathrm{gs}}=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right] a_{+-}[\uparrow \downarrow-\downarrow \uparrow]
$$

or after normalization, noting that a factor of magnitude one is always arbitrary,

$$
\psi_{\mathrm{gs}}=a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right] \frac{\uparrow \downarrow-\downarrow \uparrow}{\sqrt{2}}
$$

It is seen that the antisymmetrization requirement restricts the spin state to be the "singlet" one, as defined in the previous section. It is the singlet spin state that achieves the sign change when the two electrons are exchanged; the spatial part remains the same.

If the electrons would have been bosons, the spin state could have been any combination of the three triplet states. The symmetrization requirement for fermions is much more restrictive than the one for bosons.

Since there are a lot more electrons in the universe than just these two, you might rightly ask where antisymmetrization stops. The answer given in chapter 8.3 is: nowhere. But don't worry about it. The existence of electrons that are too far away to affect the system being studied can be ignored.

## Key Points

$0-$ The wave function must be symmetric (must stay the same) under exchange of identical bosons.
$0-$ The wave function must be antisymmetric (must turn into its negative) under exchange of identical fermions (e.g., electrons.)
$0-$ Especially the antisymmetrization requirement greatly restricts what wave functions can be.
$0-$ The antisymmetrization requirement forces the electrons in the hydrogen molecule ground state to assume the singlet spin state.

### 5.6 Review Questions

1. Check that indeed any linear combination of the triplet states is unchanged under particle exchange.

Solution ident-a
2. Suppose the electrons of the hydrogen molecule are in the excited antisymmetric spatial state

$$
a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)-\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right] .
$$

In that case what can you say about the spin state?
Yes, in this case the spin would be less restricted if the electrons were bosons. But antisymmetric spatial states themselves are pretty restrictive in general. The precise sense in which the antisymmetrization requirement is more restrictive than the symmetrization requirement will be explored in the next section.
Solution ident-b

### 5.7 Ways to Symmetrize the Wave Function

This section discusses ways in which the symmetrization requirements for wave functions of systems of identical particles can be achieved in general. This is a key issue in the numerical solution of any nontrivial quantum system, so this section will examine it in some detail.

It will be assumed that the approximate description of the wave function is done using a set of chosen single-particle functions, or "states",

$$
\psi_{1}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \psi_{2}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \ldots
$$

An example is provided by the approximate ground state of the hydrogen molecule from the previous section,

$$
a\left[\psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right)\right] \frac{\uparrow \downarrow-\downarrow \uparrow}{\sqrt{2}} .
$$

This can be multiplied out to be

$$
\begin{aligned}
& \frac{a}{\sqrt{2}}\left[\psi_{1}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 2}\right)+\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right) \psi_{1}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 2}\right)\right. \\
& \left.\quad-\psi_{1}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 2}\right)-\psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right) \psi_{1}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 2}\right)\right]
\end{aligned}
$$

and consists of four single-particle functions:

$$
\begin{array}{ll}
\psi_{1}^{\mathrm{p}}\left(\vec{r}, S_{z}\right)=\psi_{1}(\vec{r}) \uparrow\left(S_{z}\right) & \psi_{2}^{\mathrm{p}}\left(\vec{r}, S_{z}\right)=\psi_{1}(\vec{r}) \downarrow\left(S_{z}\right) \\
\psi_{3}^{\mathrm{p}}\left(\vec{r}, S_{z}\right)=\psi_{\mathrm{r}}(\vec{r}) \uparrow\left(S_{z}\right) & \psi_{4}^{\mathrm{p}}\left(\vec{r}, S_{z}\right)=\psi_{\mathrm{r}}(\vec{r}) \downarrow\left(S_{z}\right)
\end{array}
$$

The first of the four functions represents a single electron in the ground state around the left proton with spin up, the second a single electron in the same spatial state with spin down, etcetera. For better accuracy, more single-particle functions could be included, say excited atomic states in addition to the ground states. In terms of the above four functions, the expression for the hydrogen molecule ground state is

$$
\begin{aligned}
& \frac{a}{\sqrt{2}} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+\frac{a}{\sqrt{2}} \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
- & \frac{a}{\sqrt{2}} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)-\frac{a}{\sqrt{2}} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{aligned}
$$

The issue in this section is that the above hydrogen ground state is just one special case of the most general wave function for the two particles that can be formed from four single-particle states:

$$
\begin{aligned}
& \Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right)= \\
& a_{11} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{12} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+ \\
& a_{13} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{14} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+ \\
& a_{21} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{22} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+ \\
& a_{23} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{24} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+ \\
& a_{31} \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{32} \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+ \\
& a_{33} \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{34} \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+ \\
& a_{41} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{42} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+ \\
& a_{43} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{44} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{aligned}
$$

This can be written much more concisely using summation indices as

$$
\Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right)=\sum_{n_{1}=1}^{4} \sum_{n_{2}=1}^{4} a_{n_{1} n_{2}} \psi_{n_{1}}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{n_{2}}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
$$

However, the individual terms will be fully written out for now to reduce the mathematical abstraction. The individual terms are sometimes called "Hartree products."

The antisymmetrization requirement says that the wave function must be antisymmetric under exchange of the two electrons. More concretely, it must turn into its negative when the arguments $\vec{r}_{1}, S_{z 1}$ and $\vec{r}_{2}, S_{z 2}$ are swapped. To
understand what that means, the various terms need to be arranged in groups:

$$
\begin{aligned}
& a_{11} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& a_{22} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{21}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& a_{33} \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& a_{44} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{\mathrm{p}}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& a_{12} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{21} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& a_{13} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{31} \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& a_{14} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{41} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& \left.a_{23} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{32} \psi_{3}^{\mathrm{p}} \vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
& \left.\left.a_{24} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}} \vec{r}_{2}, S_{z 2}+a_{42} \psi_{4}^{\mathrm{p}} \vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}} \vec{r}_{2}, S_{22}\right) \\
& a_{34} \psi_{3}^{\mathrm{p}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+a_{43} \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)}
\end{aligned}
$$

Within each group, all terms involve the same combination of functions, but in a different order. Different groups have a different combination of functions.

Now if the electrons are exchanged, it turns the terms in groups I through IV back into themselves. Since the wave function must change sign in the exchange, and something can only be its own negative if it is zero, the antisymmetrization requirement requires that the coefficients $a_{11}, a_{22}, a_{33}$, and $a_{44}$ must all be zero. Four coefficients have been eliminated from the list of unknown quantities.

Further, in each of the groups $V$ through X with two different states, exchange of the two electrons turn the terms into each other, except for their coefficients. If that is to achieve a change of sign, the coefficients must be each other's negatives; $a_{21}=-a_{12}, a_{31}=-a_{13}, \ldots$ So only six coefficients $a_{12}$, $a_{13}, \ldots$ still need to be found from other physical requirements, such as energy minimization for a ground state. Less than half of the original sixteen unknowns survive the antisymmetrization requirement, significantly reducing the problem size.

There is a very neat way of writing the antisymmetrized wave function of systems of fermions, which is especially convenient for larger numbers of particles. It is done using determinants. The antisymmetric wave function for the above example is:

$$
\begin{aligned}
\Psi= & a_{12}\left|\begin{array}{ll}
\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \\
\psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{array}\right|+a_{13}\left|\begin{array}{ll}
\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \\
\psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{array}\right|+ \\
& a_{14}\left|\begin{array}{ll}
\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \\
\psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{array}\right|+a_{23}\left|\begin{array}{ll}
\psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \\
\psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{array}\right|+ \\
& a_{24}\left|\begin{array}{lll}
\psi_{2}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \\
\psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{array}\right|+a_{34}\left|\begin{array}{ll}
\psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{4}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \\
\psi_{3}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)
\end{array}\right|
\end{aligned}
$$

These determinants are called "Slater determinants".
To find the actual hydrogen molecule ground state from the above expression, additional physical requirements have to be imposed. For example, the
coefficients $a_{12}$ and $a_{34}$ can reasonably be ignored for the ground state, because according to the given definition of the states, their Slater determinants have the electrons around the same nucleus, and that produces elevated energy due to the mutual repulsion of the electrons. Also, following the arguments of section 5.2 , the coefficients $a_{13}$ and $a_{24}$ must be zero since their Slater determinants produce the excited antisymmetric spatial state $\psi_{1} \psi_{\mathrm{r}}-\psi_{\mathrm{r}} \psi_{1}$ times the $\uparrow \uparrow$, respectively $\downarrow \downarrow$ spin states. Finally, the coefficients $a_{14}$ and $a_{23}$ must be opposite in order that their Slater determinants combine into the lowest-energy symmetric spatial state $\psi_{1} \psi_{\mathrm{r}}+\psi_{\mathrm{r}} \psi_{1}$ times the $\uparrow \downarrow$ and $\downarrow \uparrow$ spin states. That leaves the single coefficient $a_{14}$ that can be found from the normalization requirement, taking it real and positive for convenience.

But the issue in this section is what the symmetrization requirements say about wave functions in general, whether they are some ground state or not. And for four single-particle states for two identical fermions, the conclusion is that the wave function must be some combination of the six Slater determinants, regardless of what other physics may be relevant.

The next question is how that conclusion changes if the two particles involved are not fermions, but identical bosons. The symmetrization requirement is then that exchanging the particles must leave the wave function unchanged. Since the terms in groups I through IV do remain the same under particle exchange, their coefficients $a_{11}$ through $a_{44}$ can have any nonzero value. This is the sense in which the antisymmetrization requirement for fermions is much more restrictive than the one for bosons: groups involving a duplicated state must be zero for fermions, but not for bosons.

In groups $V$ through $X$, where particle exchange turns each of the two terms into the other one, the coefficients must now be equal instead of negatives; $a_{21}$ $=a_{12}, a_{31}=a_{13}, \ldots$ That eliminates six coefficients from the original sixteen unknowns, leaving ten coefficients that must be determined by other physical requirements on the wave function.
(The equivalent of Slater determinants for bosons are "permanents," basically determinants with all minus signs in their definition replaced by plus signs. Unfortunately, many of the helpful properties of determinants do not apply to permanents.)

All of the above arguments can be extended to the general case that $N$, instead of 4 , single-particle functions $\psi_{1}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \psi_{2}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \ldots, \psi_{N}^{\mathrm{p}}\left(\vec{r}, S_{z}\right)$ are used to describe $I$, instead of 2 , particles. Then the most general possible wave function assumes the form:

$$
\begin{equation*}
\Psi=\sum_{n_{1}=1}^{N} \sum_{n_{2}=1}^{N} \ldots \sum_{n_{I}=1}^{N} a_{n_{1} n_{2} \ldots n_{I}} \psi_{n_{1}}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{n_{2}}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \ldots \psi_{n_{I}}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right) \tag{5.30}
\end{equation*}
$$

where the $a_{n_{1} n_{2} \ldots n_{I}}$ are numerical coefficients that are to be chosen to satisfy the physical constraints on the wave function, including the (anti) symmetrization requirements.

This summation is again the "every possible combination" idea of combining every possible state for particle 1 with every possible state for particle 2 , etcetera. So the total sum above contains $N^{I}$ terms: there are $N$ possibilities for the function number $n_{1}$ of particle 1 , times $N$ possibilities for the function number $n_{2}$ of particle $2, \ldots$ In general then, a corresponding total of $N^{I}$ unknown coefficients $a_{n_{1} n_{2} \ldots n_{I}}$ must be determined to find out the precise wave function.

But for identical particles, the number that must be determined is much less. That number can again be determined by dividing the terms into groups in which the terms all involve the same combination of $I$ single-particle functions, just in a different order. The simplest groups are those that involve just a single single-particle function, generalizing the groups I through IV in the earlier example. Such groups consist of only a single term; for example, the group that only involves $\psi_{1}^{\mathrm{p}}$ consists of the single term

$$
a_{11 \ldots 1} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \ldots \psi_{1}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right)
$$

At the other extreme, groups in which every single-particle function is different have as many as $I!$ terms, since $I$ ! is the number of ways that $I$ different items can be ordered. In the earlier example, that were groups V through X , each having $2!=2$ terms. If there are more than two particles, there will also be groups in which some states are the same and some are different.

For identical bosons, the symmetrization requirement says that all the coefficients within a group must be equal. Any term in a group can be turned into any other by particle exchanges; so, if they would not all have the same coefficients, the wave function could be changed by particle exchanges. As a result, for identical bosons the number of unknown coefficients reduces to the number of groups.

For identical fermions, only groups in which all single-particle functions are different can be nonzero. That follows because if a term has a duplicated singleparticle function, it turns into itself without the required sign change under an exchange of the particles of the duplicated function.

So there is no way to describe a system of $I$ identical fermions with anything less than $I$ different single-particle functions $\psi_{n}^{\mathrm{p}}$. This critically important observation is known as the "Pauli exclusion principle:" $I-1$ fermions occupying $I-1$ single-particle functions exclude a $I$-th fermion from simply entering the same $I-1$ functions; a new function must be added to the mix for each additional fermion. The more identical fermions there are in a system, the more different single-particle functions are required to describe it.

Each group involving $I$ different single-particle functions $\psi_{n_{1}}^{\mathrm{p}}, \psi_{n_{2}}^{\mathrm{p}}, \ldots \psi_{n_{I}}^{\mathrm{p}}$ reduces under the antisymmetrization requirement to a single Slater determinant
of the form

$$
\frac{1}{\sqrt{I!}}\left|\begin{array}{ccccc}
\psi_{n_{1}}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{n_{2}}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \psi_{n_{3}}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) & \cdots & \psi_{n_{I}}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right)  \tag{5.31}\\
\psi_{n_{1}}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \psi_{n_{2}}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) & \left.\psi_{n_{3}}^{\mathrm{p}} \vec{r}_{2}, S_{z 2}\right) & \cdots & \psi_{n_{I}}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \\
\psi_{n_{1}}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) & \psi_{n_{2}}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) & \left.\psi_{n_{3}}^{\mathrm{p}} \vec{r}_{3}, S_{z 3}\right) & \cdots & \psi_{n_{I}}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
\psi_{n_{1}}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right) & \psi_{n_{2}}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right) & \psi_{n_{3}}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right) & \cdots & \psi_{n_{I}}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right)
\end{array}\right|
$$

multiplied by a single unknown coefficient. The normalization factor $1 / \sqrt{I!}$ has been thrown in merely to ensure that if the functions $\psi_{n}^{\mathrm{p}}$ are orthonormal, then so are the Slater determinants. Using Slater determinants ensures the required sign changes of fermion systems automatically, because determinants change sign if two rows are exchanged.

In the case that the bare minimum of $I$ functions is used to describe $I$ identical fermions, only one Slater determinant can be formed. Then the antisymmetrization requirement reduces the $I^{I}$ unknown coefficients $a_{n_{1} n_{2} \ldots n_{I}}$ to just one, $a_{12 \ldots I}$; obviously a tremendous reduction.

At the other extreme, when the number of functions $N$ is very large, much larger than $I^{2}$ to be precise, most terms have all indices different and the reduction is "only" from $N^{I}$ to about $N^{I} / I$ ! terms. The latter would also be true for identical bosons.

The functions better be chosen to produce a good approximation to the wave function with a small number of terms. As an arbitrary example to focus the thoughts, if $N=100$ functions are used to describe an arsenic atom, with $I=$ 33 electrons, there would be a prohibitive $10^{66}$ terms in the sum (5.30). Even after reduction to Slater determinants, there would still be a prohibitive $310^{26}$ or so unknown coefficients left. The precise expression for the number of Slater determinants is called " $N$ choose $I$;" it is given by

$$
\binom{N}{I}=\frac{N!}{(N-I)!I!}=\frac{N(N-1)(N-2) \ldots(N-I+1)}{I!}
$$

since the top gives the total number of terms that have all functions different, $(N$ possible functions for particle 1 , times $N-1$ possible functions left for particle 2 , etcetera, ) and the bottom reflects that it takes $I$ ! of them to form a single Slater determinant. $\{$ D. 25$\}$.

The basic "Hartree-Fock" approach, discussed in chapter 9.3, goes to the extreme in reducing the number of functions: it uses the very minimum of $I$ single-particle functions. However, rather than choosing these functions a priori, they are adjusted to give the best approximation that is possible with a single Slater determinant. Unfortunately, if a single determinant still turns out to be not accurate enough, adding a few more functions quickly blows up in your face. Adding just one more function gives $I$ more determinants; adding another function gives another $I(I+1) / 2$ more determinants, etcetera.

## Key Points

0- Wave functions for multiple-particle systems can be formed using sums of products of single-particle wave functions.
$0-$ The coefficients of these products are constrained by the symmetrization requirements.
$0-$ In particular, for identical fermions such as electrons, the singleparticle wave functions must combine into Slater determinants.
$0-$ Systems of identical fermions require at least as many single-particle states as there are particles. This is known as the Pauli exclusion principle.
$0-$ If more single-particle states are used to describe a system, the problem size increases rapidly.

### 5.8 Matrix Formulation

When the number of unknowns in a quantum mechanical problem has been reduced to a finite number, the problem can be reduced to a linear algebra one. This allows the problem to be solved using standard analytical or numerical techniques. This section describes how the linear algebra problem can be obtained.

Typically, quantum mechanical problems can be reduced to a finite number of unknowns using some finite set of chosen wave functions, as in the previous section. There are other ways to make the problems finite, it does not really make a difference here. But in general some simplification will still be needed afterwards. A multiple sum like equation (5.30) for distinguishable particles is awkward to work with, and when various coefficients drop out for identical particles, its gets even messier. So as a first step, it is best to order the terms involved in some way; any ordering will in principle do. Ordering allows each term to be indexed by a single counter $q$, being the place of the term in the ordering.

Using an ordering, the wave function for a total of $I$ particles can be written more simply as

$$
\Psi=a_{1} \psi_{1}^{\mathrm{S}}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{I}, S_{z I}\right)+a_{2} \psi_{2}^{\mathrm{S}}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{I}, S_{z I}\right)+\ldots
$$

or in index notation:

$$
\begin{equation*}
\Psi=\sum_{q=1}^{Q} a_{q} \psi_{q}^{\mathrm{S}}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{I}, S_{z I}\right) \tag{5.32}
\end{equation*}
$$

where $Q$ is the total count of the chosen $I$-particle wave functions and the single counter $q$ in $a_{q}$ replaces a set of $I$ indices in the description used in the previous section. The $I$-particle functions $\psi_{q}^{\mathrm{S}}$ are allowed to be anything; individual (Hartree) products of single-particle wave functions for distinguishable particles as in (5.30), Slater determinants for identical fermions, permanents for identical bosons, or whatever. The only thing that will be assumed is that they are mutually orthonormal. (Which means that any underlying set of single-particle functions $\psi_{n}^{\mathrm{p}}(\vec{r})$ as described in the previous section should be orthonormal. If they are not, there are procedures like Gram-Schmidt to make them so. Or you can just put in some correction terms.)

Under those conditions, the energy eigenvalue problem $H \psi=E \psi$ takes the form:

$$
\sum_{q=1}^{Q} H a_{q} \psi_{q}^{\mathrm{S}}=\sum_{q=1}^{Q} E a_{q} \psi_{q}^{\mathrm{S}}
$$

The trick is now to take the inner product of both sides of this equation with each function $\psi_{\underline{q}}^{S}$ in the set of wave functions in turn. In other words, take an inner product with $\left\langle\psi_{1}^{\mathrm{S}}\right|$ to get one equation, then take an inner product with $\left\langle\psi_{2}^{S}\right|$ to get a second equation, and so on. This produces, using the fact that the functions are orthonormal to clean up the right-hand side,

$$
\begin{array}{ccccccccc}
H_{11} a_{1} & + & H_{12} a_{2} & + & \ldots & + & H_{1 Q} a_{Q} & =E a_{1} \\
H_{21} a_{1} & + & H_{22} a_{2} & + & \ldots & + & H_{2 Q} a_{Q} & =E a_{2} \\
\vdots & \vdots & \vdots & \vdots & & \vdots & \vdots & & \vdots \\
H_{q 1} a_{1} & + & H_{\underline{q} 2} a_{2} & + & \ldots & + & H_{\underline{q} Q} a_{Q} & =E a_{\underline{q}} \\
\vdots & \vdots & \vdots & \vdots & & \vdots & \vdots & \vdots \\
H_{Q 1} a_{1} & + & H_{Q 2} a_{2} & + & \ldots & + & H_{Q Q} a_{Q} & =E a_{Q}
\end{array}
$$

where

$$
H_{11}=\left\langle\psi_{1}^{\mathrm{S}} \mid H \psi_{1}^{\mathrm{S}}\right\rangle, \quad H_{12}=\left\langle\psi_{1}^{\mathrm{S}} \mid H \psi_{2}^{\mathrm{S}}\right\rangle, \ldots, H_{Q Q}=\left\langle\psi_{Q}^{\mathrm{S}} \mid H \psi_{Q}^{\mathrm{S}}\right\rangle
$$

are the matrix coefficients, or Hamiltonian coefficients.

This can again be written more compactly in index notation:

$$
\begin{equation*}
\sum_{q=1}^{Q} H_{\underline{q q}} a_{q}=E a_{\underline{q}} \quad \text { for } \underline{q}=1,2, \ldots, Q \quad \text { with } H_{\underline{q} q}=\left\langle\psi_{\underline{q}}^{S} \mid H \psi_{q}^{\mathrm{S}}\right\rangle \tag{5.33}
\end{equation*}
$$

which is just a finite-size matrix eigenvalue problem.
Since the functions $\psi_{q}^{S}$ are known, chosen, functions, and the Hamiltonian $H$ is also known, the matrix coefficients $H_{\underline{q} q}$ can be determined. The eigenvalues $E$ and corresponding eigenvectors ( $a_{1}, \overline{a_{2}}, \ldots$ ) can then be found using linear algebra procedures. Each eigenvector produces a corresponding approximate eigenfunction $a_{1} \psi_{1}^{\mathrm{S}}+a_{2} \psi_{2}^{\mathrm{S}}+\ldots$ with an energy equal to the eigenvalue $E$.

## Key Points

$0-$ Operator eigenvalue problems can be approximated by the matrix eigenvalue problems of linear algebra.
$0-$ That allows standard analytical or numerical techniques to be used in their solution.

### 5.8 Review Questions

1. As a relatively simple example, work out the above ideas for the $Q=2$ hydrogen molecule spatial states $\psi_{1}^{\mathrm{S}}=\psi_{1} \psi_{\mathrm{r}}$ and $\psi_{2}^{\mathrm{S}}=\psi_{1} \psi_{\mathrm{r}}$. Write the matrix eigenvalue problem and identify the two eigenvalues and eigenvectors. Compare with the results of section 5.3.
Assume that $\psi_{1}$ and $\psi_{\mathrm{r}}$ have been slightly adjusted to be orthonormal. Then so are $\psi_{1}^{\mathrm{S}}$ and $\psi_{2}^{\mathrm{S}}$ orthonormal, since the various six-dimensional inner product integrals, like

$$
\begin{aligned}
&\left\langle\psi_{1}^{\mathrm{S}} \mid \psi_{2}^{\mathrm{S}}\right\rangle \equiv\left\langle\psi_{1} \psi_{\mathrm{r}} \mid \psi_{\mathrm{r}} \psi_{1}\right\rangle \equiv \\
& \quad \int_{\text {all } \vec{r}_{1}} \int_{\text {all }} \vec{r}_{2} \psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{2}\right) \psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \psi_{1}\left(\vec{r}_{2}\right) \mathrm{d}^{3} \vec{r}_{1} \mathrm{~d}^{3} \vec{r}_{2}
\end{aligned}
$$

can according to the rules of calculus be factored into three-dimensional integrals as

$$
\begin{aligned}
& \left\langle\psi_{1}^{\mathrm{S}} \mid \psi_{2}^{\mathrm{S}}\right\rangle \\
& \quad=\left[\int_{\text {all } \vec{r}_{1}} \psi_{1}\left(\vec{r}_{1}\right) \psi_{\mathrm{r}}\left(\vec{r}_{1}\right) \mathrm{d}^{3} \vec{r}_{1}\right]\left[\int_{\text {all } \vec{r}_{2}} \psi_{\mathrm{r}}\left(\vec{r}_{2}\right) \psi_{1}\left(\vec{r}_{2}\right) \mathrm{d}^{3} \vec{r}_{2}\right] \\
& \quad=\left\langle\psi_{1} \mid \psi_{\mathrm{r}}\right\rangle\left\langle\psi_{\mathrm{r}} \mid \psi_{1}\right\rangle
\end{aligned}
$$

which is zero if $\psi_{1}$ and $\psi_{\mathrm{r}}$ are orthonormal.

Also, do not try to find actual values for $H_{11}, H_{12}, H_{21}$, and $H_{22}$. As section 5.2 noted, that can only be done numerically. Instead just refer to $H_{11}$ as $J$ and to $H_{12}$ as $-L$ :

$$
\begin{gathered}
H_{11} \equiv\left\langle\psi_{1}^{\mathrm{S}} \mid H \psi_{1}^{\mathrm{S}}\right\rangle \equiv\left\langle\psi_{1} \psi_{\mathrm{r}} \mid H \psi_{1} \psi_{\mathrm{r}}\right\rangle \equiv J \\
H_{12} \equiv\left\langle\psi_{1}^{\mathrm{S}} \mid H \psi_{2}^{\mathrm{S}}\right\rangle \equiv\left\langle\psi_{1} \psi_{\mathrm{r}} \mid H \psi_{\mathrm{r}} \psi_{1}\right\rangle \equiv-L
\end{gathered}
$$

Next note that you also have

$$
\begin{gathered}
H_{22} \equiv\left\langle\psi_{2}^{\mathrm{S}} \mid H \psi_{2}^{\mathrm{S}}\right\rangle \equiv\left\langle\psi_{\mathrm{r}} \psi_{1} \mid H \psi_{\mathrm{r}} \psi_{1}\right\rangle=J \\
H_{21} \equiv\left\langle\psi_{2}^{\mathrm{S}} \mid H \psi_{1}^{\mathrm{S}}\right\rangle \equiv\left\langle\psi_{\mathrm{r}} \psi_{1} \mid H \psi_{1} \psi_{\mathrm{r}}\right\rangle=-L
\end{gathered}
$$

because they are the exact same inner product integrals; the difference is just which electron you number 1 and which one you number 2 that determines whether the wave functions are listed as $\psi_{1} \psi_{\mathrm{r}}$ or $\psi_{\mathrm{r}} \psi_{1}$.

Solution matfor-a
2. Find the eigenstates for the same problem, but now including spin.

As section 5.7 showed, the antisymmetric wave function with spin consists of a sum of six Slater determinants. Ignoring the highly excited first and sixth determinants that have the electrons around the same nucleus, the remaining $C=4$ Slater determinants can be written out explicitly to give the two-particle states

$$
\begin{array}{ll}
\psi_{1}^{\mathrm{S}}=\frac{\psi_{1} \psi_{\mathrm{r}} \uparrow \uparrow-\psi_{\mathrm{r}} \psi_{1} \uparrow \uparrow}{\sqrt{2}} & \psi_{2}^{\mathrm{S}}=\frac{\psi_{1} \psi_{\mathrm{r}} \uparrow \downarrow-\psi_{\mathrm{r}} \psi_{1} \downarrow \uparrow}{\sqrt{2}} \\
\psi_{3}^{\mathrm{S}}=\frac{\psi_{1} \psi_{\mathrm{r}} \downarrow \uparrow-\psi_{\mathrm{r}} \psi_{1} \uparrow \downarrow}{\sqrt{2}} & \psi_{4}^{\mathrm{S}}=\frac{\psi_{1} \psi_{\mathrm{r}} \downarrow \downarrow-\psi_{\mathrm{r}} \psi_{1} \downarrow \downarrow}{\sqrt{2}}
\end{array}
$$

Note that the Hamiltonian does not involve spin, to the approximation used in most of this book, so that, following the techniques of section 5.5, an inner product like $H_{23}=\left\langle\psi_{2}^{\mathrm{S}} \mid H \psi_{3}^{\mathrm{S}}\right\rangle$ can be written out like

$$
\begin{aligned}
H_{23} & =\frac{1}{2}\left\langle\psi_{1} \psi_{\mathrm{r}} \uparrow \downarrow-\psi_{\mathrm{r}} \psi_{1} \downarrow \uparrow \mid H\left(\psi_{1} \psi_{\mathrm{r}} \downarrow \uparrow-\psi_{\mathrm{r}} \psi_{1} \uparrow \downarrow\right)\right\rangle \\
& =\frac{1}{2}\left\langle\psi_{1} \psi_{\mathrm{r}} \uparrow \downarrow-\psi_{\mathrm{r}} \psi_{1} \downarrow \uparrow \mid\left(H \psi_{1} \psi_{\mathrm{r}}\right) \downarrow \uparrow-\left(H \psi_{\mathrm{r}} \psi_{1}\right) \uparrow \downarrow\right\rangle
\end{aligned}
$$

and then multiplied out into inner products of matching spin components to give

$$
H_{23}=-\frac{1}{2}\left\langle\psi_{1} \psi_{\mathrm{r}} \mid H \psi_{\mathrm{r}} \psi_{1}\right\rangle-\frac{1}{2}\left\langle\psi_{\mathrm{r}} \psi_{1} \mid H \psi_{1} \psi_{\mathrm{r}}\right\rangle=L .
$$

The other 15 matrix coefficients can be found similarly, and most will be zero.
If you do not have experience with linear algebra, you may want to skip this question, or better, just read the solution. However, the four eigenvectors are not that hard to guess; maybe easier to guess than correctly derive.

Solution matfor-b

### 5.9 Heavier Atoms

This section solves the ground state electron configuration of the atoms of elements heavier than hydrogen. The atoms of the elements are distinguished by their "atomic number" $Z$, which is the number of protons in the nucleus. For the neutral atoms considered in this section, $Z$ is also the number of electrons circling the nucleus.

A crude approximation will be made to deal with the mutual interactions between the electrons. Still, many properties of the elements can be understood using this crude model, such as their geometry and chemical properties, and how the Pauli exclusion principle raises the energy of the electrons.

This is a descriptive section, in which no new analytical procedures are taught. However, it is a very important section to read, and reread, because much of our qualitative understanding of nature is based on the ideas in this section.

### 5.9.1 The Hamiltonian eigenvalue problem

The procedure to find the ground state of the heavier atoms is similar to the one for the hydrogen atom of chapter 4.3. The total energy Hamiltonian for the electrons of an element with atomic number $Z$ with is:

$$
\begin{equation*}
H=\sum_{i=1}^{Z}\left[-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla_{i}^{2}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{Z}{r_{i}}+\frac{1}{2} \sum_{\substack{i=1 \\ \underline{i} \neq i}}^{Z} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{\left|\vec{r}_{i}-\vec{r}_{\underline{i}}\right|}\right] \tag{5.34}
\end{equation*}
$$

Within the brackets, the first term represents the kinetic energy of electron number $i$ out of $Z$, the second the attractive potential due to the nuclear charge $Z e$, and the final term is the repulsion by all the other electrons. In the Hamiltonian as written, it is assumed that half of the energy of a repulsion is credited to each of the two electrons involved, accounting for the factor $\frac{1}{2}$.

The Hamiltonian eigenvalue problem for the energy states takes the form:

$$
H \psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{Z}, S_{z Z}\right)=E \psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{Z}, S_{z Z}\right)
$$

## Key Points

$0-$ The Hamiltonian for the electron structure has been written down.

### 5.9.2 Approximate solution using separation of variables

The Hamiltonian eigenvalue problem of the previous subsection cannot be solved exactly. The repulsive interactions between the electrons, given by the last term in the Hamiltonian are too complex.

More can be said under the, really poor, approximation that each electron "sees" a repulsion by the other $Z-1$ electrons that averages out as if the other electrons are located in the nucleus. The other $Z-1$ electrons then reduce the net charge of the nucleus from $Z e$ to $e$. An other way of saying this is that each of the $Z-1$ other electrons "shields" one proton in the nucleus, allowing only a single remaining proton charge to filter through.

In this crude approximation, the electrons do not notice each other at all; they see only a single charge hydrogen nucleus. Obviously then, the wave function solutions for each electron should be the $\psi_{n l m}$ eigenfunctions of the hydrogen atom, which were found in chapter 4.3.

To verify this explicitly, the approximate Hamiltonian is

$$
H=\sum_{i=1}^{Z}\left\{-\frac{\hbar^{2}}{2 m} \nabla_{i}^{2}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i}}\right\}
$$

since this represents a system of noninteracting electrons in which each experiences an hydrogen nucleus potential. This can be written more concisely as

$$
H=\sum_{i=1}^{Z} h_{i}
$$

where $h_{i}$ is the hydrogen-atom Hamiltonian for electron number $i$,

$$
h_{i}=-\frac{\hbar^{2}}{2 m} \nabla_{i}^{2}-\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i}} .
$$

The approximate Hamiltonian eigenvalue problem can now be solved using a method of separation of variables in which solutions are sought that take the form of products of single-electron wave functions:

$$
\psi^{Z}=\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \ldots \psi_{Z}^{\mathrm{p}}\left(\vec{r}_{Z}, S_{z Z}\right)
$$

Substitution of this assumption into the eigenvalue problem $\sum_{i} h_{i} \psi^{Z}=E \psi^{Z}$ and dividing by $\psi^{Z}$ produces

$$
\frac{1}{\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right)} h_{1} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right)+\frac{1}{\psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)} h_{2} \psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)+\ldots=E
$$

since $h_{1}$ only does anything to the factor $\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right), h_{2}$ only does anything to the factor $\psi_{2}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right)$, etcetera.

The first term in the equation above must be some constant $\epsilon_{1}$; it cannot vary with $\vec{r}_{1}$ or $S_{z 1}$ as $\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right)$ itself does, since none of the other terms in the equation varies with those variables. That means that

$$
h_{1} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right)=\epsilon_{1} \psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right)
$$

which is an hydrogen atom eigenvalue problem for the single-electron wave function of electron 1. So, the single-electron wave function of electron 1 can be any one of the hydrogen atom wave functions from chapter 4.3; allowing for spin, the possible solutions are,

$$
\psi_{100}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right), \psi_{100}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right), \psi_{200}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right), \psi_{200}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right), \ldots
$$

The energy $\epsilon_{1}$ is the corresponding hydrogen atom energy level, $E_{1}$ for $\psi_{100} \uparrow$ or $\psi_{100} \downarrow, E_{2}$ for any of the eight states $\psi_{200 \uparrow}, \psi_{200 \downarrow}, \psi_{211} \uparrow, \psi_{211 \downarrow}, \psi_{210} \uparrow, \psi_{210} \downarrow$, $\psi_{21-1} \uparrow, \psi_{21-1} \downarrow$, etcetera.

The same observations hold for the other electrons; their single-electron eigenfunctions are $\psi_{n l m} \downarrow$ hydrogen atom ones, (where $\downarrow$ can be either $\uparrow$ or $\downarrow$.) Their individual energies must be the corresponding hydrogen atom energy levels.

The final wave functions for all $Z$ electrons are then each a product of $Z$ hydrogen-atom wave functions,

$$
\psi_{n_{1} l_{1} m_{1}}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right) \psi_{n_{2} l_{2} m_{2}}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 2}\right) \ldots \psi_{n_{z} l_{Z} m_{Z}}\left(\vec{r}_{Z}\right) \mathfrak{\uparrow}\left(S_{z Z}\right)
$$

and the total energy is the sum of all the corresponding hydrogen atom energy levels,

$$
E_{n_{1}}+E_{n_{2}}+\ldots+E_{n_{Z}}
$$

This solves the Hamiltonian eigenvalue problem under the shielding approximation. The bottom line is: just multiply $Z$ hydrogen energy eigenfunctions together to get an energy eigenfunction for an heavier atom. The energy is the sum of the $Z$ hydrogen energy levels. However, the electrons are identical fermions, so different eigenfunctions must still be combined together in Slater determinants to satisfy the antisymmetrization requirements for electron exchange, as discussed in section 5.7. That will be done during the discussion of the different atoms that is next.

## Key Points

0- The Hamiltonian eigenvalue problem is too difficult to solve analytically.
$0-$ To simplify the problem, the detailed interactions between electrons are ignored. For each electron, it is assumed that the only effect of the other electrons is to cancel, or "shield," that many protons in the nucleus, leaving only a hydrogen nucleus strength.
$0-$ This is a very crude approximation.
$0-$ It implies that the $Z$-electron wave functions are products of the single-electron hydrogen atom wave functions. Their energy is the sum of the corresponding single-electron hydrogen energy levels.
$0-$ These wave functions must still be combined together to satisfy the antisymmetrization requirement (Pauli exclusion principle).

### 5.9.3 Hydrogen and helium

This subsection starts off the discussion of the approximate ground states of the elements. Atomic number $Z=1$ corresponds to hydrogen, which was already discussed in chapter 4.3. The lowest energy state, or ground state, is $\psi_{100}$, (4.40), also called the "1s" state, and the single electron can be in the spin-up or spin-down versions of that state, or in any combination of the two. The most general ground state wave function is therefore:

$$
\begin{aligned}
\Psi\left(\vec{r}_{1}, S_{z 1}\right) & =a_{1} \psi_{100}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right)+a_{2} \psi_{100}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right) \\
& =\psi_{100}\left(\vec{r}_{1}\right)\left(a_{1} \uparrow\left(S_{z 1}\right)+a_{2} \downarrow\left(S_{z 1}\right)\right)
\end{aligned}
$$

The "ionization energy" that would be needed to remove the electron from the atom is the absolute value of the energy eigenvalue $E_{1}$, or 13.6 eV , as derived in chapter 4.3.

For helium, with $Z=2$, in the ground state both electrons are in the lowest possible energy state $\psi_{100}$. But since electrons are identical fermions, the antisymmetrization requirement now rears its head. It requires that the two states $\psi_{100}(\vec{r}) \uparrow\left(S_{z}\right)$ and $\psi_{100}(\vec{r}) \downarrow\left(S_{z}\right)$ appear together in the form of a Slater determinant (chapter 5.7):

$$
\Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2} ; t\right)=\frac{a}{\sqrt{2}}\left|\begin{array}{ll}
\psi_{100}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right) & \psi_{100}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right)  \tag{5.35}\\
\psi_{100}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 2}\right) & \psi_{100}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 2}\right)
\end{array}\right|
$$

or, writing out the Slater determinant:

$$
a \psi_{100}\left(\vec{r}_{1}\right) \psi_{100}\left(\vec{r}_{2}\right) \frac{\uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
$$

The spatial part is symmetric with respect to exchange of the two electrons. The spin state is antisymmetric; it is the singlet configuration with zero net spin of section 5.5.6.

Figure 5.4 shows the approximate probability density for the first two elements, indicating where electrons are most likely to be found. In reality, the shielding approximation underestimates the nuclear attraction and the shown helium atom is much too big.

It is good to remember that the $\psi_{100} \uparrow$ and $\psi_{100 \downarrow}$ states are commonly indicated as the "K shell" after the first initial of the airline of the Netherlands.

The analysis predicts that the ionization energy to remove one electron from helium would be 13.6 eV , the same as for the hydrogen atom. This is a very bad approximation indeed; the truth is almost double, 24.6 eV .

The problem is the made assumption that the repulsion by the other electron "shields" one of the two protons in the helium nucleus, so that only a single-proton hydrogen nucleus is seen. When electron wave functions overlap

Figure 5.4: Approximate solutions for the hydrogen (left) and helium (right) atoms.
significantly as they do here, their mutual repulsion is a lot less than you would naively expect, (compare figure 13.7). As a result, the second proton is only partly shielded, and the electron is held much more tightly than the analysis predicts. See addendum \{A.38.2\} for better estimates of the helium atom size and ionization energy.

However, despite the inaccuracy of the approximation chosen, it is probably best to stay consistent, and not fool around at random. It must just be accepted that the theoretical energy levels will be too small in magnitude $\{\mathrm{N} .7\}$.

The large ionization energy of helium is one reason that it is chemically inert. Helium is called a "noble" gas, presumably because nobody expects nobility to do anything.

## Key Points

0 - The ground states of the atoms of the elements are to be discussed.
$0-$ Element one is hydrogen, solved before. Its ground state is $\psi_{100}$ with arbitrary spin. Its ionization energy is 13.6 eV .
$0-$ Element two is helium. Its ground state has both electrons in the lowest-energy spatial state $\psi_{100}$, and locked into the singlet spin state. Its ionization energy is 24.6 eV .
$0-$ The large ionization energy of helium means it holds onto its two electrons tightly. Helium is an inert noble gas.
$0-$ The two " 1 s " states $\psi_{100} \uparrow$ and $\psi_{100} \downarrow$ are called the "K shell."

### 5.9.4 Lithium to neon

The next element is lithium, with three electrons. This is the first element for which the antisymmetrization requirement forces the theoretical energy to go
above the hydrogen ground state level $E_{1}$. The reason is that there is no way to create an antisymmetric wave function for three electrons using only the two lowest energy states $\psi_{100} \uparrow$ and $\psi_{100} \downarrow$. A Slater determinant for three electrons must have three different states. One of the eight $\psi_{2 l m} \downarrow$ states with energy $E_{2}$ will have to be thrown into the mix.

This effect of the antisymmetrization requirement, that a new state must become "occupied" every time an electron is added is known as the Pauli exclusion principle. It causes the energy values to become larger and larger as the supply of low energy states runs out.

The transition to the higher energy level $E_{2}$ is reflected in the fact that in the so-called "periodic table" of the elements, figure 5.5, lithium starts a new row.

Figure 5.5: Abbreviated periodic table of the elements. Boxes below the element names indicate the quantum states being filled with electrons in that row. Cell color indicates ionization energy. The length of a bar below an atomic number indicates electronegativity. A dot pattern indicates that the element is a gas under normal conditions and wavy lines a liquid.

For the third electron of the lithium atom, the available states with theoretical energy $E_{2}$ are the $\psi_{200} \uparrow$ " 2 s " states and the $\psi_{211} \mathfrak{\imath}, \psi_{210} \mathfrak{\downarrow}$, and $\psi_{21-1} \mathfrak{\downarrow}$ " 2 p " states, a total of eight possible states. These states are, of course, commonly called the "L shell."

Within the crude nuclear shielding approximation made, all eight states have the same energy. However, on closer examination, the spherically symmetric 2 s states really have less energy than the 2 p ones. Very close to the nucleus, shielding is not a factor and the full attractive nuclear force is felt. So a state in which the electron is more likely to be close to the nucleus has less energy. Those are the 2 s states; in the 2 p states, which have nonzero orbital angular
momentum, the electron tends to stay away from the immediate vicinity of the nucleus $\{\mathrm{N} .8\}$.

Within the assumptions made, there is no preference with regard to the spin direction of the 2 s state, allowing two Slater determinants to be formed.

Figure 5.6: Approximate solutions for lithium (left) and beryllium (right).
It is common to say that the "third electron goes into a $\psi_{200}$ " state. Of course that is not quite precise; the Slater determinants above have the first two electrons in $\psi_{200}$ states too. But the third electron adds the third state to the mix, so in that sense it more or less "owns" the state. For the same reason, the Pauli exclusion principle is commonly phrased as "no two electrons may occupy the same state", even though the Slater determinants imply that all electrons share all states equally.

Since the third electron is bound with the much lower energy $\left|E_{2}\right|$ instead of $\left|E_{1}\right|$, it is rather easily given up. Despite the fact that the lithium ion has a nucleus that is $50 \%$ stronger than the one of helium, it only takes a ionization energy of 5.4 eV to remove an electron from lithium, versus 24.6 eV for helium. The theory would predict a ionization energy $\left|E_{2}\right|=3.4 \mathrm{eV}$ for lithium, which is close, so it appears that the two 1 s electrons shield their protons quite well from the 2s one. This is in fact what one would expect, since the 1s electrons are quite close to the nucleus compared to the large radial extent of the 2 s state.

Lithium will readily give up its loosely bound third electron in chemical reactions. Conversely, helium would have even less hold on a third electron
than lithium, because it has only two protons in its nucleus. Helium simply does not have what it takes to seduce an electron away from another atom. This is the second part of the reason that helium is chemically inert: it neither will give up its electrons nor take on additional ones.

Thus the Pauli exclusion principle causes different elements to behave chemically in very different ways. Even elements that are just one unit apart in atomic number such as helium (inert) and lithium (very active).

For beryllium, with four electrons, the same four states as for lithium combine in a single $4 \times 4$ Slater determinant;

$$
\frac{a}{\sqrt{24}}\left|\begin{array}{lllll}
\psi_{100}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right) & \psi_{100}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right) & \psi_{200}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right) & \psi_{200}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right) \\
\psi_{100}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 2}\right) & \psi_{100}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 2}\right) & \psi_{200}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 2}\right) & \psi_{200}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 2}\right)  \tag{5.37}\\
\psi_{100}\left(\vec{r}_{3}\right) \uparrow\left(S_{z 3}\right) & \psi_{100}\left(\vec{r}_{3}\right) \downarrow\left(S_{z 3}\right) & \psi_{200}\left(\vec{r}_{3}\right) \uparrow\left(S_{z 3}\right) & \psi_{200}\left(\vec{r}_{3}\right) \downarrow\left(S_{z 3}\right) \\
\psi_{100}\left(\vec{r}_{4}\right) \uparrow\left(S_{z 4}\right) & \psi_{100}\left(\vec{r}_{4}\right) \downarrow\left(S_{z 4}\right) & \psi_{200}\left(\vec{r}_{4}\right) \uparrow\left(S_{z 4}\right) & \psi_{200}\left(\vec{r}_{4}\right) \downarrow\left(S_{z 4}\right)
\end{array}\right|
$$

The ionization energy jumps up to 9.3 eV , due to the increased nuclear strength and the fact that the fellow 2 s electron does not shield its proton as well as the two 1s electrons do theirs.

For boron, one of the $\psi_{21 m}$ " 2 p " states will need to be occupied. Within the approximations made, there is no preference for any particular state. As an example, figure 5.7 shows the approximate solution in which the $\psi_{210}$, or " $2 \mathrm{p}_{z}$ " state is occupied. It may be recalled from figure 4.11 that this state remains close to the $z$-axis (which is horizontal in the figure.) As a result, the wave function becomes directional. The ionization energy decreases a bit to 8.3 eV ,
into say the $2 \mathrm{p}_{x}$ state. This state is around the vertical $x$-axis instead of the horizontal $z$-axis. As noted in chapter 4.3, $2 \mathrm{p}_{x}$ is a $\psi_{21 m}$ combination state.

For nitrogen, the third 2 p electron can go into the $2 \mathrm{p}_{y}$ state, which is around the $y$-axis. There are now three 2 p electrons, each in a different spatial state.

However, for oxygen the game is up. There are no more free spatial states in the L shell. The new electron will have to go, say, into the $\mathrm{p}_{y}$ state, pairing up with the electron already there in an opposite-spin singlet state. The repulsion by the fellow electron in the same state reflects in an decrease in ionization energy compared to nitrogen.

For fluorine, the next electron goes into the $2 \mathrm{p}_{x}$ state, leaving only the $2 \mathrm{p}_{z}$ state unpaired.

For neon, all 2 p electrons are paired, and the L shell is full. This makes neon an inert noble gas like helium: it cannot accommodate any more electrons at the $E_{2}$ energy level, and, with the strongest nucleus among the L-shell elements, it holds tightly onto the electrons it has.

On the other hand, the previous element, fluorine, has a nucleus that is almost as strong, and it can accommodate an additional electron in its unpaired $2 \mathrm{p}_{z}$ state. So fluorine is very willing to steal an electron if it can get away with it. The capability to draw electrons from other elements is called "electronegativity," and fluorine is the most electronegative of them all.

Neighboring elements oxygen and nitrogen are less electronegative, but oxygen can accommodate two additional electrons rather than one, and nitrogen will even accommodate three.

## Key Points

$0-$ The Pauli exclusion principle forces states of higher energy to become occupied when the number of electrons increases. This raises the energy levels greatly above what they would be otherwise.
$0-$ With the third element, lithium, one of the $\psi_{200} \uparrow$ " 2 s " states becomes occupied. Because of the higher energy of those states, the third electron is readily given up; the ionization energy is only 5.4 eV .
$0-$ Conversely, helium will not take on a third electron.
$0-$ The fourth element is beryllium, with both 2s states occupied.
$0-$ For boron, carbon, nitrogen, oxygen, fluorine, and neon, the successive $\psi_{21 m}$ " 2 p " states become occupied.
$0-$ Neon is a noble gas like helium: it holds onto its electrons tightly, and will not accommodate any additional electrons since they would have to enter the $E_{3}$ energy level states.
$0-$ Fluorine, oxygen, and nitrogen, however, are very willing to accommodate additional electrons in their vacant 2p states.
$0-$ The eight states $\psi_{2 l m} \uparrow$ are called the "L shell."

### 5.9.5 Sodium to argon

Starting with sodium (natrium), the $E_{3}$, or "M shell" begins to be filled. Sodium has a single 3 s electron in the outermost shell, which makes it much like lithium, with a single 2 s electron in its outermost shell. Since the outermost electrons are the critical ones in chemical behavior, sodium is chemically much like lithium. Both are metals with a "valence" of one; they are willing to sacrifice one electron.

Similarly, the elements following sodium in the third row of the periodic figure 5.5 mirror the corresponding elements in the previous row. Near the end of the row, the elements are again eager to accept additional electrons in the still vacant 3 p states.

Finally argon, with no 3 s and 3 p vacancies left, is again inert. This is actually somewhat of a surprise, because the $E_{3} \mathrm{M}$-shell also includes $10 \psi_{32 m} \downarrow$ states. These states of increased angular momentum are called the " 3 d " states. (What else?) According to the approximations made, the 3s, 3p, and 3d states would all have the same energy. So it might seem that argon could accept additional electrons into the 3d states.

But it was already noted that the p states in reality have more energy than the s states at the same theoretical energy level, and the d states have even more. The reason is the same: the d states stay even further away from the nucleus than the p states. Because of the higher energy of the d states, argon is really not willing to accept additional electrons.

## Key Points

0- The next eight elements mirror the properties of the previous eight, from the metal sodium to the highly electronegative chlorine and the noble gas argon.
$0-$ The states $\psi_{3 l m} \downarrow$ are called the "M shell."

### 5.9.6 Potassium to krypton

The logical continuation of the story so far would be that the potassium (kalium) atom would be the first one to put an electron into a 3d state. However, by now the shielding approximation starts to fail not just quantitatively, but qualitatively. The 3d states actually have so much more energy than the 3s states that they even exceed the energy of the 4 s states. Potassium puts its last electron into a 4s state, not a 3d one. This makes its outer shell much like the ones of lithium and sodium, so it starts a new row in the periodic table.

The next element, calcium, fills the 4 s shell, putting an end to that game. Since the six 4 p states have more energy, the next ten elements now start filling the skipped 3d states with electrons, leaving the N-shell with 2 electrons in it. (Actually, this is not quite precise; the 3 d and 4 s energies are closely together,
and for chromium and copper one of the two 4 s electrons turns out to switch to a 3d state.) In any case, it takes until gallium until the six 4p states start filling, which is fully accomplished at krypton. Krypton is again a noble gas, though it can form a weak bond with chlorine.

Continuing to still heavier elements, the energy levels get even more confused. This discussion will stop while it is still ahead.

## Key Points

$0-$ Unlike what the approximate theory says, in real life the 4s states $\psi_{400} \uparrow$ have less energy than the $\psi_{32 m} \downarrow 3 \mathrm{~d}$ states, and are filled first.
$0=$ After that, the transition metals fill the skipped 3d states before the old logic resumes.
$0-$ The states $\psi_{4 l m} \uparrow$ are called the " N shell." It all spells KLM Netherlands.
$0-$ The substates are of course called "s," "p," "d," "f," ..

### 5.9.7 Full periodic table

A complete periodic table of the elements is shown in figure 5.8. The number in the top left corner of each cell is the atomic number $Z$ of the element. The numbers to the left of the table indicate the periods. The length of the periods expands from 2 to 8 elements in period 2 when $l=2$, p, states must be filled with electrons. Then in period 4, a delayed filling of $l=2$, d , states expands the periods by another 10 elements. Finally, in period 6 , a delayed filling of $l=$ 3 , f, states adds another 14 elements per period.

The top part of the shown table is called the main group. For some reason however, hydrogen is not included in this term. Note that compared to the previous abbreviated periodic table, hydrogen and helium have been moved to the final columns. The idea is to combine elements with similar properties together into the same columns. Helium is a noble gas like the group VIII elements with filled electron shells. Helium has absolutely nothing in common with the group II alkaline metals that have two electrons in an otherwise empty shell. Similarly, hydrogen behaves much more like a halogen with 1 electron missing from a filled shell than like an alkali metal with 1 electron in an otherwise empty shell. However, hydrogen is still sufficiently different that it should not be considered an actual halogen.

The elements in the periodic table are classified as metals, metalloids, and nonmetals. Metalloids have chemical properties intermediate between metals and nonmetals. The band of metalloids is indicated by dark red cell boundaries in figure 5.8. It extends from boron to polonium. The metals are found to the

Figure 5.8: Periodic table of the elements. Cell color indicates ionization energy. Boxes indicate the outer electron structure. See the text for more information. [pdf]
left of this band and the nonmetals to the right. Hydrogen and helium are most definitely nonmetals and their shown position in the table reflects that.

The color of each cell indicates the ionization energy, increasing from bluish to reddish. The length of the bar below the atomic number gives the electronegativity. In the top right corner wavy lines indicate that the element is a liquid under normal conditions, and dots that it is a gas. A dagger indicates that the atomic nucleus is radioactive (for every isotope, chapter 14). If the dagger is followed by an exclamation mark, the radioactivity causes the nucleus to decay fast enough that there are no usable quantities of the element found in nature. These elements must be artificially prepared in a lab.

The boxes below the element names indicate the s, p, d, and f shells being filled in that period of the table. The shells already filled in the noble gas at the end of the previous period remain filled and are not shown. Note that the filling of $n \mathrm{~d}$ states is delayed one period, to period $n+1$, and the filing of $n \mathrm{f}$ states is delayed two periods, to period $n+2$.

Besides element name, symbol, and radioactivity, periodic table figure 5.8 limits itself to data for which the periodic table arrangement is meaningful. Many other periodic tables also list the average atomic mass for the isotopic composition found on earth. However, for purposes of understanding atomic masses physically, graphs in chapter 14 on nuclei, like figures 14.2 and 14.4, are much more useful.

It should be noted that periodic table figure 5.8 deviates in a number of aspects from the normal conventions. Figure 5.8 is what seems the simplest and most logical. If you put historical oddities and a few committees in charge, you get something different.

Most prominently, most periodic tables leave hydrogen in group I instead of moving it to the top of group VII. But if you move helium to group VIII because of its similarity with the other noble gases in that group, then it is ludicrous to leave hydrogen in group I. Hydrogen has virtually nothing in common with the alkali metals in group I. Like the light halogens, it is a diatomic gas under normal conditions, not a solid metal. Even at the extremely low temperatures at which hydrogen solidifies, it is a nonconducting molecular solid, not a metal. The melting, boiling, and critical points of hydrogen form a logical sequence with those of the halogens. They are totally inconsistent with those of the alkali metals. Hydrogen has the ionization energy of oxygen and the electronegativity of phosphorus. A ionic compound like NaH is a direct equivalent of NaCl , salt, with the hydrogen as the negative ion.

It is true that hydrogen can also form positive ions in chemical reactions, more or less, something that the halogens simply do not do. But do not actually expect to find bare protons when other atoms are around. Also the ionization energy and electronegativity of hydrogen are quite a bit out of line with those of the other halogens. Hydrogen is certainly not a true halogen. But if you order the elements by properties, there is no doubt that hydrogen belongs in group

VII, not I. If you want to refer to the quantum-mechanical shell structure, the term "s block" can still be used to indicate the alkali and alkaline metals along with hydrogen and helium. The remainder of the main group is the "p block." These names indicate the quantum states being filled.

The term transition metals may not include the elements in group IIB of the d-block, for reason related to the fact that their s and d shells have been completely filled. The f-block elements are sometimes referred to as the inner transition metals.

Further, according to the 2005 IUPAC Red Book the lanthanides and actinides should be more properly called the lanthanoids and actinoids, since "ide" usually means negative ion. Since "oid" means "-like," according to IUPAC the lanthanoids should not really include lanthanum, and the actinoids should not include actinium. However, the IUPAC does include them because of common usage. A rare triumph of scientific common sense over lousy terminology. If lanthanum and actinium are to be included, the lanthanides and actinides should of course simply have been renamed the lanthanum and actinium groups, or equivalent, not lanthanoids and actinoids.

More significantly, unlike figure 5.8 suggests, lutetium is included in the lanthanoids and lawrencium in the actinoids. The term rare-earth metals include the lanthanoids, as well as scandium and yttrium as found immediately above lutetium.

Also, both lutetium and lawrencium are according to IUPAC included in the f-block. That makes the f-block 15 columns wide instead of the 14 column block shown at the bottom of figure 5.8. Of course, that does not make any sense at all. The name f-block supposedly indicates that an f-shell is being filled. An f -shell holds 14 electrons, not 15 . For lutetium, the f-shell is full and other shells have begun to fill. The same is, at the time of writing, believed to be true for lawrencium. And while the first f-shell electrons for lanthanum and actinium get temporarily bumped to the d-shell, that is obviously a minor error in the overall logic of filling the f-shell. (Apparently, there is a long-standing controversy whether lanthanum and actinium or lutetium and lawrencium should be included in the f-block. By compromising and putting both in the f-block of their 2007 periodic table, the IUPAC got the worst of both worlds.)

A nice recent example of a more conventional periodic table by an authoritative source is from NIST ${ }^{1}$. This also includes the latest updates on various data, unlike the periodic table in this book. An earlier version can be found at the web location ${ }^{2}$ of this document. The hieroglyphs found in the NIST table are explained in chapter 10.7.1.

Periodic table figure 5.8 was based on data from various sources. Shell fillings and ionization energies agree with the NIST listing and table. The uncertain

[^1]shell fillings at atomic numbers 103 and 104 were left out. The classification whether the elements must be artificially prepared was taken from the NIST periodic table. The electronegativities are based on the Pauling scale. They were taken from Wikipedia "use" values, that were in turn taken from WebElements, and are mostly the same as those in the 2003 CRC Handbook of Chemistry and Physics, and the 1999 Lange's Handbook of Chemistry. Discrepancies between these sources of more than $10 \%$ occur for atomic numbers $71,74,82$, and 92 .

### 5.10 Pauli Repulsion

Before proceeding to a description of chemical bonds, one important point must first be made. While the earlier descriptions of the hydrogen molecular ion and hydrogen molecule produced many important observations about chemical bonds, they are highly misleading in one aspect.

In the hydrogen molecule cases, the repulsive force that eventually stops the atoms from getting together any closer than they do is the electrostatic repulsion between the nuclei. It is important to recognize that this is the exception, rather than the norm. Normally, the main repulsion between atoms is not due to repulsion between the nuclei, but due to the Pauli exclusion principle for their electrons. Such repulsion is called "exclusion-principle repulsion" or "Pauli repulsion."

To understand why the repulsion arises, consider two helium ions, and assume that you put them right on top of each other. Of course, with the nuclei right on top of each other, the nuclear repulsion will be infinite, but ignore that for now. There is another effect, and that is the interesting one here. There are now 4 electrons in the 1 s shell.

Without the Pauli exclusion principle, that would not be a big deal. The repulsion between the electrons would go up, but so would the combined nuclear strength double. However, Pauli says that only two electrons may go into the 1 s shell. The other two 1 s electrons will have to divert to the 2 s shell, and that requires a lot of energy.

Next consider what happens when two helium atoms are not on top of each other, but are merely starting to intrude on each other's 1s shell space. Recall that the Pauli principle is just the antisymmetrization requirement of the electron wave function applied to a description in terms of given energy states. When the atoms get closer together, the energy states get confused, but the antisymmetrization requirement stays in full force. When the filled shells start to intrude on each other's space, the electrons start to divert to increasingly higher energy to continue to satisfy the antisymmetrization requirement. This process ramps up much more quickly than the nuclear repulsions and dominates the net repulsion in almost all circumstances.

In everyday terms, the standard example of repulsion forces that ramp up very quickly is billiard balls. If billiard balls are a millimeter away from touching, there is no repulsion between them, but move them closer a millimeter, and suddenly there is this big repulsive force. The repulsion between filled atom shells does not ramp up that quickly in relative terms, of course, but it does ramp up quickly. So describing atoms with closed shells as billiard balls is quite reasonable if you are just looking for a general idea.

## Key Points

$0-$ If electron wave functions intrude on each others space, it can cause repulsion due to the antisymmetrization requirement.
$0-$ This is called Pauli repulsion or exclusion principle repulsion.
$0-$ It is the dominant repulsion in almost all cases.

### 5.11 Chemical Bonds

The electron states, or "atomic orbitals", of the elements discussed in section 5.9 form the basis for the "valence bond" description of chemical bonds. This section summarizes some of the basic ideas involved.

### 5.11.1 Covalent sigma bonds

As pointed out in section 5.9, helium is chemically inert: its outermost, and only, shell can hold two electrons, and it is full. But hydrogen has only one electron, leaving a vacant position for another 1 s electron. As discussed earlier in chapter 5.2, two hydrogen atoms are willing to share their electrons. This gives each atom in some sense two electrons in its shell, filling it up. The shared state has lower energy than the two separate atoms, so the $\mathrm{H}_{2}$ molecule stays together. A sketch of the shared 1s electrons was given in figure 5.2.

Fluorine has one vacant spot for an electron in its outer shell just like hydrogen; its outer shell can contain 8 electrons and fluorine has only seven. One of its 2 p states, assume it is the horizontal axial state $2 \mathrm{p}_{z}$, has only one electron in it instead of two. Two fluorine atoms can share their unpaired electrons much like hydrogen atoms do and form an $\mathrm{F}_{2}$ molecule. This gives each of the two atoms a filled shell. The fluorine molecular bond is sketched in figure 5.9 (all other electrons have been omitted.) This bond between p electrons looks quite different from the $\mathrm{H}_{2}$ bond between s electrons in figure 5.2 , but it is again a covalent one, in which the electrons are shared. In addition, both bonds are called "sigma" bonds: if you look at either bond from the side, it looks rotationally symmetric, just like an s state. (Sigma is the Greek equivalent of the letter s ; it is written as $\sigma$.)

Figure 5.9: Covalent sigma bond consisting of two $2 \mathrm{p}_{z}$ states.

## Key Points

$0-$ Two fluorine or similar atoms can share their unpaired 2p electrons in much the same way that two hydrogen atoms can share their unpaired 2 s electrons.
$0-$ Since such bonds look like s states when seen from the side, they are called sigma or $\sigma$ bonds.

### 5.11.2 Covalent pi bonds

The $\mathrm{N}_{2}$ nitrogen molecule is another case of covalent bonding. Nitrogen atoms have a total of three unpaired electrons, which can be thought of as one each in the $2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}$, and $2 \mathrm{p}_{z}$ states. Two nitrogen atoms can share their unpaired $2 \mathrm{p}_{z}$ electrons in a sigma bond the same way that fluorine does, longitudinally.

However, the $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ states are normal to the line through the nuclei; these states must be matched up sideways. Figure 5.10 illustrates this for the bond between the two vertical $2 \mathrm{p}_{x}$ states. This covalent bond, and the corresponding one between the $2 \mathrm{p}_{y}$ states, looks like a p state when seen from the side, and it is called a "pi" or $\pi$ bond.

So, the $\mathrm{N}_{2}$ nitrogen molecule is held together by two pi bonds in addition to a sigma bond, making a triple bond. It is a relatively inert molecule.

## Key Points

$0-$ Unpaired p states can match up sideways in what are called pi or $\pi$ bonds.

### 5.11.3 Polar covalent bonds and hydrogen bonds

Oxygen, located in between fluorine and nitrogen in the periodic table, has two unpaired electrons. It can share these electrons with another oxygen atom to

Figure 5.10: Covalent pi bond consisting of two $2 \mathrm{p}_{x}$ states.
form $\mathrm{O}_{2}$, the molecular oxygen we breath. However, it can instead bind with two hydrogen atoms to form $\mathrm{H}_{2} \mathrm{O}$, the water we drink.

In the water molecule, the lone $2 \mathrm{p}_{z}$ electron of oxygen is paired with the 1 s electron of one hydrogen atom, as shown in figure 5.11. Similarly, the lone $2 \mathrm{p}_{y}$

The reason that the actual angle is a bit more may be understood from the fact that the oxygen atom has a higher attraction for the shared electrons, or electronegativity, than the hydrogen atoms. It will pull the electrons partly away from the hydrogen atoms, giving itself some negative charge, and the hydrogen atoms a corresponding positive one. The positively charged hydrogen atoms repel each other, increasing their angle a bit. If you go down one place in the periodic table below oxygen, to the larger sulfur atom, $\mathrm{H}_{2} \mathrm{~S}$ has its hydrogen atoms under about 93 degrees, quite close to 90 degrees.

Bonds like the one in water, where the negative electron charge shifts towards the more electronegative atom, are called "polar" covalent bonds.

It has significant consequences for water, since the positively charged hydrogen atoms can electrostatically attract the negatively charged oxygen atoms on other molecules. This has the effect of creating bonds between different molecules called "hydrogen bonds." While much weaker than typical covalent bonds, they are strong enough to affect the physical properties of water. For example, they are the reason that water is normally a liquid instead of a gas, quite a good idea if you are thirsty, and that ice floats on water instead of sinking to the bottom of the oceans. Hydrogen is particularly efficient at creating such bonds because it does not have any other electrons to shield its nucleus.

## Key Points

$0=$ The geometry of the quantum states reflects in the geometry of the formed molecules.
$0-$ When the sharing of electrons is unequal, a bond is called polar.
0-A special case is hydrogen, which is particularly effective in also creating bonds between different molecules, hydrogen bonds, when polarized.
$0-$ Hydrogen bonds give water unusual properties that are critical for life on earth.

### 5.11.4 Promotion and hybridization

While valence bond theory managed to explain a number of chemical bonds so far, two important additional ingredients need to be added. Otherwise it will not at all be able to explain organic chemistry, the chemistry of carbon critical to life.

Carbon has two unpaired 2p electrons just like oxygen does; the difference between the atoms is that oxygen has in addition two paired 2p electrons. With two unpaired electrons, it might seem that carbon should form two bonds like oxygen.

But that is not what happens; normally carbon forms four bonds instead of two. In chemical bonds, one of carbon's paired 2 s electrons moves to the empty 2 p state, leaving carbon with four unpaired electrons. It is said that the 2 s electron is "promoted" to the 2 p state. This requires energy, but the energy gained by having four bonds more than makes up for it.

Promotion explains why a molecule such as $\mathrm{CH}_{4}$ forms. Including the 4 shared hydrogen electrons, the carbon atom has 8 electrons in its outer shell, so its shell is full. It has made as many bonds as it can support.

However, promotion is still not enough to explain the molecule. If the $\mathrm{CH}_{4}$ molecule was merely a matter of promoting one of the 2 s electrons into the vacant $2 \mathrm{p}_{y}$ state, the molecule should have three hydrogen atoms under 90 degrees, sharing the $2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}$, and $2 \mathrm{p}_{z}$ electrons respectively, and one hydrogen atom elsewhere, sharing the remaining 2 s electron. In reality, the $\mathrm{CH}_{4}$ molecule is shaped like a regular tetrahedron, with angles of 109.5 degrees between all four hydrogens.

The explanation is that, rather than using the $2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}, 2 \mathrm{p}_{z}$, and 2 s states directly, the carbon atom forms new combinations of the four called "hybrid" states. (This is not unlike how the torus-shaped $\psi_{211}$ and $\psi_{21-1}$ states were recombined in chapter 4.3 to produce the equivalent $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{y}$ pointer states.)

In case of $\mathrm{CH}_{4}$, the carbon converts the $2 \mathrm{~s}, 2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}$, and $2 \mathrm{p}_{z}$ states into four new states. These are called $\mathrm{sp}^{3}$ states, since they are formed from one s and three $p$ states. They are given by:

$$
\begin{aligned}
& \left|\mathrm{sp}_{a}^{3}\right\rangle=\frac{1}{2}\left(|2 \mathrm{~s}\rangle+\left|2 \mathrm{p}_{x}\right\rangle+\left|2 \mathrm{p}_{y}\right\rangle+\left|2 \mathrm{p}_{z}\right\rangle\right) \\
& \left|\mathrm{sp}_{b}^{3}\right\rangle=\frac{1}{2}\left(|2 \mathrm{~s}\rangle+\left|2 \mathrm{p}_{x}\right\rangle-\left|2 \mathrm{p}_{y}\right\rangle-\left|2 \mathrm{p}_{z}\right\rangle\right) \\
& \left|\mathrm{sp}_{c}^{3}\right\rangle=\frac{1}{2}\left(|2 \mathrm{~s}\rangle-\left|2 \mathrm{p}_{x}\right\rangle+\left|2 \mathrm{p}_{y}\right\rangle-\left|2 \mathrm{p}_{z}\right\rangle\right) \\
& \left|\mathrm{sp}_{d}^{3}\right\rangle=\frac{1}{2}\left(|2 \mathrm{~s}\rangle-\left|2 \mathrm{p}_{x}\right\rangle-\left|2 \mathrm{p}_{y}\right\rangle+\left|2 \mathrm{p}_{z}\right\rangle\right)
\end{aligned}
$$

where the kets denote the wave functions of the indicated states.
All four $\mathrm{sp}^{3}$ hybrids have the same shape, shown in figure 5.12. The asymmetrical shape can increase the overlap between the wave functions in the bond. The four $\mathrm{sp}^{3}$ hybrids are under equal 109.5 degrees angles from each other, producing the tetrahedral structure of the $\mathrm{CH}_{4}$ molecule. And of diamond, for that matter. With the atoms bound together in all spatial directions, diamond is an extremely hard material.

But carbon is a very versatile atom. In graphite, and carbon nanotubes, carbon atoms arrange themselves in layers instead of three-dimensional structures. Carbon achieves this trick by leaving the 2 p -state in the direction normal to the plane, call it $\mathrm{p}_{x}$, out of the hybridization. The two 2 p states in the plane

Figure 5.12: Shape of an $\mathrm{sp}^{3}$ hybrid state.
plus the 2 s state can then be combined into three $\mathrm{sp}^{2}$ states:

$$
\begin{aligned}
& \left|\mathrm{sp}_{a}^{2}\right\rangle=\frac{1}{\sqrt{3}}|2 \mathrm{~s}\rangle+\frac{2}{\sqrt{6}}\left|2 \mathrm{p}_{z}\right\rangle \\
& \left|\mathrm{sp}_{b}^{2}\right\rangle=\frac{1}{\sqrt{3}}|2 \mathrm{~s}\rangle-\frac{1}{\sqrt{6}}\left|2 \mathrm{p}_{z}\right\rangle+\frac{1}{\sqrt{2}}\left|2 \mathrm{p}_{y}\right\rangle \\
& \left|\mathrm{sp}_{c}^{2}\right\rangle=\frac{1}{\sqrt{3}}|2 \mathrm{~s}\rangle-\frac{1}{\sqrt{6}}\left|2 \mathrm{p}_{z}\right\rangle-\frac{1}{\sqrt{2}}\left|2 \mathrm{p}_{y}\right\rangle
\end{aligned}
$$

Each is shaped as shown in figure 5.13.

Figure 5.13: Shapes of the $\mathrm{sp}^{2}$ (left) and sp (right) hybrids.
These planar hybrids are under 120 degree angles from each other, giving graphite its hexagonal structure. The left-out p electrons normal to the plane can form pi bonds with each other. A planar molecule formed using $\mathrm{sp}^{2}$ hybridization is ethylene $\left(\mathrm{C}_{2} \mathrm{H}_{4}\right)$; it has all six nuclei in the same plane. The pi
bond normal to the plane prevents out-of-plane rotation of the nuclei around the line connecting the carbons, keeping the plane rigid.

Finally, carbon can combine the 2 s state with a single 2 p state to form two sp hybrids under 180 degrees from each other:

$$
\begin{aligned}
& \left|\mathrm{sp}_{a}\right\rangle=\frac{1}{\sqrt{2}}\left(|2 \mathrm{~s}\rangle+\left|2 \mathrm{p}_{z}\right\rangle\right) \\
& \left|\mathrm{sp}_{b}\right\rangle=\frac{1}{\sqrt{2}}\left(|2 \mathrm{~s}\rangle-\left|2 \mathrm{p}_{z}\right\rangle\right)
\end{aligned}
$$

An example sp hybridization is acetylene, $\left(\mathrm{C}_{2} \mathrm{H}_{2}\right)$, which has all its four nuclei on a single line.

## Key Points

$0-$ The chemistry of carbon is critical for life as we know it.
$0-$ It involves two additional ideas; one is promotion, where carbon kicks one of its 2 s electrons into a 2 p state. This gives carbon one 2 s and three 2 p electrons.
$0-$ The second idea is hybridization, where carbon combines these four states in creative new combinations called hybrids.
$0-$ In sp ${ }^{3}$ hybridization, carbon creates four hybrids in a regular tetrahedron combination.
$0=$ In $\mathrm{sp}^{2}$ hybridization, carbon creates three hybrids in a plane, spaced at 120 degree intervals. That leaves a conventional 2 p state in the direction normal to the plane.
$0-$ In sp hybridization, carbon creates two hybrids along a line, pointing in opposite directions. That leaves two conventional 2 p states normal to the line of the hybrids and to each other.

### 5.11.5 Ionic bonds

Ionic bonds are the extreme polar bonds; they occur if there is a big difference between the electronegativities of the atoms involved.

An example is kitchen salt, NaCl . The sodium atom has only one electron in its outer shell, a loosely bound 3s one. The chlorine has seven electrons in its outer shell and needs only one more to fill it. When the two react, the chlorine does not just share the lone electron of the sodium atom, it simply takes it away. It makes the chlorine a negatively charged ion. Similarly, it leaves the sodium as a positively charged ion.

The charged ions are bound together by electrostatic forces. Since these forces act in all directions, each ion does not just attract the opposite ion it
exchanged the electron with, but all surrounding opposite ions. And since in salt each sodium ion is surrounded by six chlorine ions and vice versa, the number of bonds that exists is large.

Since so many bonds must be broken to take a ionic substance apart, their properties are quite different from covalently bounded substances. For example, salt is a solid with a high melting point, while the covalently bounded $\mathrm{Cl}_{2}$ chlorine molecule is normally a gas, since the bonds between different molecules are weak. Indeed, the covalently bound hydrogen molecule that has been discussed much in this chapter remains a gas until especially low cryogenic temperatures.

Chapter 10.2 will give a more quantitative discussion of ionic molecules and solids.

## Key Points

$0-$ When a bond is so polar that practically speaking one atom takes the electron away from the other, the bond is called ionic.
0- Ionic substances like salt tend to form strong solids, unlike typical purely covalently bound molecules like hydrogen that tend to form gases.

### 5.11.6 Limitations of valence bond theory

Valence bond theory does a terrific job of describing chemical bonds, producing a lot of essentially correct, and very nontrivial predictions, but it does have limitations.

One place it fails is for the $\mathrm{O}_{2}$ oxygen molecule. In the molecule, the atoms share their unpaired $2 \mathrm{p}_{x}$ and $2 \mathrm{p}_{z}$ electrons. With all electrons symmetrically paired in the spatial states, the electrons should all be in singlet spin states having no net spin. However, it turns out that oxygen is strongly paramagnetic, indicating that there is in fact net spin. The problem in valence bond theory that causes this error is that it ignores the already paired-up electrons in the $2 \mathrm{p}_{y}$ states. In the molecule, the filled $2 \mathrm{p}_{y}$ states of the atoms are next to each other and they do interact. In particular, one of the total of four $2 \mathrm{p}_{y}$ electrons jumps over to the $2 \mathrm{p}_{x}$ states, where it only experiences repulsion by two other electrons instead of by three. The spatial state of the electron that jumps over is no longer equal to that of its twin, allowing them to have equal instead of opposite spin.

Valence bond theory also has problems with single-electron bonds such as the hydrogen molecular ion, or with benzene, in which the carbon atoms are held together with what is essentially 1.5 bonds, or rather, bonds shared as in a two state system. Excited states produce major difficulties. Various fixes and improved theories exist.

## Key Points

$0-$ Valence bond theory is extremely useful. It is conceptually simple and explains much of the most important chemical bonds.
$0-$ However, it does have definite limitations: some types of bonds are not correctly or not at all described by it.
$0-$ Little in life is ideal, isn't it?

## Chapter 6

## Macroscopic Systems

#### Abstract

Macroscopic systems involve extremely large numbers of particles. Such systems are very hard to analyze exactly in quantum mechanics. An exception is a system of noninteracting particles stuck in a rectangular box. This chapter therefore starts with an examination of that model. For a model of this type, the system energy eigenfunctions are found to be products of single-particle states. One thing that becomes quickly obvious is that macroscopic system normally involve a gigantic number of single-particle states. It is unrealistic to tabulate them each individually. Instead, average statistics about the states are derived. The primary of these is the so-called density of states. It is the number of single-particle states per unit energy range. But knowing the number of states is not enough by itself. Information is also needed on how many particles are in these states. Fortunately, it turns out to be possible to derive the average number of particles per state. This number depends on whether it is a system of bosons, like photons, or a system of fermions, like electrons. For bosons, the number of particles is given by the so-called Bose-Einstein distribution, while for electrons it is given by the so-called Fermi-Dirac distribution. Either distribution can be simplified to the so-called Maxwell-Boltzmann distribution under conditions in which the average number of particles per state is much less than one.

Each distribution depends on both the temperature and on a so-called chemical potential. Physically, temperature differences promote the diffusion of thermal energy, heat, from hot to cold. Similarly, differences in chemical potential promote the diffusion of particles from high chemical potential to low.

At first, systems of identical bosons are studied. Bosons behave quite strangely at very low temperatures. Even for a nonzero temperature, a finite fraction of them may stay in the single-particle state of lowest

energy. That behavior is called Bose-Einstein condensation. Bosons also show a lack of low-energy global energy eigenfunctions.
A first discussion of electromagnetic radiation, including light, will be given. The discussed radiation is the one that occurs under conditions of thermal equilibrium, and is called blackbody radiation

Next, systems of electrons are covered. It is found that electrons in typical macroscopic systems have vast amounts of kinetic energy even at absolute zero temperature. It is this kinetic energy that is responsible for the volume of solids and liquids and their resistance to compression. The electrons are normally confined to a solid despite all their kinetic energy. But at some point, they may escape in a process called thermionic emission.

The electrical conduction of metals can be explained using the simple model of noninteracting electrons. However, electrical insulators and semiconductors cannot. It turns out that these can be explained by including a simple model of the forces on the electrons.
Then semiconductors are discussed, including applications such as diodes, transistors, solar cells, light-emitting diodes, solid state refrigeration, thermocouples, and thermoelectric generators. A somewhat more general discussion of optical issues is also given.

### 6.1 Intro to Particles in a Box

Since most macroscopic systems are very hard to analyze in quantum-mechanics, simple systems are very important. They allow insight to be achieved that would be hard to obtain otherwise. One of the simplest and most important systems is that of multiple noninteracting particles in a box. For example, it is a starting point for quantum thermodynamics and the quantum description of solids.

It will be assumed that the particles do not interact with each other, nor with anything else in the box. That is a dubious assumption; interactions between particles are essential to achieve statistical equilibrium in thermodynamics. And in solids, interaction with the atomic structure is needed to explain the differences between electrical conductors, semiconductors, and insulators. However, in the box model such effects can be treated as a perturbation. That perturbation is ignored to leading order.

In the absence of interactions between the particles, the possible quantum states, or energy eigenfunctions, of the complete system take a relatively simple form. They turn out to be products of single particle energy eigenfunctions. A generic energy eigenfunction for a system of $I$ particles is:

$$
\psi_{\vec{n}_{1}, \vec{n}_{2}, \ldots, \vec{n}_{i} \ldots, \vec{n}_{I}}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{i}, S_{z i}, \ldots, \vec{r}_{I}, S_{z I}\right)=
$$

$$
\begin{equation*}
\psi_{\vec{n}_{1}}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \times \psi_{\vec{n}_{2}}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \times \ldots \times \psi_{\vec{n}_{i}}^{\mathrm{p}}\left(\vec{r}_{i}, S_{z i}\right) \times \ldots \times \psi_{\vec{n}_{I}}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right) \tag{6.1}
\end{equation*}
$$

In such a system eigenfunction, particle number $i$ out of $I$ is in a single-particle energy eigenfunction $\psi_{\vec{n}_{i}}^{\mathrm{p}}\left(\vec{r}_{i}, S_{z i}\right)$. Here $\vec{r}_{i}$ is the position vector of the particle, and $S_{z i}$ its spin in a chosen $z$-direction. The subscript $\vec{n}_{i}$ stands for whatever quantum numbers characterize the single-particle eigenfunction. A system wave function of the form above, a simple product of single-particles ones, is called a "Hartree product."

For noninteracting particles confined inside a box, the single-particle energy eigenfunctions, or single-particle states, are essentially the same ones as those derived in chapter 3.5 for a particle in a pipe with a rectangular cross section. However, to account for nonzero particle spin, a spin-dependent factor must be added. In any case, this chapter will not really be concerned that much with the detailed form of the single-particle energy states. The main quantities of interest are their quantum numbers and their energies. Each possible set of quantum numbers will be graphically represented as a point in a so-called "wave number space." The single-particle energy is found to be related to how far that point is away from the origin in that wave number space.

For the complete system of $I$ particles, the most interesting physics has to do with the (anti) symmetrization requirements. In particular, for a system of identical fermions, the Pauli exclusion principle says that there can be at most one fermion in a given single-particle state. That implies that in the above Hartree product each set of quantum numbers $\vec{n}$ must be different from all the others. In other words, any system wave function for a system of $I$ fermions must involve at least $I$ different single-particle states. For a macroscopic number of fermions, that puts a tremendous restriction on the wave function. The most important example of a system of identical fermions is a system of electrons, but systems of protons and of neutrons appear in the description of atomic nuclei.

The antisymmetrization requirement is really more subtle than the Pauli principle implies. And the symmetrization requirements for bosons like photons or helium-4 atoms are nontrivial too. This was discussed earlier in chapter 5.7. Simple Hartree product energy eigenfunctions of the form (6.1) above are not acceptable by themselves; they must be combined with others with the same single-particle states, but with the particles shuffled around between the states. Or rather, because shuffled around sounds too much like Las Vegas, with the particles exchanged between the states.

## Key Points

$0-$ Systems of noninteracting particles in a box will be studied.
$0-$ Interactions between the particles may have to be included at some later stage.
0- System energy eigenfunctions are obtained from products of singleparticle energy eigenfunctions.

0 - (anti) symmetrization requirements further restrict the system energy eigenfunctions.

### 6.2 The Single-Particle States

As the previous section noted, the objective is to understand systems of noninteracting particles stuck in a closed, impenetrable, box. To do so, the key question is what are the single-particle quantum states, or energy eigenfunctions, for the particles. They will be discussed in this section.

The box will be taken to be rectangular, with its sides aligned with the coordinate axes. The lengths of the sides of the box will be indicated by $\ell_{x}, \ell_{y}$, and $\ell_{z}$ respectively.

The single-particle energy eigenfunctions for such a box were derived in chapter 3.5 under the guise of a pipe with a rectangular cross section. The single-particle energy eigenfunctions are:

$$
\begin{equation*}
\psi_{n_{x} n_{y} n_{z}}^{\mathrm{p}}(\vec{r})=\sqrt{\frac{8}{\mathcal{V}}} \sin \left(k_{x} x\right) \sin \left(k_{y} y\right) \sin \left(k_{z} z\right) \tag{6.2}
\end{equation*}
$$

Here $\mathcal{V}=\ell_{x} \ell_{y} \ell_{z}$ is the volume of the box. The "wave numbers" $k_{x}, k_{y}$, and $k_{z}$ take the values:

$$
\begin{equation*}
k_{x}=n_{x} \frac{\pi}{\ell_{x}} \quad k_{y}=n_{y} \frac{\pi}{\ell_{y}} \quad k_{z}=n_{z} \frac{\pi}{\ell_{z}} \tag{6.3}
\end{equation*}
$$

where $n_{x}, n_{y}$, and $n_{z}$ are natural numbers. Each set of three natural numbers $n_{x}, n_{y}, n_{z}$ gives one single-particle eigenfunction. In particular, the singleparticle eigenfunction of lowest energy is $\psi_{111}^{\mathrm{p}}$, having $n_{x}=n_{y}=n_{z}=1$.

However, the precise form of the eigenfunctions is not really that important here. What is important is how many there are and what energy they have. That information can be summarized by plotting the allowed wave numbers in a $k_{x}, k_{y}, k_{z}$ axis system. Such a plot is shown in the left half of figure 6.1.

Each point in this "wave number space" corresponds to one spatial singleparticle state. The coordinates $k_{x}, k_{y}$, and $k_{z}$ give the wave numbers in the three spatial directions. In addition, the distance $k$ from the origin indicates the single-particle energy. More precisely, the single particle energy is

$$
\begin{equation*}
E^{\mathrm{p}}=\frac{\hbar^{2}}{2 m} k^{2} \quad k \equiv \sqrt{k_{x}^{2}+k_{y}^{2}+k_{z}^{2}} \tag{6.4}
\end{equation*}
$$

The energy is therefore just a constant times the square of this distance. (The above expression for the energy can be verified by applying the kinetic energy operator on the given single-particle wave function.)

Figure 6.1: Allowed wave number vectors, left, and energy spectrum, right.
One more point must be made. The single-particle energy eigenfunctions described above are spatial states. Particles with nonzero spin, which includes all fermions, can additionally have different spin in whatever is chosen to be the $z$-direction. In particular, for fermions with spin $1 / 2$, including electrons, there is a "spin-up" and a "spin-down" version of each spatial energy eigenfunction:

$$
\begin{aligned}
\psi_{n_{x} n_{y} n_{z}, \frac{1}{2}}^{\mathrm{p}}\left(\vec{r}, S_{z}\right) & =\sqrt{\frac{8}{\mathcal{V}}} \sin \left(k_{x} x\right) \sin \left(k_{y} y\right) \sin \left(k_{z} z\right) \uparrow\left(S_{z}\right) \\
\psi_{n_{x} n_{y} n_{z},-\frac{1}{2}}^{\mathrm{p}}\left(\vec{r}, S_{z}\right) & =\sqrt{\frac{8}{\mathcal{V}}} \sin \left(k_{x} x\right) \sin \left(k_{y} y\right) \sin \left(k_{z} z\right) \downarrow\left(S_{z}\right)
\end{aligned}
$$

That means that each point in the wave number space figure 6.1 stands for two single-particle states, not just one.

In general, if the particles have spin $s$, each point in wave number space corresponds to $2 s+1$ different single-particle states. However, photons are an exception to this rule. Photons have $\operatorname{spin} s=1$ but each spatial state corresponds to only 2 single-particle states, not 3 . (That is related to the fact that the spin angular momentum of a photon in the direction of motion can only be $\hbar$ or $-\hbar$, not 0 . And that is in turn related to the fact that the electromagnetic field cannot have a component in the direction of motion. If you are curious, see addendum $\{\mathrm{A} .21 .6\}$ for more.)

## Key Points

$0-$ Each single particle state is characterized by a set of three "wave numbers" $k_{x}, k_{y}$, and $k_{z}$.
$0=$ Each point in the "wave number space" figure 6.1 corresponds to one
specific spatial single-particle state.
$0=$ The distance of the point from the origin is a measure of the energy
of the single-particle state.
$0=$ In the presence of nonzero particle spin $s$, each point in wave number
space corresponds to $2 s+1$ separate single-particle states that differ
in the spin in the chosen $z$-direction. For photons, make that $2 s$
instead of $2 s+1$.

### 6.3 Density of States

Up to this point, this book has presented energy levels in the form of an energy spectrum. In these spectra, each single-particle energy was shown as a tick mark along the energy axis. The single-particle states with that energy were usually listed next to the tick marks. One example was the energy spectrum of the electron in a hydrogen atom as shown in figure 4.8.

However, the number of states involved in a typical macroscopic system can easily be of the order of $10^{20}$ or more. There is no way to show anywhere near that many energy levels in a graph. Even if printing technology was up to it, and it can only dream about it, your eyes would have only about $710^{6}$ cones and $1.310^{8}$ rods to see them.

For almost all practical purposes, the energy levels of a macroscopic system of noninteracting particles in a box form a continuum. That is schematically indicated by the hatching in the energy spectrum to the right in figure 6.1. The spacing between energy levels is however very many orders of magnitude tighter than the hatching can indicate.

|  | helium atom | electron | photon |
| :--- | :---: | :---: | :---: |
| $E_{111}^{\mathrm{p}}, \mathrm{eV}:$ | $1.510^{-18}$ | $1.110^{-14}$ | $1.110^{-4}$ |
| $T_{\text {equiv }}, \mathrm{K}:$ | $1.210^{-14}$ | $8.710^{-11}$ | 0.83 |

Table 6.1: Energy of the lowest single-particle state in a cube with 1 cm sides.
It can also normally be assumed that the lowest energy is zero for noninteracting particles in a box. While the lowest single particle energy is strictly speaking somewhat greater than zero, it is extremely small. That is numerically illustrated by the values for a $1 \mathrm{~cm}^{3}$ cubic box in table 6.1. The table gives the lowest energy as computed using the formulae given in the previous section. The lowest energy occurs for the state $\psi_{111}^{\mathrm{p}}$ with $n_{x}=n_{y}=n_{z}=1$. As is common
for single-particle energies, the energy has been expressed in terms of electron volts, one eV being about $1.610^{-19} \mathrm{~J}$. The table also shows the same energy in terms of an equivalent temperature, found by dividing it by 1.5 times the Boltzmann constant. These temperatures show that at room temperature, for all practical purposes the lowest energy is zero. However, at very low cryogenic temperatures, photons in the lowest energy state, or "ground state," may have a relatively more significant energy.

The spacing between the lowest and second lowest energy is comparable to the lowest energy, and similarly negligible. It should be noted, however, that in Bose-Einstein condensation, which is discussed later, there is a macroscopic effect of the finite spacing between the lowest and second-lowest energy states, miniscule as it might be.

The next question is why quantum mechanics is needed here at all. Classical nonquantum physics too would predict a continuum of energies for the particles. And it too would predict the energy to start from zero. The energy of a noninteracting particle is all kinetic energy; classical physics has that zero if the particle is at rest and positive otherwise.

Still, the (anti) symmetrization requirements cannot be accommodated using classical physics. And there is at least one other important quantum effect. Quantum mechanics predicts that there are more single-particle states in a given energy range at high energy than at low energy.

To express that more precisely, physicists define the "density of states" as the number of single-particle states per unit energy range. For particles in a box, the density of states is not that hard to find. First, the number $\mathrm{d} N$ of single-particle states in a small wave number range from $k$ to $k+\mathrm{d} k$ is given by, $\{\mathrm{D} .26\}$,

$$
\begin{equation*}
\mathrm{d} N=\mathcal{V}^{k} \mathrm{D}_{k} k \quad \mathcal{D}_{k}=\frac{2 s+1}{2 \pi^{2}} k^{2} \tag{6.5}
\end{equation*}
$$

Here $\mathcal{V}$ is the volume of the box that holds the particles. As you would expect, the bigger the box, the more particles it can hold, all else being the same. Similarly, the larger the wave number range $\mathrm{d} k$, the larger the number of states in it. The factor $\mathcal{D}_{k}$ is the density of states on a wave number basis. It depends on the spin $s$ of the particles; that reflects that there are $2 s+1$ possible values of the spin for every given spatial state.
(It should be noted that for the above expression for $\mathcal{D}_{k}$ to be valid, the wave number range $\mathrm{d} k$ should be small. However, $\mathrm{d} k$ should still be large enough that there are a lot of states in the range $\mathrm{d} k$; otherwise $\mathcal{D}_{k}$ cannot be approximated by a simple continuous function. If the spacing $\mathrm{d} k$ truly becomes zero, $\mathcal{D}_{k}$ turns into a distribution of infinite spikes.)

To get the density of states on an energy basis, eliminate $k$ in favor of the single-particle energy $E^{\mathrm{p}}$ using $E^{\mathrm{p}}=\hbar^{2} k^{2} / 2 m$, where $m$ is the particle mass.

That gives:

$$
\begin{equation*}
\mathrm{d} N=\mathcal{V} \mathcal{D} \mathrm{d} E^{\mathrm{p}} \quad \mathcal{D}=\frac{2 s+1}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \sqrt{E^{\mathrm{p}}} \tag{6.6}
\end{equation*}
$$

The requirements on the energy range $\mathrm{d} E^{\mathrm{p}}$ are like those on $\mathrm{d} k$.
The factor $\mathcal{D}$ is what is conventionally defined as the density of states; it is on a unit energy range and unit volume basis. In the spectrum to the right in figure 6.1, the density of states is indicated by means of the width of the spectrum.

Note that the density of states grows like $\sqrt{E^{\mathrm{p}}}$ : quickly at first, more slowly later, but it continues to grow. There are more states per unit energy range at higher energy than at lower energy. And that means that at nonzero energies, the energy states are spaced many times tighter together still than the ground state spacing of table 6.1 indicates. Assuming that the energies form a continuum is an extremely accurate approximation in most cases.

The given expression for the density of states is not valid if the particle speed becomes comparable to the speed of light. In particular for photons the Planck-Einstein expression for the energy must be used, $E^{p}=\hbar \omega$, where the electromagnetic frequency is $\omega=c k$ with $c$ the speed of light. In addition, as mentioned in section 6.2, photons have only two independent spin states, even though their spin is 1 .

It is conventional to express the density of states for photons on a frequency basis instead of an energy basis. Replacing $k$ with $\omega / c$ in (6.5) and $2 s+1$ by 2 gives

$$
\begin{equation*}
\mathrm{d} N=\mathcal{V} \mathcal{D}_{\omega} \mathrm{d} \omega \quad \mathcal{D}_{\omega}=\frac{1}{\pi^{2} c^{3}} \omega^{2} \tag{6.7}
\end{equation*}
$$

The factor $\mathcal{D}_{\omega}$ is commonly called the "density of modes" instead of density of states on a frequency basis.

## Key Points

$0-$ The spectrum of a macroscopic number of noninteracting particles in a box is practically speaking continuous.
$0-$ The lowest single-particle energy can almost always be taken to be zero.
$0-$ The density of states $\mathcal{D}$ is the number of single-particle states per unit energy range and unit volume.
$0-$ More precisely, the number of states in an energy range $\mathrm{d} E^{\mathrm{p}}$ is $\mathcal{V} \mathcal{D} \mathrm{d} E^{\mathrm{p}}$.
$0-$ To use this expression, the energy range $d E^{\mathrm{p}}$ should be small. However, $\mathrm{d} E^{\mathrm{p}}$ should still be large enough that there are a lot of states in the range.
$0-$ For photons, use the density of modes.

### 6.4 Ground State of a System of Bosons

The ground state for a system of noninteracting spinless bosons is simple. The ground state is defined as the state of lowest energy, so every boson has to be in the single-particle state $\psi_{111}^{\mathrm{p}}(\vec{r})$ of lowest energy. That makes the system energy eigenfunction for spinless bosons equal to:

$$
\begin{equation*}
\psi_{\text {gs }, \text { bosons }}=\psi_{111}^{\mathrm{p}}\left(\vec{r}_{1}\right) \times \psi_{111}^{\mathrm{p}}\left(\vec{r}_{2}\right) \times \ldots \times \psi_{111}^{\mathrm{p}}\left(\vec{r}_{I}\right) \tag{6.8}
\end{equation*}
$$

If the bosons have spin, this is additionally multiplied by an arbitrary combination of spin states. That does not change the system energy. The system energy either way is $I E_{111}^{\mathrm{p}}$, the number of bosons times the single-particle ground state energy.

Figure 6.2: Ground state of a system of noninteracting bosons in a box.

Graphically, the single-particle ground state $\psi_{111}^{\mathrm{p}}$ is the point closest to the origin in wave number space. It is shown as a fat blue dot in figure 6.2 to indicate that all $I$ bosons are bunched together in that state.

Physicists like to talk about "occupation numbers." The occupation number of a single-particle state is simply the number of particles in that state. In particular, for the ground state of the system of noninteracting spinless bosons above, the single-particle state $\psi_{111}^{\mathrm{p}}$ has occupation number $I$, while all other single-particle states have zero.

Note that for a macroscopic system, $I$ will be a humongous number. Even a millimol of particles means well over $10^{20}$ particles. Bosons in their ground state are very unfair to the single-particle states: $\psi_{111}^{\mathrm{p}}$ gets all of them, the rest gets nothing.

## Key Points

$0-$ For a system of bosons in the ground state, every boson is in the single particle state of lowest energy.

### 6.5 About Temperature

The previous section discussed the wave function for a macroscopic system of bosons in its ground state. However, that is really a very theoretical exercise.

A macroscopic system of particles is only in its ground state at what is called absolute zero temperature. Absolute zero temperature is $-273.15{ }^{\circ} \mathrm{C}$ in degrees Celsius (Centigrade) or $-459.67^{\circ} \mathrm{F}$ in degrees Fahrenheit. It is the coldest that a stable system could ever be.

Of course, you would hardly think something special was going on from the fact that it is $-273.15{ }^{\circ} \mathrm{C}$ or $-459.67^{\circ} \mathrm{F}$. That is why physicists have defined a more meaningful temperature scale than Centigrade or Fahrenheit; the Kelvin scale. The Kelvin scale takes absolute zero temperature to be 0 K , zero degrees Kelvin. A one degree temperature difference in Kelvin is still the same as in Centigrade. So 1 K is the same as $-272.15{ }^{\circ} \mathrm{C}$; both are one degree above absolute zero. Normal ambient temperatures are near 300 K. More precisely, 300 K is equal to $27.15{ }^{\circ} \mathrm{C}$ or $80.6^{\circ} \mathrm{F}$.

A temperature measured from absolute zero, like a temperature expressed in Kelvin, is called an "absolute temperature." Any theoretical computation that you do requires the use of absolute temperatures. (However, there are some empirical relations and tables that are mistakenly phrased in terms of Celsius or Fahrenheit instead of in Kelvin.)

Absolute zero temperature is impossible to achieve experimentally. Even getting close to it is very difficult. Therefore, real macroscopic systems, even very cold ones, have an energy noticeably higher than their ground state. So they have a temperature above absolute zero.

But what exactly is that temperature? Consider the classical picture of a substance, in which the molecules that it consists of are in constant chaotic thermal motion. Temperature is often described as a measure of the translational kinetic energy of this chaotic motion. The higher the temperature, the larger the thermal motion. In particular, classical statistical physics would say that the average thermal kinetic energy per particle is equal to $\frac{3}{2} k_{\mathrm{B}} T$, with $k_{\mathrm{B}}$
$=1.3810^{-23} \mathrm{~J} / \mathrm{K}$ the Boltzmann constant and $T$ the absolute temperature in degrees Kelvin.

Unfortunately, this story is only true for the translational kinetic energy of the molecules in an ideal gas. For any other kind of substance, or any other kind of kinetic energy, the quantum effects are much too large to be ignored. Consider, for example, that the electron in a hydrogen atom has 13.6 eV worth of kinetic energy even at absolute zero temperature. (The binding energy also happens to be 13.6 eV , \{A.17\}, even though physically it is not the same thing.) Classically that kinetic energy would correspond to a gigantic temperature of about 100000 K. Not to 0 K. More generally, the Heisenberg uncertainty principle says that particles that are in any way confined must have kinetic energy even in the ground state. Only for an ideal gas is the containing box big enough that it does not make a difference. Even then that is only true for the translational degrees of freedom of the ideal gas molecules. Don't look at their electrons or rotational or vibrational motion.

The truth is that temperature is not a measure of kinetic energy. Instead the temperature of a system is a measure of its capability to transfer thermal energy to other systems. By definition, if two systems have the same temperature, neither is able to transfer net thermal energy to the other. It is said that the two systems are in thermal equilibrium with each other. If however one system is hotter than the other, then if they are put in thermal contact, energy will flow from the hotter system to the colder one. That will continue until the temperatures become equal. Transferred thermal energy is referred to as "heat," so it is said that heat flows from the hotter system to the colder.

The simplest example is for systems in their ground state. If two systems in their ground state are brought together, no heat will transfer between them. By definition the ground state is the state of lowest possible energy. Therefore neither system has any spare energy available to transfer to the other system. It follows that all systems in their ground state have the same temperature. This temperature is simply defined to be absolute zero temperature, 0 K . Systems at absolute zero have zero capability of transferring heat to other systems.

Systems not in their ground state are not at zero temperature. Besides that, basically all that can be said is that they still have the same temperature as any other system that they are in thermal equilibrium with. But of course, this only defines equality of temperatures. It does not say what the value of that temperature is.

For identification and computational purposes, you would like to have a specific numerical value for the temperature of a given system. To get it, look at an ideal gas that the system is in thermal equilibrium with. A numerical value of the temperature can simply be defined by demanding that the average translational kinetic energy of the ideal gas molecules is equal to $\frac{3}{2} k_{\mathrm{B}} T$, where $k_{\mathrm{B}}$ is the Boltzmann constant, $1.3806510^{-23} \mathrm{~J} / \mathrm{K}$. That kinetic energy can be deduced from such easily measurable quantities as the pressure, volume, and
mass of the ideal gas.

## Key Points

$0=$ A macroscopic system is in its ground state if the absolute temperature is zero.
$0-$ Absolute zero temperature means 0 K (Kelvin), which is equal to $-273.15{ }^{\circ} \mathrm{C}$ (Centigrade) or $-459.67^{\circ} \mathrm{F}$ (Fahrenheit).
$0-$ Absolute zero temperature can never be fully achieved.
$0-$ If the temperature is greater than absolute zero, the system will have an energy greater than that of the ground state.
$0-$ Temperature is not a measure of the thermal kinetic energy of a system, except under very limited conditions in which there are no quantum effects.
$0-$ Instead the defining property of temperature is that it is the same for systems that are in thermal equilibrium with each other.
$0-$ For systems that are not in their ground state, a numerical value for their temperature can be defined using an ideal gas at the same temperature.

### 6.6 Bose-Einstein Condensation

This section examines what happens to a system of noninteracting bosons in a box if the temperature is somewhat greater than absolute zero.

As noted in the second last section, in the ground state all bosons are in the single-particle state of lowest energy. This was indicated by the fat blue dot next to the origin in the wave number space figure 6.2. Nonzero temperature implies that the bosons obtain an additional amount of energy above the ground state. Therefore they will spread out a bit towards states of higher energy. The single fat blue point will become a colored cloud as shown in figures 6.3 and 6.4. So far, that all seems plausible enough.

But something weird occurs for identical bosons:
Below a certain critical temperature a finite fraction of the bosons remains bunched together in the single-particle state of lowest energy.

That is indicated by the fat blue dot in figure 6.3. The lowest energy state, the one closest to the origin, holds less bosons than at absolute zero, but below a certain critical temperature, it remains a finite fraction of the total.

That is weird because the average thermal energy available to each boson dwarfs the difference in energy between the lowest energy single-particle state

Figure 6.3: The system of bosons at a very low temperature.

Figure 6.4: The system of bosons at a relatively low temperature.
and its immediate neighbors. If the energy difference between the lowest energy state and its neighbors is negligibly small, you would reasonably expect that they will hold similar numbers of bosons. And if a lot of states near the origin each hold about the same number of bosons, then that number must be a small fraction of the total, not a finite one. But reasonable or not, it is untrue. For a system of noninteracting bosons below the critical temperature, the lowest energy state holds a finite fraction of the bosons, much more than its immediate neighbors.

If you raise the temperature of the system, you "boil" away the bosons in the lowest energy state into the surrounding cloud. Above the critical temperature, the excess bosons are gone and the lowest energy state now only holds a similar number of bosons as its immediate neighbors. That is illustrated in figure 6.4. Conversely, if you lower the temperature of the system from above to below the critical temperature, the bosons start "condensing" into the lowest energy state. This process is called "Bose-Einstein condensation" after Bose and Einstein who first predicted it.

Bose-Einstein condensation is a pure quantum effect; it is due to the symmetrization requirement for the wave function. It does not occur for fermions, or if each particle in the box is distinguishable from every other particle. "Distinguishable" should here be taken to mean that there are no antisymmetrization requirements, as there are not if each particle in the system is a different type of particle from every other particle.

It should be noted that the given description is simplistic. In particular, it is certainly possible to cool a microscopic system of distinguishable particles down until say about half the particles are in the single-particle state of lowest energy. Based on the above discussion, you would then conclude that Bose-Einstein condensation has occurred. That is not true. The problem is that this supposed "condensation" disappears when you scale up the system to macroscopic dimensions and a corresponding macroscopic number of particles.

Given a microscopic system of distinguishable particles with half in the single-particle ground state, if you hold the temperature constant while increasing the system size, the size of the cloud of occupied states in wave number space remains about the same. However, the bigger macroscopic system has much more energy states, spaced much closer together in wave number space. Distinguishable particles spread out over these additional states, leaving only a vanishingly small fraction in the lowest energy state. This does not happen if you scale up a Bose-Einstein condensate; here the fraction of bosons in the lowest energy state stays finite regardless of system size.

Bose-Einstein condensation was achieved in 1995 by Cornell, Wieman, et al by cooling a dilute gas of rubidium atoms to below about 170 nK (nano Kelvin). Based on the extremely low temperature and fragility of the condensate, practical applications are very likely to be well into the future, and even determination of the condensate's basic properties will be difficult.

A process similar to Bose-Einstein condensation is also believed to occur in liquid helium when it turns into a superfluid below 2.17 K. However, this case is more tricky, $\{\mathrm{N} .21\}$. For one, the atoms in liquid helium can hardly be considered to be noninteracting. That makes the entire concept of "singleparticle states" poorly defined. Still, it is quite widely believed that for helium below 2.17 K , a finite fraction of the atoms starts accumulating in what is taken to be a single-particle state of zero wave number. Unlike for normal BoseEinstein condensation, for helium it is believed that the number of atoms in this state remains limited. At absolute zero only about $9 \%$ of the atoms end up in the state.

Currently there is a lot of interest in other systems of particles undergoing Bose-Einstein condensation. One example is liquid helium-3. Compared to normal helium, helium-3 misses a neutron in its nucleus. That makes its spin half-integer, so it is not a boson but a fermion. Therefore, it should not turn into a superfluid like normal liquid helium. And it does not. Helium 3 behaves in almost all aspects exactly the same as normal helium. It becomes liquid at a similar temperature, 3.2 K instead of 4.2 K . But it does not become a superfluid like normal helium at any temperature comparable to 2.17 K . That is very strong evidence that the superfluid behavior of normal helium is due to the fact that it is a boson.

Still it turns out that at temperatures three orders of magnitude smaller, helium-3 does turn into a superfluid. That is believed to be due to the fact that the atoms pair up. A composite of two fermions has integer spin, so it is a boson. Similarly, superconductivity of simple solids is due to the fact that the electrons pair up into "Cooper pairs." They get tied together due to their interaction with the surrounding atoms.

A variety of other particles can pair up to. At the time of writing, there is interest in polariton condensates. A polariton is a quantum mechanical superposition of a photon and an electronic excitation in a solid. It is hoped that these will allow Bose-Einstein condensation to be studied at room temperature. There is still much to be learned about it. For example, while the relationship between superfluidity and Bose-Einstein condensation is quite generally accepted, there are some issues. Snoke \& Baym point out, (in the introduction to Bose-Einstein Condensation, Griffin, A., Snoke, D.W., \& Stringari, S., Eds, 1995, Cambridge), that examples indicate that Bose-Einstein condensation is neither necessary nor sufficient for superfluidity. With only approximate theoretical models and approximate experimental data, it is often difficult to make solid specific statements.

## Key Points

### 6.6.1 Rough explanation of the condensation

The reason why bosons show Bose-Einstein condensation while systems of distinguishable particles do not is complex. It is discussed in chapter 11. However, the idea can be explained qualitatively by examining a very simple system

$$
\begin{aligned}
& \psi_{\mathrm{gs}}^{\mathrm{S}}\left(\vec{r}_{1}, \vec{r}_{2}, \vec{r}_{3}\right)=\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{3}\right) \\
& E_{\mathrm{gs}}^{\mathrm{S}}=E_{1}^{\mathrm{p}}+E_{1}^{\mathrm{p}}+E_{1}^{\mathrm{p}}=3 E_{1}^{\mathrm{p}}
\end{aligned}
$$

Figure 6.5: Ground state system energy eigenfunction for a simple model system. The system has only 6 single-particle states; each of these has one of 3 energy levels. In the specific case shown here, the system contains 3 distinguishable spinless particles. All three are in the single-particle ground state. Left: mathematical form. Right: graphical representation.

Assume that there are just three different single-particle energy levels, with values $E_{1}^{\mathrm{p}}, 2 E_{1}^{\mathrm{p}}$, and $3 E_{1}^{\mathrm{p}}$. Also assume that there is just one single-particle state with energy $E_{1}^{\mathrm{p}}$, but two with energy $2 E_{1}^{\mathrm{p}}$ and 3 with energy $3 E_{1}^{\mathrm{p}}$. That makes a total of 6 single particle-states; they are shown as "boxes" that can hold particles at the right hand side of figure 6.5. Assume also that there are just three particles and for now take them to be distinguishable. Figure 6.5 then shows the system ground state in which every particle is in the single-particle ground state with energy $E_{1}^{\mathrm{p}}$. That makes the total system energy $3 E_{1}^{\mathrm{p}}$.

$$
\begin{aligned}
& \psi_{151}^{\mathrm{S}}\left(\vec{r}_{1}, \vec{r}_{2}, \vec{r}_{3}\right)=\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}\right) \psi_{5}^{\mathrm{p}}\left(\vec{r}_{2}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{3}\right) \\
& E_{151}^{\mathrm{S}}=E_{1}^{\mathrm{p}}+3 E_{1}^{\mathrm{p}}+E_{1}^{\mathrm{p}}=5 E_{1}^{\mathrm{p}}
\end{aligned}
$$

Figure 6.6: Example system energy eigenfunction with five times the singleparticle ground state energy.

However, now assume that the system is at a nonzero temperature. In particular, assume that the total system energy is $5 E_{1}^{\mathrm{p}}$. An example system energy eigenfunction with that energy is illustrated in figure 6.6.

Figure 6.7: For distinguishable particles, there are 9 system energy eigenfunctions that have energy distribution A.

Figure 6.8: For distinguishable particles, there are 12 system energy eigenfunctions that have energy distribution B.

But there are a lot more system eigenfunctions with energy $5 E_{1}^{\mathrm{p}}$. There are two general ways to achieve that energy:

Energy distribution A: Two particles in the ground state with energy $E_{1}^{\mathrm{p}}$ and one in a state with energy $3 E_{1}^{\mathrm{p}}$.
Energy distribution B: One particle in the ground state with energy $E_{1}^{\mathrm{p}}$ and two in states with energy $2 E_{1}^{\mathrm{p}}$.
As figures 6.7 and 6.8 show, there are 9 system energy eigenfunctions that have energy distribution A , but 12 that have energy distribution B .

Therefore, all else being the same, energy distribution B is more likely to be observed than A!

Of course, the difference between 9 system eigenfunctions and 12 is minor. Also, everything else is not the same; the eigenfunctions differ. But it turns out that if the system size is increased to macroscopic dimensions, the differences in numbers of energy eigenfunctions become gigantic. There will be one energy distribution for which there are astronomically more system eigenfunctions than for any other energy distribution. Common-sense statistics then says that this energy distribution is the only one that will ever be observed. If there are countless orders of magnitude more eigenfunctions for a distribution B than for a distribution A , what are the chances of A ever being found?

It is curious to think of it: only one energy distribution is observed for a given macroscopic system. And that is not because of any physics; other energy distributions are physically just as good. It is because of a mathematical count; there are just so many more energy eigenfunctions with that distribution.

Figure 6.9: For identical bosons, there are only 3 system energy eigenfunctions that have energy distribution A.

Bose-Einstein condensation has to do with the fact that the count of eigenfunctions is different for identical bosons than for distinguishable particles. The details were worked out in chapter 5.7. The symmetrization requirement for bosons implies that system eigenfunctions that are the same except for exchanges of particles must be combined together into one. In particular for distribution A , in each of the rows of figure 6.7 the eigenfunctions are the same except for such exchanges. Simply put, they merely differ in what number is stamped on each particle. Therefore, for each row, the eigenfunctions must

Figure 6.10: For identical bosons, there are also only 3 system energy eigenfunctions that have energy distribution B.
be combined together into a single eigenfunction. That leaves only the three system eigenfunctions shown in figure 6.9.

In the combination eigenfunction, every particle occupies every single-particle state involved equally. Therefore, numbers on the particles would not add any nontrivial information and may as well be left away. Sure, you could put all three numbers 1,2 , and 3 in each of the particles in figure 6.9. But what good would that do?

Comparing figures 6.7 and 6.9 , you can see why particles satisfying symmetrization requirements are commonly called "indistinguishable." Classical quantum mechanics may imagine to stamp numbers on the three identical bosons to keep them apart, but you sure do not see the difference between them in the system energy eigenfunctions.

For distribution B of figure 6.8, under the symmetrization requirement the three energy eigenfunctions in the first row must be combined into one, the six in the second and third rows must be combined into one, and the three in the fourth row must be combined into one. That gives a total of 3 system eigenfunctions for distribution B , as shown in figure 6.10.

It follows that the symmetrization requirement reduces the number of eigenfunctions for distribution A , with 2 particles in the ground state, from 9 to 3. However, it reduces the eigenfunctions for distribution B, with 1 particle in the ground state, from 12 to 3 . Not only does the symmetrization requirement reduce the number of energy eigenfunctions, but it also tends to shift the balance towards eigenfunctions that have more particles in the ground state.

And so, if the system size is increased under conditions of Bose-Einstein condensation, it turns out that there are astronomically more system eigenfunctions for an energy distribution that keeps a finite number of bosons in the ground state than for anything else.

It may be noted from comparing figures 6.7 and 6.8 with 6.9 and 6.10 that any energy distribution that is physically possible for distinguishable particles is just as possible for identical bosons. Bose-Einstein condensation does not occur because the physics says it must, but because there are so gigantically more system eigenfunctions that have a finite fraction of bosons in the ground state than ones that do not.

It may also be noted that the reduction in the number of system energy eigenfunctions for bosons is believed to be an important factor in superfluidity. It eliminates low-energy eigenfunctions that cannot be interpreted as phonons, traveling particle wave solutions, $[18,39]$. The lack of alternate eigenfunctions leaves no mechanism for the traveling particles to get scattered by small effects.

## Key Points

$0-$ Energy distributions describe how many particles are found at each energy level.
$0-$ For macroscopic systems, one particular energy distribution has astronomically more energy eigenfunctions than any other one.
$0-$ That energy distribution is the only one that is ever observed.
$0-$ Under conditions of Bose-Einstein condensation, the observed distribution has a finite fraction of bosons in the ground state.
$0-$ This happens because the system eigenfunction count for bosons promotes it.

### 6.7 Bose-Einstein Distribution

As the previous section explained, the energy distribution of a macroscopic system of particles can be found by merely counting system energy eigenfunctions.

The details of doing so are messy but the results are simple. For a system of identical bosons, it gives the so-called:

$$
\begin{equation*}
\text { Bose-Einstein distribution: } \quad \iota^{\mathrm{b}}=\frac{1}{e^{\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T}-1} \tag{6.9}
\end{equation*}
$$

Here $\iota^{\text {b }}$ is the average number of bosons in a single-particle state with singleparticle energy $E^{\mathrm{p}}$. Further $T$ is the absolute temperature, and $k_{\mathrm{B}}$ is the Boltzmann constant, equal to $1.3806510^{-23} \mathrm{~J} / \mathrm{K}$.

Finally, $\mu$ is known as the chemical potential and is a function of the temperature and particle density. The chemical potential is an important physical quantity, related to such diverse areas as particle diffusion, the work that a device can produce, and to chemical and phase equilibria. It equals the so-called Gibbs free energy on a molar basis. It is discussed in more detail in chapter 11.12.

The Bose-Einstein distribution is derived in chapter 11. In fact, for various reasons that chapter gives three different derivations of the distribution. Fortunately they all give the same answer. Keep in mind that whatever this book tells you thrice is absolutely true.

The Bose-Einstein distribution may be used to better understand BoseEinstein condensation using a bit of simple algebra. First note that the chemical potential for bosons must always be less than the lowest single-particle energy $E_{\mathrm{gs}}^{\mathrm{p}}$. Just check it out using the formula above: if $\mu$ would be greater than $E_{\mathrm{gg}}^{\mathrm{p}}$, then the number of particles $\iota^{\mathrm{b}}$ in the lowest single-particle state would be negative. Negative numbers of particles do not exist. Similarly, if $\mu$ would equal $E_{\mathrm{gs}}^{\mathrm{p}}$ then the number of particles in the lowest single-particle state would be infinite.

The fact that $\mu$ must stay less than $E_{\mathrm{gs}}^{\mathrm{p}}$ means that the number of particles in anything but the lowest single-particle state has a limit. It cannot become greater than

$$
\iota_{\max }^{\mathrm{b}}=\frac{1}{e^{\left(E^{\mathrm{p}}-E_{\mathrm{gs}}^{\mathrm{p}}\right) / k_{\mathrm{B}} T}-1}
$$

Now assume that you keep the box size and temperature both fixed and start putting more and more particles in the box. Then eventually, all the singleparticle states except the ground state hit their limit. Any further particles have nowhere else to go than into the ground state. That is when Bose-Einstein condensation starts.

The above argument also illustrates that there are two main ways to produce Bose-Einstein condensation: you can keep the box and number of particles constant and lower the temperature, or you can keep the temperature and box constant and push more particles in the box. Or a suitable combination of these two, of course.

If you keep the box and number of particles constant and lower the temperature, the mathematics is more subtle. By itself, lowering the temperature lowers the number of particles $\iota^{\mathrm{b}}$ in all states. However, that would lower the total number of particles, which is kept constant. To compensate, $\mu$ inches closer to $E_{\mathrm{gs}}^{\mathrm{p}}$. This eventually causes all states except the ground state to hit their limit, and beyond that stage the left-over particles must then go into the ground state.

You may recall that Bose-Einstein condensation is only Bose-Einstein condensation if it does not disappear with increasing system size. That too can be verified from the Bose-Einstein distribution under fairly general conditions that include noninteracting particles in a box. However, the details are messy and will be left to chapter 11.14.1.

## Key Points

0- The Bose-Einstein distribution gives the number of bosons per singleparticle state for a macroscopic system at a nonzero temperature.
$0-$ It also involves the Boltzmann constant and the chemical potential.
$0-$ It can be used to explain Bose-Einstein condensation.

### 6.8 Blackbody Radiation

The Bose-Einstein distribution of the previous section can also be used for understanding the emission of light and other electromagnetic radiation. If you turn on an electric stove, the stove plate heats up until it becomes red hot. The red glow that you see consists of photons with energies in the visible red range. When the stove plate was cold, it also emitted photons, but those were of too low energy to be seen by our unaided eyes.

The radiation system that is easiest to analyze is the inside of an empty box. Empty should here be read as devoid of matter. For if the temperature inside the box is above absolute zero, then the inside of the box will still be filled with the electromagnetic radiation that the atoms in the box surfaces emit. This radiation is representative of the radiation that truly black surfaces emit. Therefore, the radiation inside the box is called "blackbody radiation."

Before the advent of quantum mechanics, Rayleigh and Jeans had computed using classical physics that the energy of the radiation in the box would vary with electromagnetic frequency $\omega$ and temperature $T$ as

$$
\rho(\omega)=\frac{\omega^{2}}{\pi^{2} c^{3}} k_{\mathrm{B}} T
$$

where $k_{\mathrm{B}}=1.3810^{-23} \mathrm{~J} / \mathrm{K}$ is the Boltzmann constant and $c$ the speed of light. That was clearly all wrong except at low frequencies. For one thing, the radiation energy would become infinite at infinite frequencies!

It was this very problem that led to the beginning of quantum mechanics. To fix the problem, in 1900 Planck made the unprecedented assumption that energy would not come in arbitrary amounts, but only in discrete chunks of size $\hbar \omega$. The constant $\hbar$ was a completely new physical constant whose value could be found by fitting theoretical radiation spectra to experimental ones. Planck's assumption was however somewhat vague about exactly what these chunks of energy were physically. It was Einstein who proposed, in his 1905 explanation of the photoelectric effect, that $\hbar \omega$ gives the energy of photons, the particles of electromagnetic radiation.

Photons are bosons, relativistic ones, to be sure, but still bosons. Therefore the Bose-Einstein distribution should describe their statistics. More specifically, the average number of photons in each single-particle state should be

$$
\begin{equation*}
\iota_{\gamma}^{\mathrm{b}}=\frac{1}{e^{E^{\mathrm{P}} / k_{\mathrm{B}} T}-1} \tag{6.10}
\end{equation*}
$$

where $\gamma$ is the standard symbol for a photon. Note the missing chemical potential. As discussed in chapter 11, the chemical potential is related to conservation of the number of particles. It does not apply to photons that are readily created out of nothing or absorbed by the atoms in the walls of the box. (One consequence is that Bose-Einstein condensation does not occur for photons, $\{\mathrm{N} .21\}$.)

To get the energy of the photons in a small frequency range $\mathrm{d} \omega$, simply multiply the number of single particle states in that range, (6.7), by the number of photons per state $\iota_{\gamma}^{\mathrm{b}}$ above, and that by the single-photon energy $E^{\mathrm{p}}=\hbar \omega$.

That gives the radiation energy per unit volume of the box and per unit energy range as

$$
\begin{equation*}
\rho(\omega)=\frac{\omega^{2}}{\pi^{2} c^{3}} \frac{\hbar \omega}{e^{\hbar \omega / k_{\mathrm{B}} T}-1} \tag{6.11}
\end{equation*}
$$

This expression is known as "Planck's blackbody spectrum."
For low frequencies, the final ratio is about $k_{\mathrm{B}} T$, giving the Rayleigh-Jeans result. That is readily verified from writing a Taylor series for the exponential in the denominator. For high frequencies the energy is much less because of the rapid growth of the exponential for large values of its argument. In particular, the energy no longer becomes infinite at high frequencies. It becomes zero instead.

To rewrite the blackbody spectrum in terms of the frequency $f=\omega / 2 \pi$ in cycles per second, make sure to convert the actual energy in a frequency range, $\mathrm{d} E=\rho(\omega) \mathrm{d} \omega$, to $\mathrm{d} E=\bar{\rho}(f) \mathrm{d} f$. Merely trying to convert $\rho$ will get you into trouble. The same if you want to rewrite the blackbody spectrum in terms of the wave length $\lambda=c / f$.

For engineering purposes, what is often the most important is the amount of radiation emitted by a surface into its surroundings. Now it so happens that if you drill a little hole in the box, you get a perfect model for a truly black surface. An ideal black surface is defined as a surface that absorbs, rather than reflects, all radiation that hits it. If the hole in the box is small enough, any radiation that hits the hole enters the box and is never seen again. In that sense the hole is perfectly black.

And note that a black surface does not have to look black. If the black plate of your electric stove is hot enough, it will glow red. Similarly, if you would heat the inside of the box to the same temperature, the radiation inside the box would make the hole shine just as red. If you would heat the box to 6000 K , about as hot as the surface of the sun, the hole would radiate sunlight.

The amount of radiation that is emitted by the hole can be found by simply multiplying Planck's spectrum by one quarter of the speed of light $c,\{\mathrm{D} .27\}$. That gives for the radiation energy emitted per unit area, per unit frequency range, and per unit time:

$$
\begin{equation*}
\mathcal{I}(\omega)=\frac{\omega^{2}}{4 \pi^{2} c^{2}} \frac{\hbar \omega}{e^{\hbar \omega / k_{\mathrm{B}} T}-1} \tag{6.12}
\end{equation*}
$$

A perfectly black surface area would radiate the same amount as the hole.
If you see the hole under an angle, it will look just as bright per unit area as when you see it straight on, but it will seem smaller. So your eyes will receive less radiation. More generally, if $A_{e}$ is a small black surface at temperature
$T$ that emits radiation, then the amount of that radiation received by a small surface $A_{r}$ is given by

$$
\begin{equation*}
\mathrm{d} E=\frac{\omega^{2}}{4 \pi^{3} c^{2}} \frac{A_{e} \cos \theta_{e} A_{r} \cos \theta_{r}}{r^{2}} \frac{\hbar \omega}{e^{\hbar \omega / k_{\mathrm{B}} T}-1} \mathrm{~d} \omega \mathrm{~d} t \tag{6.13}
\end{equation*}
$$

Here $r$ is the distance between the small surfaces, while $\theta_{e}$ and $\theta_{r}$ are the angles that the connecting line between the surfaces makes with the normals to the emitting and receiving surfaces respectively.

Often the total amount of energy radiated away by a black surface is of interest. To get it, simply integrate the emitted radiation (6.12) over all values of the frequency. You will want to make a change of integration variable to $\hbar \omega / k_{\mathrm{B}} T$ while doing this and then use a table book like [41, 18.80, p. 132]. The result is called the "Stefan-Boltzmann law:

$$
\begin{equation*}
\mathrm{d} E_{\text {total emitted }}=A \sigma_{B} T^{4} \mathrm{~d} t \quad \sigma_{B}=\frac{\pi^{2} k_{\mathrm{B}}^{4}}{60 \hbar^{3} c^{2}} \approx 5.6710^{-8} \mathrm{~W} / \mathrm{m}^{2} \mathrm{~K}^{4} \tag{6.14}
\end{equation*}
$$

Since this is proportional to $T^{4}$, at 6000 K 160000 times as much radiation will be emitted as at room temperature. In addition, a much larger part of that radiation will be in the visible range. That is the reason you will see light coming from a hole in a box if it is at 6000 K , but not when it is at room temperature.

A surface that is not perfectly black will absorb only a fraction of the radiation that hits it. The fraction is called the "absorptivity" $a$. Such a surface will also radiate less energy than a perfectly black one by a factor called the "emissivity" $e$. This assumes that the surface is in stable thermal equilibrium. More simply put, it assumes that no external source of energy is directed at the surface.

Helmholtz discovered that the absorptivity and emissivity of a surface are equal in thermal equilibrium, $\{\mathrm{D} .28\}$. So poor absorbers are also poor emitters of radiation. That is why lightweight emergency blankets typically have reflective metallic coatings. You would think that they would want to absorb, rather than reflect, the heat of incoming radiation. But if they did, then according to Helmholtz they would also radiate precious body heat away to the surroundings.

Since a surface cannot absorb more radiation than hits it, the absorptivity cannot be greater than one, It follows that the emissivity cannot be greater than one either. No surface can absorb better or emit better than a perfectly black one. At least not when in thermodynamic equilibrium.

Note that absorptivity and emissivity typically depend on electromagnetic frequency. Substances that seem black to the eye may not be at invisible electromagnetic frequencies and vice-verse. It remains true for any given electromagnetic frequency that the absorptivity and emissivity at that frequency are equal. To soak up the heat of the sun in a solar energy application, you want
your material to be black in the visible frequency range emitted by the 6000 K surface of the sun. However, you want it to be "white" in the infrared range emitted at the operating temperature of the material, in order that it does not radiate the heat away again.

Absorptivity and emissivity may also depend on the direction of the radiation, polarization, temperature, pressure, etcetera. In thermodynamic equilibrium, absorptivity and emissivity must still be equal, but only at the same frequency and same directions of radiation and polarization.

For surfaces that are not black, formula (6.13) will need to be modified for the relevant emissivity. A simplifying "grey body" assumption is often made that the absorptivity, and so the emissivity, is constant. Absorptivity and emissivity are usually defined as material properties, cited for infinitely thick samples. For objects, the terms absorptance and emittance are used.

Fluorescence/phosphorescence and stimulated emission (lasers) are important examples of radiative processes that are not in thermal equilibrium. The above discussion simply does not apply to them.

## Key Points

$0-$ Blackbody radiation is the radiation emitted by a black surface that is in thermal equilibrium.
$0-$ Planck's blackbody spectrum determines how much is radiated at each frequency.
$0-$ Surfaces that are not black emit radiation that is less by a factor called the emissivity.
$0 \simeq$ Emissivity equals absorptivity for the same frequency and direction of radiation.
$0-$ If the material is not in thermal equilibrium, like energized materials, it is a completely different ball game.

### 6.9 Ground State of a System of Electrons

So far, only the physics of bosons has been discussed. However, by far the most important particles in physics are electrons, and electrons are fermions. The electronic structure of matter determines almost all engineering physics: the strength of materials, all chemistry, electrical conduction and much of heat conduction, power systems, electronics, etcetera. It might seem that nuclear engineering is an exception because it primarily deals with nuclei. However, nuclei consist of protons and neutrons, and these are spin $1 / 2$ fermions just like electrons. The analysis below applies to them too.

Noninteracting electrons in a box form what is called a "free-electron gas." The valence electrons in a block of metal are often modeled as such a freeelectron gas. These electrons can move relatively freely through the block. As long as they do not try to get off the block, that is. Sure, a valence electron experiences repulsions from the surrounding electrons, and attractions from the nuclei. However, in the interior of the block these forces come from all directions and so they tend to average away.

Of course, the electrons of a "free" electron gas are confined. Since the term "noninteracting-electron gas" would be correct and understandable, there were few possible names left. So "free-electron gas" it was.

At absolute zero temperature, a system of fermions will be in the ground state, just like a system of bosons. However, the ground state of a macroscopic system of electrons, or any other type of fermions, is dramatically different from that of a system of bosons. For a system of bosons, in the ground state all bosons crowd together in the single-particle state of lowest energy. That was illustrated in figure 6.2. Not so for electrons. The Pauli exclusion principle allows only two electrons to go into the lowest energy state; one with spin up and the other with spin down. A system of $I$ electrons needs at least $I / 2$ spatial states to occupy. Since for a macroscopic system $I$ is a some gigantic number like $10^{20}$, that means that a gigantic number of states needs to be occupied.

Figure 6.11: Ground state of a system of noninteracting electrons, or other fermions, in a box.

In the system ground state, the electrons crowd into the $I / 2$ spatial states of lowest energy. Now the energy of the spatial states increases with the distance from the origin in wave number space. Therefore, the electrons occupy the $I / 2$ states closest to the origin in this space. That is shown to the left in figure 6.11.

Every red spatial state is occupied by 2 electrons, while the black states are unoccupied. The occupied states form an octant of a sphere. Of course, in a real macroscopic system, there would be many more states than a figure could show.

The spectrum to the right in figure 6.11 shows the occupied energy levels in red. The width of the spectrum indicates the density of states, the number of single-particle states per unit energy range.

## Key Points

$0-$ Noninteracting electrons in a box are called a free-electron gas.
$0 \_$In the ground state, the $I / 2$ spatial states of lowest energy are occupied by two electrons each. The remaining states are empty.
$0-$ The ground state applies at absolute zero temperature.

### 6.10 Fermi Energy of the Free-Electron Gas

As the previous section discussed, a system of noninteracting electrons, a freeelectron gas, occupies a range of single-particle energies. Now the electrons with the highest single-particle energies are particularly important. The reason is that these electrons have empty single-particle states available at just very slightly higher energy. Therefore, these electrons are easily excited to do useful things, like conduct electricity for example. In contrast, electrons in energy states of lower energy do not have empty states within easy reach. Therefore lower energy electron are essentially stuck in their states; they do not usually contribute to nontrivial electronic effects.

Valence electrons in metals behave qualitatively much like a free-electron gas. For them too, the electrons in the highest energy single-particle states are the critical ones for the metallic properties. Therefore, the highest singleparticle energy occupied by electrons in the system ground state has been given a special name; the "Fermi energy." In the energy spectrum of the free-electron gas to the right in figure 6.11, the Fermi energy is indicated by a red tick mark on the axis.

Also, the surface that the electrons of highest energy occupy in wave number space is called the "Fermi surface." For the free-electron gas the wave number space was illustrated to the left in figure 6.11. The Fermi surface is outlined in red in the figure; it is the spherical outside surface of the occupied region.

One issue that is important for understanding the properties of systems of electrons is the overall magnitude of the Fermi energy. Recall first that for a system of bosons, in the ground state all bosons are in the single-particle state of lowest energy. That state corresponds to the point closest to the origin in
wave number space. It has very little energy, even in terms of atomic units of electronic energy. That was illustrated numerically in table 6.1. The lowest single-particle energy is, assuming that the box is cubic

$$
\begin{equation*}
E_{111}^{\mathrm{p}}=3 \pi^{2} \frac{\hbar^{2}}{2 m_{e}} \frac{1}{\mathcal{V}^{2 / 3}} \tag{6.15}
\end{equation*}
$$

where $m_{\mathrm{e}}$ is the electron mass and $\mathcal{V}$ the volume of the box.
Unlike for bosons, for electrons only two electrons can go into the lowest energy state. Or in any other spatial state for that matter. And since a macroscopic system has a gigantic number of electrons, it follows that a gigantic number of states must be occupied in wave number space. Therefore the states on the Fermi surface in figure 6.11 are many orders of magnitude further away from the origin than the state of lowest energy. And since the energy is proportional to the square distance from the origin, that means that the Fermi energy is many orders of magnitude larger than the lowest single-particle energy $E_{111}^{\mathrm{p}}$.

More precisely, the Fermi energy of a free-electron gas can be expressed in terms of the number of electrons per unit volume $I / \mathcal{V}$ as:

$$
\begin{equation*}
E_{\mathrm{F}}^{\mathrm{p}}=\left(3 \pi^{2}\right)^{2 / 3} \frac{\hbar^{2}}{2 m_{e}}\left(\frac{I}{\mathcal{V}}\right)^{2 / 3} \tag{6.16}
\end{equation*}
$$

To check this relationship, integrate the density of states (6.6) given in section 6.3 from zero to the Fermi energy. That gives the total number of occupied states, which equals the number of electrons $I$. Inverting the expression to give the Fermi energy in terms of $I$ produces the result above.

It follows that the Fermi energy is larger than the lowest single-particle energy by the gigantic factor

$$
\frac{I^{2 / 3}}{\left(3 \pi^{2}\right)^{1 / 3}}
$$

It is instructive to put some ballpark number to the Fermi energy. In particular, take the valence electrons in a block of copper as a model. Assuming one valence electron per atom, the electron density $I / \mathcal{V}$ in the expression for the Fermi energy equals the atom density. That can be estimated to be $8.510^{28}$ atoms $/ \mathrm{m}^{3}$ by dividing the mass density, $9000 \mathrm{~kg} / \mathrm{m}^{3}$, by the molar mass, 63.5 $\mathrm{kg} / \mathrm{kmol}$, and then multiplying that by Avogadro's number, $6.0210^{26}$ particles $/$ kmol. Plugging it in (6.16) then gives a Fermi energy of 7 eV (electron Volt). That is quite a lot of energy, about half the 13.6 eV ionization energy of hydrogen atoms.

The Fermi energy gives the maximum energy that an electron can have. The average energy that they have is comparable but somewhat smaller:

$$
\begin{equation*}
E_{\text {average }}^{\mathrm{p}}=\frac{3}{5} E_{\mathrm{F}}^{\mathrm{p}} \tag{6.17}
\end{equation*}
$$

To verify this expression, find the total energy $E=\int E^{\mathrm{p}} \mathcal{V} \mathcal{D} \mathrm{d} E^{\mathrm{p}}$ of the electrons using (6.6) and divide by the number of electrons $I=\int \mathcal{V} \mathcal{D} \mathrm{d} E^{\mathrm{p}}$. The integration is again over the occupied states, so from zero to the Fermi energy.

For copper, the ballpark average energy is 4.2 eV . To put that in context, consider the equivalent temperature at which classical particles would need to be to have the same average kinetic energy. Multiplying 4.2 eV by $e / \frac{3}{2} k_{\mathrm{B}}$ gives an equivalent temperature of 33000 K . That is gigantic even compared to the melting point of copper, 1356 K . It is all due to the exclusion principle that prevents the electrons from dropping down into the already filled states of lower energy.

## Key Points

$0-$ The Fermi energy is the highest single-particle energy that a system of electrons at absolute zero temperature will occupy.
$0-$ It is normally a very high energy.
$0-$ The Fermi surface is the surface that the electrons with the Fermi energy occupy in wave number space.
$0=$ The average energy per electron for a free-electron gas is $60 \%$ of the Fermi energy.

### 6.11 Degeneracy Pressure

According to the previous sections, electrons, being fermions, behave in a way very differently from bosons. A system of bosons has very little energy in its ground state, as all bosons collect in the spatial state of lowest energy. Electrons cannot do so. At most two electrons can go into a single spatial state. A macroscopic system of electrons must occupy a gigantic number of states, ranging from the lowest energy state to states with many orders of magnitude more energy.

As a result, a "free-electron gas" of $I$ noninteracting electrons ends up with an average energy per electron that is larger than of a corresponding system of bosons by a gigantic factor of order $I^{2 / 3}$. That is all kinetic energy; all forces on the electrons are ignored in the interior of a free-electron gas, so the potential energy can be taken to be zero.

Having so much kinetic energy, the electrons exert a tremendous pressure on the walls of the container that holds them. This pressure is called "degeneracy pressure." It explains qualitatively why the volume of a solid or liquid does not collapse under normally applied pressures.

Of course, degeneracy pressure is a poorly chosen name. It is really due to the fact that the energy distribution of electrons is not degenerate, unlike that
of bosons. Terms like "exclusion-principle pressure" or "Pauli pressure" would capture the essence of the idea. So they are not acceptable.

The magnitude of the degeneracy pressure for a free-electron gas is

$$
\begin{equation*}
P_{\mathrm{d}}=\frac{2}{5}\left(3 \pi^{2}\right)^{2 / 3} \frac{\hbar^{2}}{2 m_{e}}\left(\frac{I}{\mathcal{V}}\right)^{5 / 3} \tag{6.18}
\end{equation*}
$$

This may be verified by equating the work $-P_{\mathrm{d}} \mathrm{d} \mathcal{V}$ done when compressing the volume a bit to the increase in the total kinetic energy $E^{S}$ of the electrons:

$$
-P_{\mathrm{d}} \mathrm{~d} \mathcal{V}=\mathrm{d} E^{\mathrm{S}}
$$

The energy $E^{\mathrm{S}}$ is $I$ times the average energy per electron. According to section 6.10, that is $\frac{3}{5} I$ times the Fermi energy (6.16).

A ballpark number for the degeneracy pressure is very instructive. Consider once again the example of a block of copper, with its valence electrons modeled as a free-electron gas, Using the same numbers as in the previous section, the degeneracy pressure exerted by these valence electrons is found to be $4010^{9} \mathrm{~Pa}$, or 40 GPa .

This tremendous outward pressure is balanced by the nuclei that pull on electrons that try to leave the block. The details are not that simple, but electrons that try to escape repel other, easily displaced, electrons that might aid in their escape, leaving the nuclei unopposed to pull them back. Obviously, electrons are not very smart.

It should be emphasized that it is not mutual repulsion of the electrons that causes the degeneracy pressure; all forces on the electrons are ignored in the interior of the block. It is the uncertainty relationship that requires spatially confined electrons to have momentum, and the exclusion principle that explodes the resulting amount of kinetic energy, creating fast electrons that are as hard to contain as students on the day before Thanksgiving.

Compared to a $10^{10} \mathrm{~Pa}$ degeneracy pressure, the normal atmospheric pressure of $10^{5} \mathrm{~Pa}$ cannot add any noticeable further compression. Pauli's exclusion principle makes liquids and solids quite incompressible under normal pressures.

However, under extremely high pressures, the electron pressure can lose out. In particular, for neutron stars the spatial electron states collapse under the very weight of the massive star. This is related to the fact that the degeneracy pressure grows less quickly with compression when the velocity of the electrons becomes relativistic. (For very highly relativistic particles, the kinetic energy is not given in terms of the momentum $p$ by the Newtonian value $E^{\mathrm{p}}=p^{2} / 2 m$, but by the Planck-Einstein relationship $E^{\mathrm{p}}=p c$ like for photons.) That makes a difference since gravity too increases with compression. If gravity increases more quickly, all is lost for the electrons. For neutron stars, the collapsed electrons combine with the protons in the star to form neutrons. It is the degeneracy pressure of the neutrons, also spin $1 / 2$ fermions but 2000 times heavier, that carries the weight of a neutron star.

## Key Points

0- Because typical confined electrons have so much kinetic energy, they exert a great degeneracy pressure on what is holding them.
$0-$ This pressure makes it very hard to compress liquids and solids significantly in volume.
$0-$ Differently put, liquids and solids are almost incompressible under typical conditions.

### 6.12 Confinement and the DOS

The motion of a single particle in a confining box was described in chapter 3.5.9. Nontrivial motion in a direction in which the box is sufficiently narrow can become impossible. This section looks at what happens to the density of states for such a box. The density of states gives the number of single-particle states per unit energy range. It is interesting for many reasons. For example, for systems of electrons the density of states at the Fermi energy determines how many electrons in the box pick up thermal energy if the temperature is raised above zero. It also determines how many electrons will be involved in electrical conduction if their energy is raised.

By definition, the density of states $\mathcal{D}$ gives the number of single-particle states $\mathrm{d} N$ in an energy range from $E^{\mathrm{p}}$ to $E^{\mathrm{p}}+\mathrm{d} E^{\mathrm{p}}$ as

$$
\mathrm{d} N=\mathcal{V} \mathcal{D} \mathrm{d} E^{\mathrm{p}}
$$

where $\mathcal{V}$ is the volume of the box containing the particles. To use this expression, the size of the energy range $\mathrm{d} E^{\mathrm{p}}$ should be small, but still big enough that the number of states $\mathrm{d} N$ in it remains large.

For a box that is not confining, the density of states is proportional to $\sqrt{E^{\mathrm{p}}}$. To understand why, consider first the total number of states $N$ that have energy less than some given value $E^{\mathrm{p}}$. For example, the wave number space to the left in figure 6.11 shows all states with energy less than the Fermi energy in red. Clearly, the number of such states is about proportional to the volume of the octant of the sphere that holds them. And that volume is in turn proportional to the cube of the sphere radius $k$, which is proportional to $\sqrt{E^{\mathrm{p}}},(6.4)$, so

$$
N=(\text { some constant })\left(E^{\mathrm{p}}\right)^{3 / 2}
$$

This gives the number of states that have energies less than some value $E^{\mathrm{p}}$. To get the number of states in an energy range from $E^{\mathrm{p}}$ to $E^{\mathrm{p}}+\mathrm{d} E^{\mathrm{p}}$, take a differential:

$$
\mathrm{d} N=(\text { some other constant }) \sqrt{E^{\mathrm{p}}} \mathrm{~d} E^{\mathrm{p}}
$$

So the density of states is proportional to $\sqrt{E^{\mathrm{p}}}$. (The constant of proportionality is worked out in derivation $\{\mathrm{D} .26\}$.) This density of states is shown as the width of the energy spectrum to the right in figure 6.11.

Figure 6.12: Severe confinement in the $y$-direction, as in a quantum well.
Confinement changes the spacing between the states. Consider first the case that the box containing the particles is very narrow in the $y$-direction only. That produces a quantum well, in which motion in the $y$-direction is inhibited. In wave number space the states become spaced very far apart in the $k_{y}$-direction. That is illustrated to the left in figure 6.12. The red states are again the ones with an energy below some given example value $E^{\mathrm{p}}$, say the Fermi energy. Clearly, now the number of states inside the red sphere is proportional not to its volume, but to the area of the quarter circle holding the red states. The density of states changes correspondingly, as shown to the right in figure 6.12.

Consider the variation in the density of states for energies starting from zero. As long as the energy is less than that of the smaller blue sphere in figure 6.12, there are no states at or below that energy, so there is no density of states either. However, when the energy becomes just a bit higher than that of the smaller blue sphere, the sphere gobbles up quite a lot of states compared to the small box volume. That causes the density of states to jump up. However, after that jump, the density of states does not continue grow like the unconfined case. The unconfined case keeps gobbling up more and more circles of states when the energy grows. The confined case remains limited to a single circle until the energy hits that of the larger blue sphere. At that point, the density of states jumps up again. Through jumps like that, the confined density of states eventually starts resembling the unconfined case when the energy levels get high enough.

As shown to the right in the figure, the density of states is piecewise constant for a quantum well. To understand why, note that the number of states on a circle is proportional to its square radius $k_{x}^{2}+k_{z}^{2}$. That is the same as $k^{2}-k_{y}^{2}$, and $k^{2}$ is directly proportional to the energy $E^{\mathrm{p}}$. So the number of states varies linearly with energy, making its derivative, the density of states, constant. (The detailed mathematical expressions for the density of states for this case and the ones below can again be found in derivation \{D.26\}.)

Figure 6.13: Severe confinement in both the $y$ and $z$ directions, as in a quantum wire.

The next case is that the box is very narrow in the $z$-direction as well as in the $y$-direction. This produces a quantum wire, where there is full freedom of motion only in the $x$-direction. This case is shown in figure 6.13. Now the states separate into individual lines of states. The smaller blue sphere just reaches the line of states closest to the origin. There are no energy states until the energy exceeds the level of this blue sphere. Just above that level, a lot of states are encountered relative to the very small box volume, and the density of states jumps way up. When the energy increases further, however, the density of states comes down again: compared to the less confined cases, no new lines of states are added until the energy hits the level of the larger blue sphere. When the latter happens, the density of states jumps way up once again. Mathematically, the density of states produced by each line is proportional to the reciprocal square root of the excess energy above the one needed to reach the line.

The final possibility is that the box holding the particles is very narrow in all three directions. This produces a quantum dot or artificial atom. Now each energy state is a separate point, figure 6.14. The density of states is now zero unless the energy sphere exactly hits one of the individual points, in which

Figure 6.14: Severe confinement in all three directions, as in a quantum dot or artificial atom.
case the density of states is infinite. So, the density of states is a set of spikes. Mathematically, the contribution of each state to the density of states is a delta function located at that energy.
(It may be pointed out that very strictly speaking, every density of states is a set of delta functions. After all, the individual states always remain discrete points, however extremely densely spaced they might be. Only if you average the delta functions over a small energy range $d E^{\mathrm{p}}$ do you get the smooth mathematical functions of the quantum wire, quantum well, and unconfined box. It is no big deal, as a perfect confining box does not exist anyway. In real life, energy spikes do broaden out bit; there is always some uncertainty in energy due to various effects.)

## Key Points

$0-$ If one or more dimensions of a box holding a system of particles becomes very small, confinement effects show up.
$0-$ In particular, the density of states shows a staging behavior that is typical for each reduced dimensionality.

### 6.13 Fermi-Dirac Distribution

The previous sections discussed the ground state of a system of fermions like electrons. The ground state corresponds to absolute zero temperature. This
section has a look at what happens to the system when the temperature becomes greater than zero.

For nonzero temperature, the average number of fermions $\iota^{\mathrm{f}}$ per singleparticle state can be found from the so-called

$$
\begin{equation*}
\text { Fermi-Dirac distribution: } \quad \iota^{\mathrm{f}}=\frac{1}{e^{\left(E^{\mathrm{P}}-\mu\right) / k_{\mathrm{B}} T}+1} \tag{6.19}
\end{equation*}
$$

This distribution is derived in chapter 11. Like the Bose-Einstein distribution for bosons, it depends on the energy $E^{\mathrm{p}}$ of the single-particle state, the absolute temperature $T$, the Boltzmann constant $k_{\mathrm{B}}=1.3810^{-23} \mathrm{~J} / \mathrm{K}$, and a chemical potential $\mu$. In fact, the mathematical difference between the two distributions is merely that the Fermi-Dirac distribution has a plus sign in the denominator where the Bose-Einstein one has a minus sign. Still, that small change makes for very different statistics.

The biggest difference is that $\iota^{\mathrm{f}}$ is always less than one: the Fermi-Dirac distribution can never have more than one fermion in a given single-particle state. That follows from the fact that the exponential in the denominator of the distribution is always greater than zero, making the denominator greater than one.

It reflects the exclusion principle: there cannot be more than one fermion in a given state, so the average per state cannot exceed one either. The BoseEinstein distribution can have many bosons in a single state, especially in the presence of Bose-Einstein condensation.

Note incidentally that both the Fermi-Dirac and Bose-Einstein distributions count the different spin versions of a given spatial state as separate states. In particular for electrons, the spin-up and spin-down versions of a spatial state count as two separate states. Each can hold one electron.

Consider now the system ground state that is predicted by the Fermi-Dirac distribution. In the limit that the temperature becomes zero, single-particle states end up with either exactly one electron or exactly zero electrons. The states that end up with one electron are the ones with energies $E^{\mathrm{p}}$ below the chemical potential $\mu$. Similarly the states that end up empty are the ones with $E^{\mathrm{p}}$ above $\mu$.

To see why, note that for $E^{\mathrm{p}}-\mu<0$, in the limit $T \rightarrow 0$ the argument of the exponential in the Fermi-Dirac distribution becomes minus infinity. That makes the exponential zero, and $\iota^{\mathrm{f}}$ is then equal to one. Conversely, for $E^{\mathrm{p}}-\mu$ $>0$, in the limit $T \rightarrow 0$ the argument of the exponential in the Fermi-Dirac distribution becomes positive infinity. That makes the exponential infinite, and $\iota^{\mathrm{f}}$ is then zero.

The correct ground state, as pictured earlier in figure 6.11, has one electron per state below the Fermi energy $E_{\mathrm{F}}^{\mathrm{p}}$ and zero electrons per state above the Fermi energy. The Fermi-Dirac ground state can only agree with this if the chemical
potential at absolute zero temperature is the same as the Fermi energy:

$$
\begin{equation*}
\mu=E_{\mathrm{F}}^{\mathrm{p}} \quad \text { at } \quad T=0 \tag{6.20}
\end{equation*}
$$

Figure 6.15: A system of fermions at a nonzero temperature.
Next consider what happens if the absolute temperature is not zero but a bit larger than that. The story given above for zero temperature does not change significantly unless the value of $E^{\mathrm{p}}-\mu$ is comparable to $k_{\mathrm{B}} T$. Only in a energy range of order $k_{\mathrm{B}} T$ around the Fermi energy does the average number of particles in a state change from its value at absolute zero temperature. Compare the spectrum at absolute zero temperature as sketched to the right in figure 6.11 to the one at a nonzero temperature shown in figure 6.15. The sharp transition from one particle per state, red, below the Fermi energy to zero particles per state, grey, above it smooths out a bit. As the wave number space to the left in figure 6.15 illustrates, at nonzero temperature a typical system energy eigenfunction has a few electrons slightly beyond the Fermi surface. Similarly it has a few "holes" (states that have lost their electron) immediately below the Fermi surface.

Put in physical terms, some electrons just below the Fermi energy pick up some thermal energy, which gives them an energy just above the Fermi energy. The affected energy range, and also the typical energy that the electrons in this range pick up, is comparable to $k_{\mathrm{B}} T$.

You may at first hardly notice the effect in the wave number space shown in figure 6.15. And that figure greatly exaggerates the effect to ensure that it is visible at all. Recall the ballpark Fermi energy given earlier for copper. It was equal to a $k_{\mathrm{B}} T$ value for an equivalent temperature of 33000 K . Since the
melting point of copper is only $1356 \mathrm{~K}, k_{\mathrm{B}} T$ is still negligibly small compared to the Fermi energy when copper melts. To good approximation, the electrons always remain like they were in their ground state at 0 K .

One of the mysteries of physics before quantum mechanics was why the valence electrons in metals do not contribute to the heat capacity. At room temperature, the atoms in typical metals were known to have picked up an amount of thermal energy comparable to $k_{\mathrm{B}} T$ per atom. Classical physics predicted that the valence electrons, which could obviously move independently of the atoms, should pick up a similar amount of energy per electron. That should increase the heat capacity of metals. However, no such increase was observed.

The Fermi-Dirac distribution explains why: only the electrons within a distance comparable to $k_{\mathrm{B}} T$ of the Fermi energy pick up the additional $k_{\mathrm{B}} T$ of thermal energy. This is only a very small fraction of the total number of electrons, so the contribution to the heat capacity is usually negligible. While classically the electrons may seem to move freely, in quantum mechanics they are constrained by the exclusion principle. Electrons cannot move to higher energy states if there are already electrons in these states.

To discourage the absence of confusion, some or all of the following terms may or may not indicate the chemical potential $\mu$, depending on the physicist: Fermi level, Fermi brim, Fermi energy, and electrochemical potential. It is more or less common to reserve "Fermi energy" to absolute zero temperature, but to not do the same for "Fermi level" or "Fermi brim." In any case, do not count on it. This book will occasionally use the term Fermi level for the chemical potential where it is common to do so. In particular, a Fermi-level electron has an energy equal to the chemical potential.

The term "electrochemical potential" needs some additional comment. The surfaces of solids are characterized by unavoidable layers of electric charge. These charge layers produce an electrostatic potential inside the solid that shifts all energy levels, including the chemical potential, by that amount. Since the charge layers vary, so does the electrostatic potential and with it the value of the chemical potential. It would therefore seem logical to define some "intrinsic" chemical potential, and add to it the electrostatic potential to get the total, or "electrochemical" potential.

For example, you might consider defining the "intrinsic" chemical potential $\mu_{\mathrm{i}}$ of a solid as the value of the chemical potential $\mu$ when the solid is electrically neutral and isolated. Now, when you bring dissimilar solids at a given temperature into electrical contact, double layers of charge build up at the contact surfaces between them. These layers change the electrostatic potentials inside the solids and with it their total electrochemical potential $\mu$.

In particular, the strengths of the double layers adjust so that in thermal equilibrium, the electrochemical potentials $\mu$ of all the solids (intrinsic plus additional electrostatic contribution due to the changed surface charge layers) are equal. They have to; solids in electrical contact become a single system of
electrons. A single system should have a single chemical potential.
Unfortunately, the assumed "intrinsic" chemical potential in the above description is a somewhat dubious concept. Even if a solid is uncharged and isolated, its chemical potential is not a material property. It still depends unavoidably on the surface properties: their contamination, roughness, and angular orientation relative to the atomic crystal structure. If you mentally take a solid attached to other solids out to isolate it, then what are you to make of the condition of the surfaces that were previously in contact with other solids?

Because of such concerns, nowadays many physicists disdain the concept of an intrinsic chemical potential and simply refer to $\mu$ as "the" chemical potential. Note that this means that the actual value of the chemical potential depends on the detailed conditions that the solid is in. But then, so do the electron energy levels. The location of the chemical potential relative to the spectrum is well defined regardless of the electrostatic potential.

And the chemical potentials of solids in contact and in thermal equilibrium still line up.

The Fermi-Dirac distribution is also known as the "Fermi factor." Note that in proper quantum terms, it gives the probability that a state is occupied by an electron.

## Key Points

0- The Fermi-Dirac distribution gives the number of electrons, or other fermions, per single-particle state for a macroscopic system at a nonzero temperature.
0 - Typically, the effects of nonzero temperature remain restricted to a, relatively speaking, small number of electrons near the Fermi energy.
$0-$ These electrons are within a distance comparable to $k_{\mathrm{B}} T$ of the Fermi energy. They pick up a thermal energy that is also comparable to $k_{\mathrm{B}} T$.
$0-$ Because of the small number of electrons involved, the effect on the heat capacity can usually be ignored.
0- When solids are in electrical contact and in thermal equilibrium, their (electro)chemical potentials / Fermi levels / Fermi brims / whatever line up.

### 6.14 Maxwell-Boltzmann Distribution

The previous sections showed that the thermal statistics of a system of identical bosons is normally dramatically different from that of a system of identical fermions. However, if the temperature is high enough, and the box holding the particles big enough, the differences disappear. These are ideal gas conditions.

Under these conditions the average number of particles per single-particle state becomes much smaller than one. That average can then be approximated by the so-called

$$
\begin{equation*}
\text { Maxwell-Boltzmann distribution: } \quad \iota^{\mathrm{d}}=\frac{1}{e^{\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T}} \quad \iota^{\mathrm{d}} \ll 1 \tag{6.21}
\end{equation*}
$$

Here $E^{\mathrm{p}}$ is again the single-particle energy, $\mu$ the chemical potential, $T$ the absolute temperature, and $k_{\mathrm{B}}$ the Boltzmann constant. Under the given conditions of a low particle number per state, the exponential is big enough that the $\pm 1$ found in the Bose-Einstein and Fermi-Dirac distributions (6.9) and (6.19) can be ignored.

Figure 6.16 gives a picture of the distribution for noninteracting particles in a box. The energy spectrum to the right shows the average number of particles per state as the relative width of the red region. The wave number space to the left shows a typical system energy eigenfunction; states with a particle in them are in red.

Figure 6.16: Particles at high-enough temperature and low-enough particle density.

Since the (anti) symmetrization requirements no longer make a difference, the Maxwell-Boltzmann distribution is often represented as applicable to "distinguishable" particles. But of course, where are you going to get a macroscopic number of, say, $10^{20}$ particles, each of a different type? The imagination boggles. Still, the "d" in $\iota^{\mathrm{d}}$ refers to distinguishable.

The Maxwell-Boltzmann distribution was already known before quantum mechanics. The factor $e^{-E^{\mathrm{P}} / k_{\mathrm{B}} T}$ in it implies that the number of particles at a given energy decreases exponentially with the energy. A classical example
is the decrease of density with height in the atmosphere. In an equilibrium (i.e. isothermal) atmosphere, the number of molecules at a given height $h$ is proportional to $e^{-m g h / k_{\mathrm{B}} T}$ where $m g h$ is the gravitational potential energy of the molecules. (It should be noted that normally the atmosphere is not isothermal because of the heating of the earth surface by the sun and other effects.)

The example of the isothermal atmosphere can be used to illustrate the idea of intrinsic chemical potential. Think of the entire atmosphere as build up out of small boxes filled with particles. The walls of the boxes conduct some heat and they are very slightly porous, to allow an equilibrium to develop if you are very patient. Now write the energy of the particles as the sum of their gravitational potential energy plus an intrinsic energy (which is just their kinetic energy for the model of noninteracting particles). Similarly write the chemical potential as the sum of the gravitational potential energy plus an intrinsic chemical potential:

$$
E^{\mathrm{p}}=m g h+E_{\mathrm{i}}^{\mathrm{p}} \quad \mu=m g h+\mu_{\mathrm{i}}
$$

Since $E^{\mathrm{p}}-\mu=E_{\mathrm{i}}^{\mathrm{p}}-\mu_{\mathrm{i}}$, the Maxwell-Boltzmann distribution is not affected by the switch to intrinsic quantities. But that implies that the relationship between kinetic energy, intrinsic chemical potential, and number of particles in each individual box is the same as if gravity was not there. In each box, the normal ideal gas law applies in terms of intrinsic quantities.

However, different boxes have different intrinsic chemical potentials. The entire system of boxes has one global temperature and one global chemical potential, since the porous walls make it a single system. But the global chemical potential that is the same in all boxes includes gravity. That makes the intrinsic chemical potential in boxes at different heights different, and with it the number of particles in the boxes.

In particular, boxes at higher altitudes have less molecules. Compare states with the same intrinsic, kinetic, energy for boxes at different heights. According to the Maxwell-Boltzmann distribution, the number of particles in a state with intrinsic energy $E_{\mathrm{i}}^{\mathrm{p}}$ is $1 / e^{\left(E_{\mathrm{i}}^{\mathrm{p}}+m g h-\mu\right) / k_{\mathrm{B}} T}$. That decreases with height proportional to $e^{-m g h / k_{\mathrm{B}} T}$, just like classical analysis predicts.

Now suppose that you make the particles in one of the boxes hotter. There will then be a flow of heat out of that box to the neighboring boxes until a single temperature has been reestablished. On the other hand, assume that you keep the temperature unchanged, but increase the chemical potential in one of the boxes. That means that you must put more particles in the box, because the Maxwell-Boltzmann distribution has the number of particles per state equal to $e^{\mu / k_{\mathrm{B}} T}$. The excess particles will slowly leak out through the slightly porous walls until a single chemical potential has been reestablished. Apparently, then, too high a chemical potential promotes particle diffusion away from a site, just like too high a temperature promotes thermal energy diffusion away from a site.

While the Maxwell-Boltzmann distribution was already known classically, quantum mechanics adds the notion of discrete energy states. If there are more
energy states at a given energy, there are going to be more particles at that energy, because (6.21) is per state. For example, consider the number of thermally excited atoms in a thin gas of hydrogen atoms. The number $I_{2}$ of atoms that are thermally excited to energy $E_{2}$ is in terms of the number $I_{1}$ with the ground state energy $E_{1}$ :

$$
\frac{I_{2}}{I_{1}}=\frac{8}{2} e^{-\left(E_{2}-E_{1}\right) / k_{\mathrm{B}} T}
$$

The final exponential is due to the Maxwell-Boltzmann distribution. The leading factor arises because there are eight electron states at energy $E_{2}$ and only two at energy $E_{1}$ in a hydrogen atom. At room temperature $k_{\mathrm{B}} T$ is about 0.025 eV , while $E_{2}-E_{1}$ is 10.2 eV , so there are not going to be any thermally excited atoms at room temperature.

## Key Points

$0-$ The Maxwell-Boltzmann distribution gives the number of particles per single-particle state for a macroscopic system at a nonzero temperature.
0- It assumes that the particle density is low enough, and the temperature high enough, that (anti) symmetrization requirements can be ignored.
$0-$ In particular, the average number of particles per single-particle state should be much less than one.
$0-$ According to the distribution, the average number of particles in a state decreases exponentially with its energy.
$0-$ Systems for which the distribution applies can often be described well by classical physics.
$0-$ Differences in chemical potential promote particle diffusion.

### 6.15 Thermionic Emission

The valence electrons in a block of metal have tremendous kinetic energy, of the order of electron volts. These electrons would like to escape the confines of the block, but attractive forces exerted by the nuclei hold them back. However, if the temperature is high enough, typically 1000 to 2500 K , a few electrons can pick up enough thermal energy to get away. The metal then emits a current of electrons. This is called "thermionic emission." It is important for applications such as electron tubes and fluorescent lamps.

The amount of thermionic emission depends not just on temperature, but also on how much energy electrons inside the metal need to escape. Now the energies of the most energetic electrons inside the metal are best expressed in
terms of the Fermi energy level. Therefore, the energy required to escape is conventionally expressed relative to that level. In particular, the additional energy that a Fermi-level electron needs to escape is traditionally written in the form $e \varphi_{\mathrm{w}}$ where $e$ is the electron charge and $\varphi_{\mathrm{w}}$ is called the "work function." The magnitude of the work function is typically on the order of volts. That makes the energy needed for a Fermi-level electron to escape on the order of electron volts, comparable to atomic ionization energies.

The thermionic emission equation gives the current density of electrons as, \{D.29\},

$$
\begin{equation*}
j=A T^{2} e^{-e \varphi_{\mathrm{w}} / k_{\mathrm{B}} T} \tag{6.22}
\end{equation*}
$$

where $T$ is the absolute temperature and $k_{\mathrm{B}}$ is the Boltzmann constant. The constant $A$ is typically one quarter to one half of its theoretical value

$$
\begin{equation*}
A_{\text {theory }}=\frac{m_{\mathrm{e}} e k_{\mathrm{B}}}{2 \pi^{2} \hbar^{3}} \approx 1.210^{6} \mathrm{amp} / \mathrm{m}^{2} \mathrm{~K}^{2} \tag{6.23}
\end{equation*}
$$

Note that thermionic emission depends exponentially on the temperature; unless the temperature is high enough, extremely little emission will occur. You see the Maxwell-Boltzmann distribution at work here. This distribution is applicable since the number of electrons per state is very small for the energies at which the electrons can escape.

Despite the applicability of the Maxwell-Boltzmann distribution, classical physics cannot explain thermionic emission. That is seen from the fact that the constant $A_{\text {theory }}$ depends nontrivially, and strongly, on $\hbar$. The dependence on quantum theory comes in through the density of states for the electrons that have enough energy to escape, $\{\mathrm{D} .29\}$.

Thermionic emission can be helped along by applying an additional electric field $\mathcal{E}_{\text {ext }}$ that drives the electrons away from the surface of the solid. That is known as the "Schottky effect." The electric field has the approximate effect of lowering the work function value by an amount, $\{\mathrm{D} .29\}$,

$$
\begin{equation*}
\sqrt{\frac{e \mathcal{E}_{\mathrm{ext}}}{4 \pi \epsilon_{0}}} \tag{6.24}
\end{equation*}
$$

For high-enough electric fields, significant numbers of electrons may also "tunnel" out due to their quantum uncertainty in position. That is called "field emission." It depends exponentially on the field strength, which must be very high as the quantum uncertainty in position is small.

It may be noted that the term "thermionic emission" may be used more generally to indicate the flow of charge carriers, either electrons or ions, over a potential barrier. Even for standard thermionic emission, it should be cautioned that the work function depends critically on surface conditions. For example, surface pollution can dramatically change it.

## Key Points

0- Some electrons can escape from solids if the temperature is sufficiently high. That is called thermionic emission.
0- The work function is the minimum energy required to take a Fermilevel electron out of a solid, per unit charge.
$0-$ An additional electric field can help the process along, in more ways than one.

### 6.16 Chemical Potential and Diffusion

The chemical potential, or Fermi level, that appears in the Fermi-Dirac distribution is very important for solids in contact. If two solids are put in electrical contact, at first electrons will diffuse to the solid with the lower chemical potential. It is another illustration that differences in chemical potential cause particle diffusion.

Of course the diffusion cannot go on forever. The electrons that transfer to the solid with the lower chemical potential will give it a negative charge. They will also leave a net positive charge behind on the solid with the higher chemical potential. Therefore, eventually an electrostatic force builds up that terminates the further transfer of electrons. With the additional electrostatic contribution, the chemical potentials of the two solids have then become equal. As it should. If electrons can transfer from one solid to the other, the two solids have become a single system. In thermal equilibrium, a single system should have a single Fermi-Dirac distribution with a single chemical potential.

The transferred net charges will collect at the surfaces of the two solids, mostly where the two meet. Consider in particular the contact surface of two metals. The interiors of the metals have to remain completely free of net charge, or there would be a variation in electric potential and a current would flow to eliminate it. The metal that initially has the lower Fermi energy receives additional electrons, but these stay within an extremely thin layer at its surface. Similarly, the locations of missing electrons in the other metal stay within a thin layer at its surface. Where the two metals meet, a "double layer" exists; it consists of a very thin layer of highly concentrated negative net charges next to a similar layer of highly concentrated positive net charges. Across this double layer, the mean electrostatic potential changes almost discontinuously from its value in the first metal to that in the second. The step in electrostatic potential is called the "Galvani potential."

Galvani potentials are not directly measurable; attaching voltmeter leads to the two solids adds two new contact surfaces whose potentials will change the measured potential difference. More specifically, they will make the measured
potential difference exactly zero. To see why, assume for simplicity that the two leads of the voltmeter are made of the same material, say copper. All chemical potentials will level up, including those in the two copper leads of the meter. But then there is no way for the actual voltmeter to see any difference between its two leads.

Of course, it would have to be so. If there really was a net voltage in thermal equilibrium that could move a voltmeter needle, it would violate the second law of thermodynamics. You cannot get work for nothing.

Note however that if some contact surfaces are at different temperatures than others, then a voltage can in fact be measured. But the physical reason for that voltage is not the Galvani potentials at the contact surfaces. Instead diffusive processes in the bulk of the materials cause it. See section 6.28 .2 for more details. Here it must suffice to note that the usable voltage is powered by temperature differences. That does not violate the second law; you are depleting temperature differences to get whatever work you extract from the voltage.

Similarly, chemical reactions can produce usable electric power. That is the principle of the battery. It too does not violate the second law; you are using up chemical fuel. The chemical reactions do physically occur at contact surfaces.

Somewhat related to Galvani potentials, there is an electric field in the gap between two different metals that are in electrical contact elsewhere. The corresponding change in electric potential across the gap is called the "contact potential" or "Volta potential."

As usual, the name is poorly chosen: the potential does not occur at the contact location of the metals. In fact, you could have a contact potential between different surfaces of the same metal, if the two surface properties are different. "Surface potential difference" or "gap potential" would have been a much more reasonable term. Only physicists would describe what really is a "gap potential" as a "contact potential."

The contact potential is equal to the difference in the work functions of the surfaces of the metals. As discussed in the previous section, the work function is the energy needed to take a Fermi-level electron out of the solid, per unit charge. To see why the contact potential equals the difference in work functions, imagine taking a Fermi-level electron out of the first metal, moving it through the gap, and putting it into the second metal. Since the electron is back at the same Fermi level that it started out at, the net work in this process should be zero. But if the work function of the second metal is different from the first, putting the electron back in the second metal does not recover the work needed to take it out of the first metal. Then electric work in the gap must make up the difference.

## Key Points

$0-$ When two solids are brought in contact, their chemical potentials, or Fermi levels, must line up. A double layer of positive and negative
charges forms at the contact surface between the solids. This double layer produces a step in voltage between the interiors of the solids.
$0-$ There is a voltage difference in the gap between two metals that are electrically connected and have different work functions. It is called the contact potential.

### 6.17 Intro to the Periodic Box

This chapter so far has shown that lots can be learned from the simple model of noninteracting particles inside a closed box. The biggest limitation of the model is particle motion. Sustained particle motion is hindered by the fact that the particles cannot penetrate the walls of the box.

One way of dealing with that is to make the box infinitely large. That produces motion in infinite and empty space. It can be done, as shown in chapter 7.9 and following. However, the analysis is nasty, as the eigenfunctions cannot be properly normalized. In many cases, a much simpler approach is to assume that the particles are in a finite, but periodic box. A particle that exits such a box through one side reenters it at the same time through the opposing side.

To understand the idea, consider the one-dimensional case. Studying one-dimensional motion along an infinite straight line $-\infty<x<\infty$ is typically nasty. One-dimensional motion along a circle is likely to be easier. Unlike the straight line, the circumference of the circle, call it $\ell_{x}$, is finite. So you can define a coordinate $x$ along the circle with a finite range $0<x<\ell_{x}$. Yet despite the finite circumference, a particle can keep moving along the circle without getting stuck. When the particle reaches the position $x=\ell_{x}$ along the circle, it is back at its starting point $x=0$. It leaves the defined $x$-range through $x=\ell_{x}$, but it reenters it at the same time through $x=0$. The position $x=\ell_{x}$ is physically exactly the same point as $x=0$.

Similarly a periodic box of dimensions $\ell_{x}, \ell_{y}$, and $\ell_{z}$ assumes that $x=\ell_{x}$ is physically the same as $x=0, y=\ell_{y}$ the same as $y=0$, and $z=\ell_{z}$ the same as $z=0$. That is of course hard to visualize. It is just a mathematical trick, but one that works well. Typically at the end of the analysis you take the limit that the box dimensions become infinite. That makes this artificial box disappear and you get the valid infinite-space solution.

The biggest difference between the closed box and the periodic box is linear momentum. For noninteracting particles in a periodic box, the energy eigenfunctions can be taken to be also eigenfunctions of linear momentum $\overrightarrow{\vec{p}}$. They then have definite linear momentum in addition to definite energy. In fact, the linear momentum is just a scaled wave number vector; $\vec{p}=\hbar \vec{k}$. That is discussed in more detail in the next section.

## Key Points

$0=\mathrm{A}$ periodic box is a mathematical concept that allows unimpeded motion of the particles in the box. A particle that exits the box through one side reenters it at the opposite side at the same time.
0 - For a periodic box, the energy eigenfunctions can be taken to be also eigenfunctions of linear momentum.

### 6.18 Periodic Single-Particle States

The single-particle quantum states, or energy eigenfunctions, for noninteracting particles in a closed box were given in section 6.2, (6.2). They were a product of a sine in each axial direction. Those for a periodic box can similarly be taken to be a product of a sine or cosine in each direction. However, it is usually much better to take the single-particle energy eigenfunctions to be exponentials:

$$
\begin{equation*}
\psi_{n_{x} n_{y} n_{z}}^{\mathrm{p}}(\vec{r})=\mathcal{V}^{-\frac{1}{2}} e^{\mathrm{i}\left(k_{x} x+k_{y} y+k_{z} z\right)}=\mathcal{V}^{-\frac{1}{2}} e^{\mathrm{i} \vec{k} \cdot \vec{r}} \tag{6.25}
\end{equation*}
$$

Here $\mathcal{V}$ is the volume of the periodic box, while $\vec{k}=\left(k_{x}, k_{y}, k_{z}\right)$ is the "wave number vector" that characterizes the state.

One major advantage of these eigenfunctions is that they are also eigenfunction of linear momentum. For example. the linear momentum in the $x$-direction equals $p_{x}=\hbar k_{x}$. That can be verified by applying the $x$-momentum operator $\hbar \partial / \mathrm{i} \partial x$ on the eigenfunction above. The same for the other two components of linear momentum, so:

$$
\begin{equation*}
p_{x}=\hbar k_{x} \quad p_{y}=\hbar k_{y} \quad p_{z}=\hbar k_{z} \quad \vec{p}=\hbar \vec{k} \tag{6.26}
\end{equation*}
$$

This relationship between wave number vector and linear momentum is known as the "de Broglie relation."

The reason that the momentum eigenfunctions are also energy eigenfunctions is that the energy is all kinetic energy. It makes the energy proportional to the square of linear momentum. (The same is true inside the closed box, but momentum eigenstates are not acceptable states for the closed box. You can think of the surfaces of the closed box as infinitely high potential energy barriers. They reflect the particles and the energy eigenfunctions then must be a $50 / 50$ mix of forward and backward momentum.)

Like for the closed box, for the periodic box the single-particle energy is still given by

$$
\begin{equation*}
E^{\mathrm{p}}=\frac{\hbar^{2}}{2 m} k^{2} \quad k \equiv \sqrt{k_{x}^{2}+k_{y}^{2}+k_{z}^{2}} \tag{6.27}
\end{equation*}
$$

That may be verified by applying the kinetic energy operator on the eigenfunctions. It is simply the Newtonian result that the kinetic energy equals $\frac{1}{2} m v^{2}$ since the velocity is $v=p / m$ by the definition of linear momentum and $p=\hbar k$ in quantum terms.

Unlike for the closed box however, the wave numbers $k_{x}, k_{y}$, and $k_{z}$ are now constrained by the requirement that the box is periodic. In particular, since $x$ $=\ell_{x}$ is supposed to be the same physical plane as $x=0$ for a periodic box, $e^{\mathrm{i} k_{x} \ell_{x}}$ must be the same as $e^{\mathrm{i} k_{x} 0}$. That restricts $k_{x} \ell_{x}$ to be an integer multiple of $2 \pi,(2.5)$. The same for the other two components of the wave number vector, so:

$$
\begin{equation*}
k_{x}=n_{x} \frac{2 \pi}{\ell_{x}} \quad k_{y}=n_{y} \frac{2 \pi}{\ell_{y}} \quad k_{z}=n_{z} \frac{2 \pi}{\ell_{z}} \tag{6.28}
\end{equation*}
$$

where the quantum numbers $n_{x}, n_{y}$, and $n_{z}$ are integers.
In addition, unlike for the sinusoidal eigenfunctions of the closed box, zero and negative values of the wave numbers must now be allowed. Otherwise the set of eigenfunctions will not be complete. The difference is that for the closed box, $\sin \left(-k_{x} x\right)$ is just the negative of $\sin \left(k_{x} x\right)$, while for the periodic box, $e^{-\mathrm{i} k_{x} x}$ is not just a multiple of $e^{i k_{x} x}$ but a fundamentally different function.

Figure 6.17 shows the wave number space for a system of electrons in a periodic box. The wave number vectors are no longer restricted to the first quadrant like for the closed box in figure 6.11; they now fill the entire space. In the ground state, the states occupied by electrons, shown in red, now form a complete sphere. For the closed box they formed just an octant of one. The Fermi surface, the surface of the sphere, is now a complete spherical surface.

It may also be noted that in later parts of this book, often the wave number vector or momentum vector is used to label the eigenfunctions:

$$
\psi_{n_{x} n_{y} n_{z}}^{\mathrm{p}}(\vec{r})=\psi_{k_{x} k_{y} k_{z}}^{\mathrm{p}}(\vec{r})=\psi_{p_{x} p_{y} p_{z}}^{\mathrm{p}}(\vec{r})
$$

In general, whatever is the most relevant to the analysis is used as label. In any scheme, the single-particle state of lowest energy is $\psi_{000}^{\mathrm{p}}(\vec{r})$; it has zero energy, zero wave number vector, and zero momentum.

## Key Points

$0-$ The energy eigenfunctions for a periodic box are usually best taken to be exponentials. Then the wave number values can be both positive and negative.
$0-$ The single-particle kinetic energy is still $\hbar^{2} k^{2} / 2 m$.
$0-$ The momentum is $\hbar \vec{k}$.
$0-$ The eigenfunction labelling may vary.

### 6.19 DOS for a Periodic Box

The density of states is the number of single-particle states per unit energy range. It turns out that the formulae for the density of states given in section 6.3 may be used for the periodic box as well as for the closed box. A box can hold about the same number of particles per unit volume whether the boundary conditions are periodic or not.

It is not that hard to verify. For a periodic box, the wave numbers can be both positive and negative, not just positive like for a closed box. On the other hand, a comparison of (6.3) and (6.28) shows that the wave number spacing for a periodic box is twice as large as for a corresponding closed box. That cancels the effect of the additional negative wave numbers and the total number of wave number vectors in a given energy range remains the same. Therefore the density of states is the same.

For the periodic box it is often convenient to have the density of states on a linear momentum basis. It can be found by substituting $k=p / \hbar$ into (6.5).

That gives the number of single-particle states $\mathrm{d} N$ in a momentum range of size $\mathrm{d} p$ as:

$$
\begin{equation*}
\mathrm{d} N=\mathcal{V}^{p} \mathrm{~d} p \quad \mathcal{D}_{p}=\frac{2 s+1}{2 \pi^{2} \hbar^{3}} p^{2} \tag{6.29}
\end{equation*}
$$

Here $\mathcal{D}_{p}$ is the density of states per unit momentum range and unit volume. Also, $s$ is again the particle spin. Recall that $2 s+1$ becomes $2 s$ for photons.

The staging behavior due to confinement gets somewhat modified compared to section 6.12 , since zero wave numbers are now included. The analysis is however essentially unchanged.

## Key Points

$0-$ The density of states is essentially the same for a periodic box as for a closed one.

### 6.20 Intro to Electrical Conduction

Some of the basic physics of electrical conduction in metals can be understood using a very simple model. That model is a free-electron gas, i.e. noninteracting electrons, in a periodic box.

The classical definition of electric current is moving charges. That can readily be converted to quantum terms for noninteracting electrons in a periodic box. The single-particle energy states for these electrons have definite velocity. That velocity is given by the linear momentum divided by the mass.

Consider the possibility of an electric current in a chosen $x$-direction. Figure 6.18 shows a plot of the single-particle energy $E^{\mathrm{p}}$ against the single-particle velocity $v_{x}^{\mathrm{p}}$ in the $x$-direction. The states that are occupied by electrons are shown in red. The parabolic outer boundary reflects the classical expression $E^{\mathrm{p}}=\frac{1}{2} m_{\mathrm{e}} \mathrm{v}^{\mathrm{p} 2}$ for the kinetic energy: for the single-particle states on the outer boundary, the velocity is purely in the $x$-direction.

In the system ground state, shown to the left in figure 6.18, no current will flow, because there are just as many electrons that move toward negative $x$ as there are that move towards positive $x$. To get net electron motion in the $x$ direction, electrons must be moved from states that have negative velocity in the $x$-direction to states that have positive velocity. That is indicated to the right in figure 6.18. The asymmetric occupation of states now produces net electron motion in the positive $x$-direction. That produces a current in the negative $x$ direction because of the fact that the charge $-e$ of electrons is negative.

Note that the electrons must pick up a bit of additional energy when they are moved from states with negative velocity to states with positive velocity. That is because the Pauli exclusion principle forbids the electrons from entering the lower energy states of positive velocity that are already filled with electrons.

Figure 6.18: Conduction in the free-electron gas model.

However, the required energy is small. You might just briefly turn on an external voltage source to produce an electric field that gets the electrons moving. Then you can turn off the voltage source again, because once set into motion, the noninteracting electrons will keep moving forever.

In physical terms, it is not really that just a few electrons make a big velocity change from negative to positive due to the applied voltage. In quantum mechanics electrons are completely indistinguishable, and all the electrons are involved equally in the changes of state. It is better to say that all electrons acquire a small additional drift velocity $\Delta v_{x}^{\mathrm{p}}$ in the positive $x$-direction. In terms of the wave number space figure 6.17 , this shifts the entire sphere of occupied states a bit towards the right, because velocity is proportional to wave number for a free-electron gas.

The net result is still the energy versus velocity distribution shown to the right in figure 6.18. Electrons at the highest energy levels with positive velocities go up a bit in energy. Electrons at the highest energy levels with negative velocities go down a bit in energy. The electrons at lower energy levels move along to ensure that there is no more than one electron in each quantum state. The fact remains that the system of electrons picks up a bit of additional energy. (The last subsection of derivation $\{$ D. 45$\}$ discusses the effect of the applied voltage in more detail.)

Conduction electrons in an actual metal wire behave similar to free electrons. However, they must move around the metal atoms, which are normally arranged in some periodic pattern called the crystal structure. The conduction electrons
will periodically get scattered by thermal vibrations of the crystal structure, (in quantum terms, by phonons), and by crystal structure imperfections and impurities. That kills off their organized drift velocity $\Delta v_{x}^{\mathrm{p}}$, and a small permanent electric field is required to replenish it. In other words, there is resistance. But it is not a large effect. For one, in macroscopic terms the conduction electrons in a metal carry quite a lot of charge per unit volume. So they do not have to go fast. Furthermore, conduction electrons in copper or similar good metal conductors may move for thousands of Ångstroms before getting scattered, slipping past thousands of atoms. Electrons in extremely pure copper at liquid helium temperatures may even move millimeters or more before getting scattered. The average distance between scattering events, or "collisions," is called the "free path" length $\ell$. It is very large on an atomic scale.

Of course, that does not make much sense from a classical point of view. Common sense says that a point-size classical electron in a solid should pretty much bounce off every atom it encounters. Therefore the free path of the electrons should be of the order of a single atomic spacing, not thousands of atoms or much more still. However, in quantum mechanics electrons are not particles with a definite position. Electrons are described by a wave function. It turns out that electron waves can propagate through perfect crystals without scattering, much like electromagnetic waves can. The free-electron gas wave functions adapt to the crystal structure, allowing the electrons to flow past the atoms without reflection.

It is of some interest to compare the quantum picture of conduction to that of a classical, nonquantum, description. In the classical picture, all conduction electrons would have a random thermal motion. The average velocity $v$ of that motion would be proportional to $\sqrt{k_{\mathrm{B}} T / m_{\mathrm{e}}}$, with $k_{\mathrm{B}}$ the Boltzmann constant, $T$ the absolute temperature, and $m_{\mathrm{e}}$ the electron mass. In addition to this random thermal motion in all directions, the electrons would also have a small organized drift velocity $\Delta v_{x}^{\mathrm{p}}$ in the positive $x$-direction that produces the net current. This organized motion would be created by the applied electric field in between collisions. Whenever the electrons collide with atoms, they lose much of their organized motion, and the electric field has to start over again from scratch.

Based on this picture, a ballpark expression for the classical conductivity can be written down. First, by definition the current density $j_{x}$ equals the number of conduction electrons per unit volume $i_{\mathrm{e}}$, times the electric charge $-e$ that each carries, times the small organized drift velocity $\Delta v_{x}^{\mathrm{p}}$ in the $x$-direction that each has:

$$
\begin{equation*}
j_{x}=-i_{\mathrm{e}} e \Delta v_{x}^{\mathrm{p}} \tag{6.30}
\end{equation*}
$$

The drift velocity $\Delta v_{x}^{\mathrm{p}}$ produced by the electric field between collisions can be found from Newton's second law as the force on an electron times the time interval between collisions during which this force acts and divided by the electron
mass. The average drift velocity would be half that, assuming for simplicity that the drift is totally lost in collisions, but the half can be ignored in the ballpark anyway. The force on an electron equals $-e \mathcal{E}_{x}$ where $\mathcal{E}_{x}$ is the electric field due to the applied voltage. The time between collisions can be computed as the distance between collisions, which is the free path length $\ell$, divided by the velocity of motion $v$. Since the drift velocity is small compared to the random thermal motion, $v$ can be taken to be the thermal velocity. The "conductivity" $\sigma$ is the current density per unit electric field, so putting it all together,

$$
\begin{equation*}
\sigma \sim \frac{i_{\mathrm{e}} e^{2} \ell}{m_{\mathrm{e}} v} \tag{6.31}
\end{equation*}
$$

Neither the thermal velocity $v$ nor the free path $\ell$ will be the same for all electrons, so suitable averages have to be used in more detailed expressions. The "resistivity" is defined as the reciprocal of the conductivity, so as $1 / \sigma$. It is the resistance of a unit cube of material.

For metals, things are a bit different because of quantum effects. In metals random collisions are restricted to a small fraction of electrons at the highest energy levels. These energy levels are characterized by the Fermi energy, the highest occupied energy level in the spectrum to the left in figure 6.18. Electrons of lower energies do not have empty states nearby to be randomly scattered into. The velocity of electrons near the Fermi energy is much larger than the thermal value $\sqrt{k_{\mathrm{B}} T / m_{\mathrm{e}}}$, because there are much too few states with thermallevel energies to hold all conduction electrons, section 6.10. The bottom line is that for metals, in the ballpark for the conductivity the free path length $\ell$ and velocity $v$ of the Fermi-level electrons must be used. In addition, the electron mass $m_{\mathrm{e}}$ may need to be changed into an effective one to account for the forces exerted by the crystal structure on the electrons. That will be discussed in more detail in section 6.22.3.

The classical picture works much better for semiconductors, since these have much less conduction electrons than would be needed to fill all the quantum states available at thermal energies. The mass correction remains required.

## Key Points

$0-$ The free-electron gas can be used to understand conduction in metals in simple terms.
$0-$ In the absence of a net current the electrons are in states with velocities in all directions. The net electron motion therefore averages out to zero.
0-A A net current is achieved by giving the electrons an additional small organized motion.
$0-$ The energy needed to do this is small.

0 - In real metals, the electrons lose their organized motion due to collisions with phonons and crystal imperfections. Therefore a small permanent voltage must be applied to maintain the net motion. That means that there is electrical resistance. However, it is very small for typical metals.

### 6.21 Intro to Band Structure

Quantum mechanics is essential to describe the properties of solid materials, just as it is for lone atoms and molecules. One well-known example is superconductivity, in which current flows without any resistance. The complete absence of any resistance cannot be explained by classical physics, just like superfluidity cannot for fluids.

But even normal electrical conduction simply cannot be explained without quantum theory. Consider the fact that at ordinary temperatures, typical metals have electrical resistivities of a few times $10^{-8}$ ohm-m (and up to a hundred thousand times less still at very low temperatures), while Wikipedia lists a resistance for teflon of up to $10^{24} \mathrm{ohm}-\mathrm{m}$. (Teflon's "one-minute" resistivity can be up to $10^{19} \mathrm{ohm}-\mathrm{m}$.) That is a difference in resistance between the best conductors and the best insulators by over thirty orders of magnitude!

There is simply no way that classical physics could even begin to explain it. As far as classical physics is concerned, all of these materials are quite similar combinations of positive nuclei and negative electrons.

Consider an ordinary sewing needle. You would have as little trouble supporting its tiny 60 mg weight as a metal has conducting electricity. But multiply it by $10^{30}$. Well, don't worry about supporting its weight. Worry about the entire earth coming up over your ears and engulfing you, because the needle now has ten times the mass of the earth. That is how widely different the electrical conductivities of solids are.

Only quantum mechanics can explain why it is possible, by making the electron energy levels discrete, and more importantly, by grouping them together in "bands."

## Key Points

0- Even excluding superconductivity, the electrical conductivities of solids vary enormously.

### 6.21.1 Metals and insulators

To understand electrical conduction in solids requires consideration of their electron energy levels.

Typical energy spectra are sketched in figure 6.19. The spectrum of a freeelectron gas, noninteracting electrons in a box, is shown to the left. The energy $E^{\mathrm{p}}$ of the single-particle states is shown along the vertical axis. The energy levels allowed by quantum mechanics start from zero and reach to infinity. The energy levels are spaced many orders of magnitude more tightly together than the hatching in the figure can indicate. For almost all practical purposes, the energy levels form a continuum. In the ground state, the electrons fill the lowest of these energy levels, one electron per state. In the figure, the occupied states are shown in red. For a macroscopic system, the number of electrons is practically speaking infinite, and so is the number of occupied states.

Figure 6.19: Sketch of electron energy spectra in solids at absolute zero temperature. (No attempt has been made to picture a density of states). Far left: the free-electron gas has a continuous band of extremely densely spaced energy levels. Far right: lone atoms have only a few discrete electron energy levels. Middle: actual metals and insulators have energy levels grouped into densely spaced bands separated by gaps. Insulators completely fill up the highest occupied band.

However, the free-electron gas assumes that there are no forces on the electrons. Inside a solid, this would only be true if the electric charges of the nuclei and fellow electrons would be homogeneously distributed throughout the entire solid. In that case the forces come equally from all directions and cancel each other out perfectly. In a true solid, forces from different directions do tend to cancel each other out, but this is far from perfect. For example, an electron very close to one particular nucleus experiences a strong attraction from that nucleus, much too strong for the rest of the solid to cancel.

The diametrical opposite of the free-electron gas picture is the case that the atoms of the solid are spaced so far apart that they are essentially lone atoms. In that case, of course, the "solid" would not physically be a solid at all, but a thin gas. Lone atoms do not have a continuum of electron energy levels, but discrete ones, as sketched to the far right in figure 6.19. One basic example is the hydrogen spectrum shown in figure 4.8. Every lone atom in the system
has the exact same discrete energy levels. Widely spaced atoms do not conduct electricity, assuming that not enough energy is provided to ionize them. While for the free-electron gas conduction can be achieved by moving a few electrons to slightly higher energy levels, for lone atoms there are no slightly higher energy levels.

When the lone atoms are brought closer together to form a true solid, however, the discrete atomic energy levels broaden out into bands. In particular, the outer electrons start to interact strongly with surrounding atoms. The different forms that these interactions can take produce varying energies, causing initially equal electron energies to broaden into bands. The result is sketched in the middle of figure 6.19. The higher occupied energy levels spread out significantly. (The inner atomic electrons, having the most negative net energies, do not interact significantly with different atoms, and their energy levels do not broaden much. This is not just because these electrons are farther from the surrounding atoms, but also because the inner electrons have much greater kinetic and much more negative potential energy levels to start with.)

For metals, conduction now becomes possible. Electrons at the highest occupied energy level, the Fermi energy, can be moved to slightly higher energy levels to provide net motion in a particular direction. That is just like they can for a free-electron gas as discussed in the previous section. The net motion produces a current.

Insulators are different. As sketched in figure 6.19, they completely fill up the highest occupied energy band. That filled band is called the "valence band." The next higher and empty band is called the "conduction band."

Now it is no longer possible to prod electrons to slightly higher energy levels to create net motion. There are no slightly higher energy levels available; all levels in the valence band are already filled with electrons.

To create a state with net motion, some electrons would have to be moved to the conduction band. But that would require large amounts of energy. The minimum energy required is the difference between the top of the valence band and the bottom of the conduction band. This energy is appropriately called the "band gap" energy $E_{\text {gap }}^{\mathrm{p}}$. It is typically of the order of electron volts, comparable to atomic potentials for outer electrons. That is in turn comparable to ionization energies, a great amount of energy on an atomic scale.

Resistance is determined for voltages low enough that Ohm's law applies. Such voltages do not provide anywhere near the energy required to move electrons to the conduction band. So the electrons in an insulator are stuck. They cannot achieve net motion at all. And without net motion, there is no current. That makes the resistance infinite. In this way the band gaps are responsible for the enormous difference in resistance between metals and insulators.

Note that a normal applied voltage will not have a significant effect on the band structure. Atomic potential energies are in terms of eV or more. For the applied voltage to compete with that would require a voltage drop comparable
to volts per atom. On a microscopic scale, the applied potential does not change the states.

## Key Points

0- Quantum mechanics allows only discrete energy levels for the electrons in a solid, and these levels group together in bands with gaps in between them.
0- If the electrons fill the spectrum right up to a gap between bands, the electrons are stuck. It will require a large amount of energy to activate them to conduct electricity or heat. Such a solid is an insulator at absolute zero temperature.
0 - The filled band is called the valence band, and the empty band above it the conduction band.

### 6.21.2 Typical metals and insulators

If a material completely fills up its valence band with electrons, it is an insulator. But what materials would do that? This subsection gives a few rules of thumb.

One important rule is that the elements towards the left in the periodic table figure 5.8 are metals. A relatively small group of elements towards the right are nonmetals.

Consider first the alkali metals found in group I to the far left in the table. The lone atoms have only one valence electron per atom. It is in an atomic " s " state that can hold two electrons, chapter 5.9.4. Every spatial state, including the s state, can hold two electrons that differ in spin.

Now if the lone atoms are brought closer together to form a solid, the spatial states change. Their energy levels broaden out into a band. However, the total number of states does not change. One spatial state per atom stays one spatial state per atom. Since each spatial state can hold two electrons, and there is only one, the band formed from the s states is only half filled. Therefore, like the name says, the alkali metals are metals.

In helium the spatial 1s states are completely filled with the two electrons per atom. That makes solid helium an insulator. It should be noted that helium is only a solid at very low temperatures and very high pressures. The atoms are barely held together by very weak Van der Waals forces.

The alkaline metals found in group II of the periodic table also have two valence electrons per atom. So you would expect them to be insulators too. However, like the name says, the alkaline metals are metals. What happens is that the filled band originating from the atomic s states merges with an empty band originating from the atomic p states. That produces a partially filled combined band.

This does not apply to helium because there are no 1 p states. The lowest empty energy states for helium are the 2 s ones. Still, computations predict that helium will turn metallic at extremely high pressures. Compressing a solid has the primary effect of increasing the kinetic energy of the electrons. Roughly speaking, the kinetic energy is inversely proportional to the square of the electron spacing, compare the Fermi energy (6.16). And increasing the kinetic energy of the electrons brings them closer to a free-electron gas.

A case resembling that of helium is ionic materials in which the ions have a noble-gas electron structure. A basic example is salt, sodium chloride. These materials are insulators, as it takes significant energy to take apart the noble-gas electron configurations. See however the discussion of ionic conductivity later in this section.

Another case that requires explanation is hydrogen. Like the alkali metals, hydrogen has only one valence electron per atom. That is not enough to fill up the energy band resulting from the atomic 1s states. So you would expect solid hydrogen to be a metal. But actually, hydrogen is an insulator. What happens is that the energy band produced by the 1s states splits into two. And the lower half is completely filled with electrons.

The reason for the splitting is that in the solid, the hydrogen atoms combine pairwise into molecules. In an hydrogen molecule, there are not two separate spatial 1 s states of equal energy, chapter 5.2. Instead, there is a lowered-energy two-electron spatial state in which the two electrons are symmetrically shared. There is also a raised-energy two-electron spatial state in which the two electrons are antisymmetrically shared. So there are now two energy levels with a gap in between them. The two electrons occupy the lower-energy symmetric state with opposite spins. In the solid, the hydrogen molecules are barely held together by weak Van der Waals forces. The interactions between the molecules are small, so the two molecular energy levels broaden only slightly into two thin bands. The gap between the filled symmetric states and the empty antisymmetric ones remains.

Note that sharing electrons in pairs involves a nontrivial interaction between the two electrons in each pair. The truth must be stretched a bit to fit it within the band theory idea of noninteracting electrons. Truly noninteracting electrons would have the spatial states of the hydrogen molecular ion available to them, chapter 4.6. Here the lower energy state is one in which a single electron is symmetrically shared between the atoms. And the higher energy state is one in which a single electron is antisymmetrically shared. In the model of noninteracting electrons, both electrons occupy the lower-energy single-electron spatial state, again with opposite spins. One problem with this picture is that the single-electron states do not take into account where the other electron is. There is then a significant chance that both electrons can be found around the same atom. In the correct two-electron state, the electrons largely avoid that. Being around the same atom would increase their energy, since the electrons
repel each other.
Note also that using the actual hydrogen molecular ion states may not be the best approach. It might be better to account for the presence of the other electron approximately using some nuclear shielding approach like the one used for atoms in chapter 5.9. An improved, but still approximate way of accounting for the second electron would be to use a so-called "Hartree-Fock" method. More generally, the most straightforward band theory approach tends to work better for metals than for insulators. Alternative numerical methods exist that work better for insulators. At the time of writing there is no simple magic bullet that works well for every material.

Group IV elements like diamond, silicon, and germanium pull a similar trick as hydrogen. They are insulators at absolute zero temperature. However, their 4 valence electrons per atom are not enough to fill the merged band arising from the s and p states. That band can hold 8 electrons per atom. Like hydrogen, a gap forms within the band. First the s and p states are converted into hybrids, chapter 5.11.4. Then states are created in which electrons are shared symmetrically between atoms and states in which they are shared antisymmetrically. There is an energy gap between these states. The lower energy states are filled with electrons and the higher energy states are empty, producing again an insulator. But unlike in hydrogen, each atom is now bonded to four others. That turns the entire solid into essentially one big molecule. These materials are much stronger and more stable than solid hydrogen. Like helium, hydrogen is only a solid at very low temperatures.

It may be noted that under extremely high pressures, hydrogen might become metallic. Not only that, as the smallest atom of them all, and in the absence of 1 p atomic states, metallic hydrogen is likely to have some very unusual properties. It makes metallic hydrogen the holy grail of high pressure physics.

It is instructive to examine how the band theory of noninteracting electrons accounts for the fact that hydrogen is an insulator. Unlike the discussion above, band theory does not actually look at the number of valence electrons per atom. For one, a solid may consist of atoms of more than one kind. In general, crystalline solids consist of elementary building blocks called "primitive cells" that can involve several atoms. Band theory predicts the solid to be a metal if the number of electrons per primitive cell is odd. If the number of electrons per primitive cell is even, the material may be an insulator. In solid hydrogen each primitive cell holds a complete molecule, so there are two atoms per primitive cell. Each atom contributes an electron, so the number of electrons per primitive cell is even. According to band theory, that allows hydrogen to be an insulator. In a similar way group $V$ elements can fill up their valence bands with an odd number of valence electrons per atom. And like hydrogen, diamond, silicon, and germanium have two atoms per primitive cell, reflecting the gap that forms in the merged $s$ and $p$ bands.

Of course, that cannot be the complete story. It does not explain why atoms towards the right in the periodic table would group together into primitive cells that allow them to be insulators. Why don't the atoms to the left in the periodic table do the same? Why don't the alkali metals group together in two-atom molecules like hydrogen does? Qualitatively speaking, metals are characterized by valence electrons that are relatively loosely bound. Suppose you compare the size of the 2 s state of a lithium atom with the spacing of the atoms in solid lithium. If you do, you find that on average the 2 s valence electron is no closer to the atom to which it supposedly "belongs" than to the neighboring atoms. Therefore, the electrons are what is called "delocalized." They are not bound to one specific location in the atomic crystal structure. So they are not really interested in helping bond "their" particular atom to its immediate neighbors. On the other hand, to the right in the periodic table, including hydrogen and helium, the valence electrons are much more tightly held. To delocalize them would require that the atoms would be squeezed much more tightly together. That does not happen under normal pressures because it produces very high kinetic energy of the electrons.

Where hydrogen refuses to be a metal with one valence electron per atom, boron refuses to do so with three. However, boron is very ambivalent about it. It does not really feel comfortable with either metallic or covalent behavior. A bit of impurity can readily turn it metallic. That great sensitivity to impurity makes the element very hard to study. At the time of writing, it is believed that boron has a covalent ground state under normal pressures. The convoluted crystal structure is believed to have a unit cell with either 12 or 106 atoms, depending on precise conditions.

In group IV, tin is metallic above $13{ }^{\circ} \mathrm{C}$, as white tin, but covalent below this temperature, as grey tin. It is often difficult to predict whether an element is a metal or covalent near the middle of the periodic table. Lead, of course, is a metal.

It should further be noted that band theory can be in error because it ignores the interactions between the electrons. "Mott insulators" and "charge transfer insulators" are, as the name says, insulators even though conventional band theory would predict that they are metals.

## Key Points

$0-$ In the periodic table, the group I, II, and III elements are normally metals.
$0=$ Hydrogen and helium are nonmetals. Don't ask about boron.
$0-$ The group IV elements diamond, silicon, and germanium are insulators at absolute zero temperature.

### 6.21.3 Semiconductors

Temperature can have significant effects on electrical conduction. As the previous section noted, higher temperature decreases the conduction in metals, as there are more crystal vibrations that the moving electrons can get scattered by. But a higher temperature also changes which energy states the electrons occupy. And that can produce semiconductors.

Figure 6.19 showed which energy states the electrons occupy at absolute zero temperature. There are no electrons with energies above the Fermi level indicated by the red tick mark. Figure 6.20 shows how that changes for a nonzero temperature. Now random thermal motion allows electrons to reach energy levels up to roughly $k_{\mathrm{B}} T$ above the Fermi level. Here $k_{\mathrm{B}}$ is the Boltzmann constant and $T$ the absolute temperature. This change in electron energies is described mathematically by the Fermi-Dirac distribution discussed earlier.

Figure 6.20: Sketch of electron energy spectra in solids at a nonzero temperature.

It does not make much difference for a free-electron gas or a metal. However, for an insulator it may make a dramatic difference. If the band gap is not too large compared to $k_{\mathrm{B}} T$, random thermal motion will put a few very lucky electrons in the previously empty conduction band. These electrons can then be prodded to slightly higher energies to allow some electric current to flow. Also, the created "holes" in the valence band, the states that have lost their electrons, allow some electric current. Valence band electrons can be moved into holes that have a preferred direction of motion from states that do not. These electrons will then leave behind holes that have the opposite direction of motion.

It is often more convenient to think of the moving holes instead of the electrons as the electric current carriers in the valence band. Since a hole means that a negatively charged electron is missing, a hole acts much like a positively charged particle would.

Because both the electrons in the conduction band and the holes in the valence band allow some electrical conduction, the original insulator has turned
into what is called a "semiconductor."
The previous section mentioned that a classical picture of moving electrons simply does not work for metals. Their motion is much too much restrained by a lack of available empty energy states. However, the conduction band of semiconductors is largely empty. Therefore a classical picture works much better for the motion of the electrons in the conduction band of a semiconductor.

## Key Points

$0-$ For semiconductors, conduction can occur because some electrons from the valence band are thermally excited to the conduction band.
$0-$ Both the electrons that get into the conduction band and the holes they leave behind in the valence band can conduct electricity.

### 6.21.4 Semimetals

One additional type of electron energy spectrum for solids should be mentioned. For a "semimetal," two distinct energy bands overlap slightly at the Fermi level. In terms of the simplistic spectra of figure 6.19, that would mean that semimetals are metals. Indeed they do allow conduction at absolute zero temperature. However, their further behavior is noticeably different from true metals because the overlap of the two bands is only small. One difference is that the electrical conduction of semimetals increases with temperature, unlike that of metals. Like for semiconductors, for semimetals a higher temperature means that there are more electrons in the upper band and more holes in the lower band. That effect is sketched to the far right in figure 6.20.

The classical semimetals are arsenic, antimony, and bismuth. Arsenic and antimony are not just semimetals, but also "metalloids," a group of elements whose chemical properties are considered to be intermediate between metals and nonmetals. But semimetal and metalloid are not the same thing. Semimetals do not have to consist of a single element. Conversely, metalloids include the semiconductors silicon and germanium.

A semimetal that is receiving considerable attention at the time of writing is graphite. Graphite consists of sheets of carbon atoms. A single sheet of carbon, called graphene, is right on the boundary between semimetal and semiconductor. A carbon nanotube can be thought of as a strip cut from a graphene sheet that then has its long edges attached together to produce a cylinder. Carbon nanotubes have electrical properties that are fundamentally different depending on the direction in which the strip is cut from the sheet. They can either be metallic or nonmetallic.
$0-$ Semimetals have properties intermediate between metals and semiconductors.

### 6.21.5 Electronic heat conduction

The valence electrons in metals are not just very good conductors of electricity, but also of heat. In insulators electrons do not assist in heat conduction; it takes too much energy to excite them. However, atomic vibrations in solids can conduct heat too. For example, diamond, an excellent electrical insulator, is also an excellent conductor of heat. Therefore the differences in heat conduction between solids are not by far as large as those in electrical conduction. Because atoms can conduct significant heat, no solid material will be a truly superb thermal insulator. Practical thermal insulators are highly porous materials whose volume consists largely of voids.

## Key Points

$0-$ Electrons conduct heat very well, but atoms can do it too.
$0-$ Practical thermal insulators use voids to reduce atomic heat conduction.

### 6.21.6 Ionic conductivity

It should be mentioned that electrons do not have an absolute monopoly on electrical conduction in solids. A different type of electrical conduction is possible in ionic solids. These solids consist of a mixture of positively and negatively charged ions. Positive ions, or "cations," are atoms that have lost one or more electrons. Negative ions, or "anions," are atoms that have absorbed one or more additional electrons. A simple example of a ionic solid is salt, which consists of $\mathrm{Na}^{+}$sodium cations and $\mathrm{Cl}^{-}$chlorine anions. For ionic solids a small amount of electrical conduction may be possible due to motion of the ions. This requires defects in the atomic crystal structure in order to give the atoms some room to move.

Typical defects include "vacancies," in which an atom is missing from the crystal structure, and "interstitials," in which an additional atom has been forced into one of the small gaps between the atoms in the crystal. Now if a ion gets removed from its normal position in the crystal to create a vacancy, it must go somewhere. One possibility is that it gets squeezed in between the other atoms in the crystal. In that case both a vacancy and an interstitial have been produced at the same time. Such a combination of a vacancy and an interstitial is called a "Frenkel defect." Another possibility occurs in, for example, salt;
along with the original vacancy, a vacancy for a ion of the opposite kind is created. Such a combination of two opposite vacancies is called a "Schottky defect." In this case there is no need to squeeze an atom in the gaps in the crystal structure; there are now equal numbers of ions of each kind to fill the surrounding normal crystal sites. Creating defects in Frenkel or Schottky pairs ensures that the complete crystal remains electrically neutral as it should.

Impurities are another important defect. For example, in salt a $\mathrm{Ca}^{2+}$ calcium ion might be substituted for a $\mathrm{Na}^{+}$sodium ion. The calcium ion has the charge of two sodium ions, so a sodium vacancy ensures electric neutrality of the crystal. In yttria-stabilized zirconia, (YSZ), oxygen vacancies are created in zirconia, $\mathrm{ZrO}_{2}$, by replacing some $\mathrm{Zr}^{4+}$ zirconium ions with $\mathrm{Y}^{3+}$ yttrium ones. Calcium ions can also be used. The oxygen vacancies allow mobility for the oxygen ions. That is important for applications such as oxygen sensors and solid oxide fuel cells.

For salt, the main conduction mechanism is by natrium vacancies. But the ionic conductivity of salt is almost immeasurably small at room temperature. That is due to the high energy needed to create Schottky defects and for natrium ions to migrate into the natrium vacancies. Indeed, whatever little conduction there is at room temperature is due to impurities. Heating will help, as it increases the thermal energy available for both defect creation and ion mobility. As seen from the Maxwell-Boltzmann distribution discussed earlier, thermal effects increase exponentially with temperature. Still, even at the melting point of salt its conductivity is eight orders of magnitude less than that of metals.

There are however ionic materials that have much higher conductivities. They cannot compete with metals, but some ionic solids can compete with liquid electrolytes. These solids may be referred to as "solid electrolytes, "fast ion conductors," or "superionic conductors." They are important for such applications as batteries, fuel cells, and gas sensors. Yttria-stabilized zirconia is an example, although unfortunately only at temperatures around $1000{ }^{\circ} \mathrm{C}$. In the best ionic conductors, the crystal structure for one kind of ion becomes so irregular that these ions are effectively in a molten state. For example, this happens for the silver ions in the classical example of hot silver iodide. Throw in $25 \%$ of rubidium chloride and $\mathrm{RbAg}_{4} \mathrm{Cl}_{5}$ stays superionic to room temperature.

Crystal surfaces are also crystal defects, in a sense. They can enhance ionic conductivity. For example, nanoionics can greatly improve the ionic conductivity of poor ionic conductors by combining them in nanoscale layers.

## Key Points

$0-$ In ionic solids, some electrical conduction may occur through the motion of the ions instead of individual electrons.
$0-$ It is important for applications such as batteries, fuel cells, and gas sensors.

### 6.22 Electrons in Crystals

A meaningful discussion of semiconductors requires some background on how electrons move through solids. The free-electron gas model simply assumes that the electrons move through an empty periodic box. But of course, to describe a real solid the box should really be filled with the countless atoms around which the conduction electrons move.

This subsection will explain how the motion of electrons gets modified by the atoms. To keep things simple, it will still be assumed that there is no direct interaction between the electrons. It will also be assumed that the solid is crystalline, which means that the atoms are arranged in a periodic pattern. The atomic period should be assumed to be many orders of magnitude shorter than the size of the periodic box. There must be many atoms in each direction in the box.

Figure 6.21: Potential energy seen by an electron along a line of nuclei. The potential energy is in green, the nuclei are in red.

The effect of the crystal is to introduce a periodic potential energy for the electrons. For example, figure 6.21 gives a sketch of the potential energy seen by an electron along a line of nuclei. Whenever the electron is right on top of a nucleus, its potential energy plunges. Close enough to a nucleus, a very strong attractive Coulomb potential is seen. Of course, on a line that does not pass exactly through nuclei, the potential will not plunge that low.

Figure 6.22: Potential energy seen by an electron in the one-dimensional simplified model of Kronig \& Penney.

Kronig \& Penney developed a very simple one-dimensional model that explains much of the motion of electrons through crystals. It assumes that the potential energy seen by the electrons is periodic on some atomic-scale period $d_{x}$. It also assumes that this potential consists of square dips, like in figure 6.22. You might think of the regions of lowered potential energy as the immediate vicinity of the nuclei. This is the model that will be examined. The atomic period $d_{x}$ is assumed to be much smaller than the periodic box size $\ell_{x}$, i.e. the
size of the complete "crystal." In particular, the box should contain a large and whole number of atomic periods.

Three-dimensional Kronig \& Penney quantum states can be formed as products of one-dimensional ones, compare chapter 3.5.8. However, such states are limited to potentials that are sums of one-dimensional ones. In any case, this section will restrict itself mostly to the one-dimensional case.

### 6.22.1 Bloch waves

This subsection examines the single-particle quantum states, or energy eigenfunctions, of electrons in one-dimensional solids.

For free electrons, the energy eigenfunctions were given in section 6.18. In one dimension they are:

$$
\psi_{n_{x}}^{\mathrm{p}}(x)=C e^{\mathrm{i} k_{x} x}
$$

where integer $n_{x}$ merely numbers the eigenfunctions and $C$ is a normalization constant that is not really important. What is important is that these eigenfunctions do not just have definite energy $E_{x}^{\mathrm{p}}=\hbar^{2} k_{x}^{2} / 2 m_{\mathrm{e}}$, they also have definite linear momentum $p_{x}=\hbar k_{x}$. Here $m_{e}$ is the electron mass and $\hbar$ the reduced Planck constant. In classical terms, the electron velocity is given by the linear momentum as $v_{x}^{\mathrm{p}}=p_{x} / m_{\mathrm{e}}$.

To find the equivalent one-dimensional energy eigenfunctions $\psi_{n_{x}}^{\mathrm{p}}(x)$ in the presence of a crystal potential $V_{x}(x)$ is messy. It requires solution of the one-dimensional Hamiltonian eigenvalue problem

$$
-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \frac{\partial^{2} \psi^{\mathrm{p}}}{\partial x^{2}}+V_{x} \psi^{\mathrm{p}}=E_{x}^{\mathrm{p}} \psi^{\mathrm{p}}
$$

where $E_{x}^{\mathrm{p}}$ is the energy of the state. The solution is best done on a computer, even for a potential as simple as the Kronig \& Penney one, \{N.9\}.

However, it can be shown that the eigenfunctions can always be written in the form:

$$
\begin{equation*}
\psi_{n_{x}}^{\mathrm{p}}(x)=\psi_{\mathrm{p}, n_{x}}^{\mathrm{p}}(x) e^{\mathrm{i} k_{x} x} \tag{6.32}
\end{equation*}
$$

in which $\psi_{\mathrm{p}, n_{x}}^{\mathrm{p}}(x)$ is an periodic function on the atomic period. Note that as long as $\psi_{\mathrm{p}, n_{x}}^{\mathrm{p}}(x)$ is a simple constant, this is exactly the same as the eigenfunctions of the free-electron gas in one dimension; mere exponentials. But if the periodic potential $V_{x}(x)$ is not a constant, then neither is $\psi_{\mathrm{p}, n_{x}}^{\mathrm{p}}(x)$. In that case, all that can be said a priori is that it is periodic on the atomic period.

Energy eigenfunctions of the form (6.32) are called "Bloch waves." It may be pointed out that this form of the energy eigenfunctions was discovered by Floquet, not Bloch. However, Floquet was a mathematician. In naming the solutions after Bloch instead of Floquet, physicists celebrate the physicist who could do it too, just half a century later.

The reason why the energy eigenfunctions take this form, and what it means for the electron motion are discussed further in chapter 7.10.5. There are only two key points of interest for now. First, the possible values of the wave number $k_{x}$ are exactly the same as for the free-electron gas, given in (6.28). Otherwise the eigenfunction would not be periodic on the period of the box. Second, the electron velocity can be found by differentiating the single particle energy $E_{x}^{\mathrm{p}}$ with respect to the "crystal momentum" $p_{\mathrm{cm}, x}=\hbar k_{x}$. That is the same as for the free-electron gas. If you differentiate the one-dimensional free-electron gas kinetic energy $E_{x}^{\mathrm{p}}=\left(\hbar k_{x}\right)^{2} / 2 m_{\mathrm{e}}$ with respect to $p_{x}=\hbar k_{x}$, you get the velocity.

## Key Points

$0-$ In the presence of a periodic crystal potential, the energy eigenfunctions pick up an additional factor that has the atomic period.
0- The wave number values do not change.
0- The velocity is found by differentiating the energy with respect to the crystal momentum.

### 6.22.2 Example spectra

As the previous section discussed, the difference between metals and insulators is due to differences in their energy spectra. The one-dimensional Kronig \& Penney model can provide some insight into it.

Figure 6.23: Example Kronig \& Penney spectra.
Finding the energy eigenvalues is not difficult on a computer, $\{\mathrm{N} .9\}$. A couple of example spectra are shown in figure 6.23. The vertical coordinate is
the single-electron energy, as usual. The horizontal coordinate is the electron velocity. (So the free electron example is the one-dimensional version of the spectrum in figure 6.18, but the axes are much more compressed here.) Quantum states occupied by electrons are again in red.

The example to the left in figure 6.23 tries to roughly model a metal like lithium. The depth of the potential drops in figure 6.22 was chosen so that for lone "atoms," (i.e. for widely spaced potential drops), there is one bound spatial state and a second marginally bound state. You might think of the bound state as holding lithium's two inner " 1 s " electrons, and the marginally bound state as holding its loosely bound single " 2 s " valence electron.

Note that the 1 s state is just a red dot in the lower part of the left spectrum in figure 6.23. The energy of the inner electrons is not visibly affected by the neighboring "atoms." Also, the velocity does not budge from zero; electrons in the inner states would hardly move even if there were unfilled states. These two observations are related, because as mentioned earlier, the velocity is the derivative of the energy with respect to the crystal momentum. If the energy does not vary, the velocity is zero.

The second energy level has broadened into a half-filled "conduction band." Like for the free-electron gas in figure 6.18, it requires little energy to move some Fermi-level electrons in this band from negative to positive velocities to achieve net electrical conduction.

The spectrum in the middle of figure 6.23 tries to roughly model an insulator like diamond. (The one-dimensional model is too simple to model an alkaline metal with two valence electrons like beryllium. The spectra of these metals involve different energy bands that merge together, and merging bands do not occur in the one-dimensional model.) The voltage drops have been increased a bit to make the second energy level for lone "atoms" more solidly bound. And it has been assumed that there are now four electrons per "atom," so that the second band is completely filled.

Now the only way to achieve net electrical conduction is to move some electrons from the filled "valence band" to the empty "conduction band" above it. That requires much more energy than a normal applied voltage could provide. So the crystal is an insulator.

The reasons why the spectra look as shown in figure 6.23 are not obvious. Note $\{\mathrm{N} .9\}$ explains by example what happens to the free-electron gas energy eigenfunctions when there is a crystal potential. A much shorter explanation that hits the nail squarely on the head is "That is just the way the Schrödinger equation is."

## Key Points

- A periodic crystal potential produces energy bands.

### 6.22.3 Effective mass

The spectrum to the right in figure 6.23 shows the one-dimensional free-electron gas. The relationship between velocity and energy is given by the classical expression for the kinetic energy in the $x$-direction:

$$
E_{x}^{\mathrm{p}}=\frac{1}{2} m_{\mathrm{e}} v_{x}^{\mathrm{p} 2}
$$

This leads to the parabolic spectrum shown.
It is interesting to compare this spectrum to that of the "metal" to the left in figure 6.23. The occupied part of the conduction band of the metal is approximately parabolic just like the free-electron gas spectrum. To a fair approximation, in the occupied part of the conduction band

$$
E_{x}^{\mathrm{p}}-E_{\mathrm{c}, x}^{\mathrm{p}}=\frac{1}{2} m_{\mathrm{eff}, x} v_{x}^{\mathrm{p} 2}
$$

where $E_{\mathrm{c}, x}^{\mathrm{p}}$ is the energy at the bottom of the conduction band and $m_{\mathrm{eff}, x}$ is a constant called the "effective mass."

This illustrates that conduction band electrons in metals behave much like free electrons. And the similarity to free electrons becomes even stronger if you define the zero level of energy to be at the bottom of the conduction band and replace the true electron mass by an effective mass. For the metal shown in figure 6.23 , the effective mass is $61 \%$ of the true electron mass. That makes the parabola somewhat flatter than for the free-electron gas. For electrons that reach the conduction band of the insulator in figure 6.23, the effective mass is only $18 \%$ of the true mass.

In previous sections, the valence electrons in metals were repeatedly approximated as free electrons to derive such properties as degeneracy pressure and thermionic emission. The justification was given that the forces on the valence electrons tend to come from all directions and average out. But as the example above now shows, that approximation can be improved upon by replacing the true electron mass by an effective mass. For the valence electrons in copper, the appropriate effective mass is about one and a half times the true electron mass, [42, p. 257]. So the use of the true electron mass in the examples was not dramatically wrong.

And the agreement between conduction band electrons and free electrons is even deeper than the similarity of the spectra indicates. You can also use the density of states for the free-electron gas, as given in section 6.3, if you substitute in the effective mass.

To see why, assume that the relationship between the energy $E_{x}^{\mathrm{p}}$ and the velocity $v_{x}^{\mathrm{p}}$ is the same as that for a free-electron gas whose electrons have the appropriate effective mass. Then so is the relationship between the energy $E_{x}^{\mathrm{p}}$ and the wave number $k_{x}$ the same as for that electron gas. That is because the velocity is merely the derivative of $E_{x}^{\mathrm{p}}$ with respect to $\hbar k_{x}$. You need the
same $E_{x}^{\mathrm{p}}$ versus $k_{x}$ relation to get the same velocity. (This assumes that you measure both the energy and the wave number from the location of minimum conduction band energy.) And if the $E_{x}^{\mathrm{p}}$ versus $k_{x}$ relation is the same as for the free-electron gas, then so is the density of states. That is because the quantum states have the same wave number spacing regardless of the crystal potential.

It should however be pointed out that in three dimensions, things get messier. Often the effective masses are different in different crystal directions. In that case you need to define some suitable average to use the free-electron gas density of states. In addition, for typical semiconductors the energy structure of the holes at the top of the valence band is highly complex.

## Key Points

$0-$ The electrons in a conduction band and the holes in a valence band are often modeled as free particles.
$0-$ The errors can be reduced by giving them an effective mass that is different from the true electron mass.
$0-$ The density of states of the free-electron gas can also be used.

### 6.22.4 Crystal momentum

The crystal momentum of electrons in a solid is not the same as the linear momentum of free electrons. However, it is similarly important. It is related to optical properties such as the difference between direct and indirect gap semiconductors. Because of this importance, spectra are usually plotted against the crystal momentum, rather than against the electron velocity. The Kronig \& Penney model provides a simple example to explain some of the ideas.

Figure 6.24 shows the single-electron energy plotted against the crystal momentum. Note that this is equivalent to a plot against the wave number $k_{x}$; the crystal momentum is just a simple multiple of the wave number, $p_{\mathrm{cm}, x}=$ $\hbar k_{x}$. The figure has nondimensionalized the wave number by multiplying it by the atomic period $d_{x}$. Both the example insulator and the free-electron gas are shown in the figure.

There is however an ambiguity in the figure:
The crystal wave number, and so the crystal momentum, is not unique.
Consider once more the general form of a Bloch wave,

$$
\psi_{n_{x}}^{\mathrm{p}}(x)=\psi_{\mathrm{p}, n_{x}}^{\mathrm{p}}(x) e^{\mathrm{i} k_{x} x}
$$

If you change the value of $k_{x}$ by a whole multiple of $2 \pi / d_{x}$, it remains a Bloch wave in terms of the new $k_{x}$. The change in the exponential can be absorbed in

Figure 6.24: Spectrum against wave number in the extended zone scheme.
the periodic part $\psi_{\mathrm{p}, n_{x}}^{\mathrm{p}}$. The periodic part changes, but it remains periodic on the atomic scale $d_{x}$.

Therefore there is a problem with how to define a unique value of $k_{x}$. There are different solutions to this problem. Figure 6.24 follows the so-called "extended zone scheme." It takes the wave number to be zero at the minimum energy and then keeps increasing the magnitude with energy. This is a good scheme for the free-electron gas. It also works nicely if the potential is so weak that the energy states are almost the free-electron gas ones.

A second approach is much more common, though. It uses the indeterminacy in $k_{x}$ to shift it into the range $-\pi \leqslant k_{x} d_{x} \leqslant \pi$. That range is called the "first Brillouin zone." Restricting the wave numbers to the first Brillouin zone produces figure 6.25. This is called the "reduced zone scheme." Esthetically, it is clearly an improvement in case of a nontrivial crystal potential.

But it is much more than that. For one, the different energy curves in the reduced zone scheme can be thought of as modified atomic energy levels of lone atoms. The corresponding Bloch waves can be thought of as modified atomic states, modulated by a relatively slowly varying exponential $e^{i k_{x} x}$.

Second, the reduced zone scheme is important for optical applications of semiconductors. In particular,

## A lone photon can only produce an electron transition along the same vertical line in the reduced zone spectrum.

The reason is that crystal momentum must be conserved. That is much like linear momentum must be preserved for electrons in free space. Since a photon has negligible crystal momentum, the crystal momentum of the electron cannot

insulator

free electrons

Figure 6.25: Spectrum against wave number in the reduced zone scheme.
change. That means it must stay on the same vertical line in the reduced zone scheme.

To see why that is important, suppose that you want to use a semiconductor to create light. To achieve that, you need to somehow excite electrons from the valence band to the conduction band. How to do that will be discussed in section 6.27.7. The question here is what happens next. The excited electrons will eventually drop back into the valence band. If all is well, they will emit the energy they lose in doing so as a photon. Then the semiconductor will emit light.

Figure 6.26: Some one-dimensional energy bands for a few basic semiconductors.
It turns out that the excited electrons are mostly in the lowest energy states in the conduction band. For various reasons. that tends to be true despite the absence of thermal equilibrium. They are created there or evolve to it. Also, the holes that the excited electrons leave behind in the valence band are mostly at the highest energy levels in that band.

Now consider the energy bands of some actual semiconductors shown to the left in figure 6.26. In particular, consider the spectrum of gallium arsenide. The excited electrons are at the lowest point of the conduction band. That is at zero crystal momentum. The holes are at the highest point in the valence band, which is also at zero crystal momentum. Therefore, the excited electrons can drop vertically down into the holes. The crystal momentum does not change, it stays zero. There is no problem. In fact, the first patent for a light emitting diode was for a gallium arsenide one, in 1961. The energy of the emitted photons is given by the band gap of gallium arsenide, somewhat less than 1.5 eV . That is slightly below the visible range, in the near infrared. It is suitable for remote controls and other nonvisible applications.

But now consider germanium in figure 6.26. The highest point of the valence band is still at zero crystal momentum. But the lowest point of the conduction band is now at maximum crystal momentum in the reduced zone scheme. When the excited electrons drop back into the holes, their crystal momentum changes. Since crystal momentum is conserved, something else must account for the difference. And the photon does not have any crystal momentum to speak of. It is a phonon of crystal vibration that must carry off the difference in crystal momentum. Or supply the difference, if there are enough pre-existing thermal phonons. The required involvement of a phonon in addition to the photon makes the entire process much more cumbersome. Therefore the energy of the electron is much more likely to be released through some alternate mechanism that produces heat instead of light.

The situation for silicon is like that for germanium. However, the lowest energy in the conduction band occurs for a different direction of the crystal momentum. The spectrum for that direction of the crystal momentum is shown to the right in figure 6.26. It still requires a change in crystal momentum.

At the time of writing, there is a lot of interest in improving the light emission of silicon. The reason is its prevalence in semiconductor applications. If silicon itself can be made to emit light efficiently, there is no need for the complications of involving different materials to do it. One trick is to minimize processes that allow electrons to drop back into the valence band without emitting photons. Another is to use surface modification techniques that promote absorption of photons in solar cell applications. The underlying idea is that at least in thermal equilibrium, the best absorbers of electromagnetic radiation are also the best emitters, section 6.8.

Gallium arsenide is called a "direct-gap semiconductor" because the electrons can fall straight down into the holes. Silicon and germanium are called "indirect-gap semiconductors" because the electrons must change crystal momentum. Note that these terms are accurate and understandable, a rarity in physics.

Conservation of crystal momentum does not just affect the emission of light. It also affects its absorption. Indirect-gap semiconductors do not absorb photons
very well if the photons have little more energy than the band gap. They absorb photons with enough energy to induce vertical electron transitions a lot better.

It may be noted that conservation of crystal momentum is often called "conservation of wave vector." It is the same thing of course, since the crystal momentum is simply $\hbar$ times the wave vector. However, those pesky new students often have a fairly good understanding of momentum conservation, and the term momentum would leave them insufficiently impressed with the brilliance of the physicist using it.
(If you wonder why crystal momentum is preserved, and how it even can be if the crystal momentum is not unique, the answer is in the discussion of conservation laws in chapter 7.3 and its note. It is not really momentum that is conserved, but the product of the single-particle eigenvalues $e^{\mathrm{i} k_{x} d_{x}}$ of the operator that translates the system involved over a distance $d_{x}$. These eigenvalues do not change if the wave numbers change by a whole multiple of $2 \pi / d_{x}$, so there is no violation of the conservation law if they do. For a system of particles in free space, the potential is trivial; then you can take $d_{x}$ equal to zero to eliminate the ambiguity in $k_{x}$ and so in the momentum. But for a nontrivial crystal potential, $d_{x}$ is fixed. Also, since a photon moves so fast, its wave number is almost zero on the atomic scale, giving it negligible crystal momentum. At least it does for the photons in the eV range that are relevant here.)

Figure 6.27: Spectrum against wave number in the periodic zone scheme.
Returning to the possible ways to plot spectra, the so-called "periodic zone scheme" takes the reduced zone scheme and extends it periodically, as in figure 6.27. That makes for very esthetic pictures, especially in three dimensions.

Of course, in three dimensions there is no reason for the spectra in the $y$ and $z$ directions to be the same as the one in the $x$-direction. Each can in principle
be completely different from the other two. Regardless of the differences, valid three-dimensional Kronig \& Penney energy eigenfunctions are obtained as the product of the $x, y$ and $z$ eigenfunctions, and their energy is the sum of the eigenvalues.

Similarly, typical spectra for real solids have to show the spectrum versus wave number for more than one crystal direction to be comprehensive. One example was for silicon in figure 6.26. A more complete description of the onedimensional spectra of real semiconductors is given in the next subsection.

## Key Points

$0-$ The wave number and crystal momentum values are not unique.
$0-$ The extended, reduced, and periodic zone schemes make different choices for which values to use.
0- The reduced zone scheme limits the wave numbers to the first Brillouin zone.
$0-$ For a photon to change the crystal momentum of an electron in the reduced zone scheme requires the involvement of a phonon.
$0-$ That makes indirect gap semiconductors like silicon and germanium undesirable for some optical applications.

### 6.22.5 Three-dimensional crystals

A complete description of the theory of three-dimensional crystals is beyond the scope of the current discussion. Chapter 10 provides a first introduction. However, because of the importance of semiconductors such as silicon, germanium, and gallium arsenide, it may be a good idea to explain a few ideas already.

Consider first a gallium arsenide crystal. Gallium arsenide has the same crystal structure as zinc sulfide, in the form known as zinc blende or sphalerite. The crystal is sketched in figure 6.28. The larger spheres represent the nuclei and inner electrons of the gallium atoms. The smaller spheres represent the nuclei and inner electrons of the arsenic atoms. Because arsenic has a more positively charged nucleus, it holds its electrons more tightly. The figure exaggerates the effect to keep the atoms visually apart.

The grey gas between these atom cores represents the valence electrons. Each gallium atom contributes 3 valence electrons and each arsenic atom contributes 5. That makes an average of 4 valence electrons per atom.

As the figure shows, each gallium atom core is surrounded by 4 arsenic ones and vice-versa. The grey sticks indicate the directions of the covalent bonds between these atom cores. You can think of these bonds as somewhat polar $\mathrm{sp}^{3}$ hybrids. They are polar since the arsenic atom is more electronegative than the gallium one.

Figure 6.28: Schematic of the zinc blende ( ZnS ) crystal relevant to important semiconductors including silicon.

It is customary to think of crystals as being build up out of simple building blocks called "unit cells." The conventional unit cells for the zinc blende crystal are the little cubes outlined by the thicker red lines in figure 6.28. Note in particular that you can find gallium atoms at each corner of these little cubes, as well as in the center of each face of them. That makes zinc blende an example of what is called a "face-centered cubic" lattice. For obvious reasons, everybody abbreviates that to FCC.

You can think of the unit cells as subdivided further into 8 half-size cubes, as indicated by the thinner red lines. There is an arsenic atom in the center of every other of these smaller cubes.

The simple one-dimensional Kronig \& Penney model assumed that the crystal was periodic with a period $d_{x}$. For real three-dimensional crystals, there is not just one period, but three. More precisely, there are three so-called "primitive translation vectors" $\vec{d}_{1}, \vec{d}_{2}$, and $\vec{d}_{3}$. A set of primitive translation vectors for the FCC crystal is shown in figure 6.28. If you move around by whole multiples of these vectors, you arrive at points that look identical to your starting point.

For example, if you start at the center of a gallium atom, you will again be at the center of a gallium atom. And you can step to whatever gallium atom you like in this way. At least as long as the whole multiples are allowed to be both positive and negative. In particular, suppose you start at the gallium atom with the Ga label in figure 6.28 . Then $\vec{d}_{1}$ allows you to step to any other gallium atom on the same line going towards the right and left. Vector $\vec{d}_{2}$ allows you to step to the next or previous line in the same horizontal plane. And vector $\overrightarrow{d_{3}}$ allows you to step to the next higher or lower horizontal plane.

The choice of primitive translation vectors is not unique. In particular, many sources prefer to draw the vector $\vec{d}_{1}$ towards the gallium atom in the front face center rather than to the one at the right. That is more symmetric, but moving around with them gets harder to visualize. Then you would have to step over $\vec{d}_{1}, \vec{d}_{2}$, and $-\vec{d}_{3}$ just to reach the atom to the right.

You can use the primitive translation vectors also to mentally create the zinc blende crystal. Consider the pair of atoms with the Ga and As labels in figure 6.28. Suppose that you put a copy of this pair at every point that you can reach by stepping around with the primitive translation vectors. Then you get the complete zinc blende crystal. The pair of atoms is therefore called a "basis" of the zinc blende crystal.

This also illustrates another point. The choice of unit cell for a given crystal structure is not unique. In particular, the parallelepiped with the primitive translation vectors as sides can be used as an alternative unit cell. Such a unit cell has the smallest possible volume, and is called a primitive cell.

The crystal structure of silicon and germanium, as well as diamond, is identical to the zinc blende structure, but all atoms are of the same type. This crystal structure is appropriately called the diamond structure. The basis is still a two-atom pair, even if the two atoms are now the same. Interestingly enough, it is not possible to create the diamond crystal by distributing copies of a single atom. Not as long as you step around with only three primitive translation vectors.

For the one-dimensional Kronig \& Penney model, there was only a single wave number $k_{x}$ that characterized the quantum states. For a three-dimensional crystal, there is a three-dimensional wave number vector $\vec{k}$ with components $k_{x}, k_{y}$, and $k_{z}$. That is just like for the free-electron gas in three dimensions as discussed in earlier sections.

In the Kronig \& Penney model, the wave numbers could be reduced to a finite interval

$$
-\frac{\pi}{d_{x}} \leqslant k_{x}<\frac{\pi}{d_{x}}
$$

This interval was called the first Brillouin zone. Wave numbers outside this zone are equivalent to ones inside. The general rule was that wave numbers a whole multiple of $2 \pi / d_{x}$ apart are equivalent.

In three dimensions, the first Brillouin zone is no longer a one-dimensional interval but a three-dimensional volume. And the separations over which wave number vectors are equivalent are no longer so simple. Instead of simply taking an inverse of the period $d_{x}$, as in $2 \pi / d_{x}$, you have to take an inverse of the matrix formed by the three primitive translation vectors $\vec{d}_{1}, \overrightarrow{d_{2}}$, and $\vec{d}_{3}$. Next you have to identify the wave number vectors closest to the origin that are enough to describe all quantum states. If you do all that for the FCC crystal, you will end up with the first Brillouin zone shown in figure 6.29. It is shaped like a cube with its 8 corners cut off.

Figure 6.29: First Brillouin zone of the FCC crystal.

The shape of the first Brillouin zone is important for understanding graphs of three-dimensional spectra. Every single point in the first Brillouin zone corresponds to multiple Bloch waves, each with its own energy. To plot all those energies is not possible; it would require a four-dimensional plot. Instead, what is done is plot the energies along representative lines. Such plots will here be indicated as one-dimensional energy bands. Note however that they are one-dimensional bands of true three-dimensional crystals. They are not just Kronig \& Penney model bands.

Typical points between which one-dimensional bands are drawn are indicated in figure 6.29. You and I would probably name such points something like F (face), E (edge), and C (corner), with a clarifying subscript as needed. However, physicists come up with names like K, L, W, and X, and declare them standard. The center of the Brillouin zone is the origin, where the wave number vector is zero. Normal people would therefore indicate it as O or 0 . However, physicists are not normal people. They indicate the origin by $\Gamma$ because the shape of this Greek letter reminds them of a gallows. Physicists just love gallows humor.

Computed one-dimensional energy bands between the various points in the Brillouin zone can be found in the plot to the left in figure 6.30. The plot is for germanium. The zero level of energy was chosen as the top of the valence band. The various features of the plot agree well with other experimental and computational data.

The earlier spectrum for germanium in figure 6.26 showed only the part within the little frame in figure 6.30. That part is for the line between zero wave number and the point L in figure 6.29. Unlike figure 6.30, the earlier spectrum figure 6.26 showed both negative and positive wave numbers, as its left and right halves. On the other hand, the earlier spectrum showed only the highest one-dimensional valence band and the lowest one-dimensional conduction band. It was sufficient to show the top of the valence band and the bottom of the

Figure 6.30: Sketch of a more complete spectrum of germanium. (Based on results of the VASP 5.2 commercial computer code.)
conduction band, but little else. As figure 6.30 shows, there are actually four different types of Bloch waves in the valence band. The energy range of each of the four is within the range of the combined valence band.

The complete valence band, as well as the lower part of the conduction band, is sketched in the spectrum to the right in figure 6.30. It shows the energy plotted against the density of states $\mathcal{D}$. Note that the computed density of states for the conduction electrons is a mess when seen over its complete range. It is nowhere near parabolic as it would be for electrons in empty space, figure 6.1. Similarly the density of states applicable to the valence band holes is nowhere near an inverted parabola over its complete range. However, typically only about $1 / 40$ th of an eV below the top of the valence band and above the bottom of the conduction band is relevant for applications. That is very small on the scale of the figure.

An interesting feature of figure 6.30 is that two different energy bands merge at the top of the valence band. These two bands have the same energy at the top of the valence band, but very different curvature. And according to the earlier
subsection 6.22.3, that means that they have different effective mass. Physicists therefore speak of "light holes" and "heavy holes" to keep the two types of quantum states apart. Typically even the heavy holes have effective masses less than the true electron mass, [29, pp. 214-216]. Diamond is an exception.

The spectrum of silicon is not that different from germanium. However, the bottom of the conduction band is now on the line from the origin $\Gamma$ to the point X in figure 6.29.

## Key Points

$0-$ Silicon and germanium have the same crystal structure as diamond. Gallium arsenide has a generalized version, called the zinc blende structure.
$0-$ The spectra of true three-dimensional crystals are considerably more complex than those of the one-dimensional Kronig \& Penney model.
$0-$ In three dimensions, the period turns into three primitive translation vectors.
$0-$ The first Brillouin zone becomes three-dimensional.
$0-$ There are light holes and heavy holes at the top of the valence band of typical semiconductors.

### 6.23 Semiconductors

Semiconductors are at the core of modern technology. This section discusses some basic properties of semiconductors that will be needed to explain how the various semiconductor applications work. The main semiconductor manipulation that must be described in this section is "doping," adding a small amount of impurity atoms.

If semiconductors did not conduct electricity, they would not be very useful. Consider first the pure, or "intrinsic," semiconductor. The vicinity of the band gap in its spectrum is shown to the left in figure 6.31. The vertical coordinate shows the energy $E^{p}$ of the single-electron quantum states. The horizontal coordinate shows the density of states $\mathcal{D}$, the number of quantum states per unit energy range. Recall that there are no quantum states in the band gap. States occupied by electrons are shown in red. At room temperature there are some thermally excited electrons in the conduction band. They left behind some holes in the valence band. Both the electrons and the holes can provide electrical conduction.

Time for a reality check. The number of such electrons and holes is very much smaller than the figure indicates. The number $\iota_{\mathrm{e}}$ of electrons per quantum state is given by the Fermi-Dirac distribution (6.19). In the conduction band, that

Figure 6.31: Vicinity of the band gap in the spectra of intrinsic and doped semiconductors. The amounts of conduction band electrons and valence band holes have been vastly exaggerated to make them visible.
may be simplified to the Maxwell-Boltzmann one (6.21) because the number of electrons in the conduction band is small. The average number of electrons per state in the conduction band is then:

$$
\begin{equation*}
\iota_{\mathrm{e}}=e^{-\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T} \tag{6.33}
\end{equation*}
$$

Here $T$ is the absolute temperature, $k_{\mathrm{B}}$ is the Boltzmann constant, and $\mu$ is the chemical potential, also known as the Fermi level. The Fermi level is shown by a red tick mark in figure 6.31.

For an intrinsic semiconductor, the Fermi level is about in the middle of the band gap. Therefore the average number of electrons per quantum state at the bottom of the conduction band is

$$
\text { Bottom of the conduction band: } \iota_{\mathrm{e}}=e^{-E_{\mathrm{gap}}^{\mathrm{p}} / 2 k_{\mathrm{B}} T}
$$

At room temperature, $k_{\mathrm{B}} T$ is about 0.025 eV while for silicon, the band gap energy is about 1.12 eV . That makes $\iota_{\mathrm{e}}$ about $210^{-10}$. In other words, only about 1 in 5 billion quantum states in the lower part of the conduction band has an electron in it. And it is even less higher up in the band. A figure cannot show a fraction that small; there are just not enough atoms on a page.

So it is not surprising that pure silicon conducts electricity poorly. It has a resistivity of several thousand ohm-m where good metals have on the order of $10^{-8}$. Pure germanium, with a smaller band gap of 0.66 eV , has a much larger $\iota_{\mathrm{e}}$ of about $310^{-6}$ at the bottom of the conduction band. Its resistivity is correspondingly lower at about half an ohm- m . That is still many orders of magnitude larger than for a metal.

And the number of conduction electrons becomes much smaller still at cryogenic temperatures. If the temperature is a frigid 150 K instead of a 300 K room temperature, the number of electrons per state in silicon drops by another factor of a billion. That illustrates one important rule:

> You cannot just forget about temperature to understand semiconductors.

Usually, you like to analyze the ground state at absolute zero temperature of your system, because it is easier. But that simply does not work for semiconductors.

The number of holes per state in the valence band may be written in a form similar to that for the electrons in the conduction band:

$$
\begin{equation*}
\iota_{\mathrm{h}}=e^{-\left(\mu-E^{\mathrm{p}}\right) / k_{\mathrm{B}} T} \tag{6.34}
\end{equation*}
$$

Note that in the valence band the energy is less than the Fermi level $\mu$, so that the exponential is again very small. The expression above may be checked by noting that whatever states are not filled with electrons are holes, so $\iota_{\mathrm{h}}=1-\iota_{\mathrm{e}}$. If you plug the Fermi-Dirac distribution into that, you get the expression for $\iota_{\mathrm{h}}$ above as long as the number of holes per state is small.

From a comparison of the expressions for the number of particles per state $\iota_{\mathrm{e}}$ and $\iota_{\mathrm{h}}$ it may already be understood why the Fermi level $\mu$ is approximately in the middle of the band gap. If the Fermi level is exactly in the middle of the band gap, $\iota_{\mathrm{e}}$ at the bottom of the conduction band is the same as $\iota_{\mathrm{h}}$ at the top of the valence band. Then there is the same number of electrons per state at the bottom of the conduction band as holes per state at the top of the valence band. That is about as it should be, since the total number of electrons in the conduction band must equal the total number of holes in the valence band. The holes in the valence band is where the electrons in the conduction band came from.

Note that figure 6.31 is misleading in the sense that it depicts the same density of states $\mathcal{D}$ in the conduction band as in the valence band. In reality, the number of states per unit energy range in the conduction band could easily be twice that at the corresponding location in the valence band. It seems that this should invalidate the above argument that the Fermi level $\mu$ must be in the middle of the band gap. But it does not. To change the ratio between $\iota_{\mathrm{e}}$ and $\iota_{\mathrm{h}}$ by a factor 2 requires a shift in $\mu$ of about 0.01 eV at room temperature. That is very small compared to the band gap. And the shift would be much smaller still closer to absolute zero temperature. At absolute zero temperature, the Fermi level must move to the exact middle of the gap.

That illustrates another important rule of thumb for semiconductors:
Keep your eyes on the thermal exponentials. Usually, their variations dwarf everything else.
If $E^{\mathrm{p}}$ or $\mu$ changes just a little bit, $e^{-\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T}$ changes dramatically.
(For gallium arsenide, the difference between the densities of states for holes and electrons is much larger than for silicon or germanium. That makes the shift in Fermi level at room temperature more substantial.)

The Fermi level may be directly computed. Expressions for the total number of conduction electrons per unit volume and the total number of holes per unit volume are, $\{\mathrm{D} .30\}$ :

$$
i_{\mathrm{e}}=2\left(\frac{m_{\mathrm{eff}, \mathrm{e}} k_{\mathrm{B}} T}{2 \pi \hbar^{2}}\right)^{3 / 2} e^{-\left(E_{\mathrm{c}}^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T} \quad i_{\mathrm{h}}=2\left(\frac{m_{\mathrm{eff}, \mathrm{~h}} k_{\mathrm{B}} T}{2 \pi \hbar^{2}}\right)^{3 / 2} e^{-\left(\mu-E_{\mathrm{v}}^{\mathrm{p}}\right) / k_{\mathrm{B}} T}
$$

Here $E_{\mathrm{c}}^{\mathrm{p}}$ and $E_{\mathrm{v}}^{\mathrm{p}}$ are the energies at the bottom of the conduction band, respectively the top of the valence band. The appropriate effective masses for electrons and holes to use in these expressions are comparable to the true electron masses for silicon and germanium. Setting the two expressions above equal allows $\mu$ to be computed.

The first exponential in (6.35) is the value of the number of electrons per state $\iota_{\mathrm{e}}$ at the bottom of the conduction band, and the second exponential is the number of holes per state $\iota_{\mathrm{h}}$ at the top of the valence band. The bottom line remains that semiconductors have much too few current carriers to have good conductivity.

That can be greatly improved by what is called doping the material. Suppose you have a semiconductor like germanium, that has 4 valence electrons per atom. If you replace a germanium atom in the crystal by a stray atom of a different element that has 5 valence electrons, then that additional electron is mismatched in the crystal structure. It can easily become dislocated and start roving through the conduction band. That allows additional conduction to occur. Even at very small concentrations, such impurity atoms can make a big difference. For example, you can increase the conductivity of germanium by a factor of a thousand by replacing 1 in a million germanium atoms by an arsenic one.

Because such valence-5 impurity atoms add electrons to the conduction band, they are called "donors." Because electrical conduction occurs by the negatively charged additional electrons provided by the doping, the doped semiconductor is called " $n$-type."

Alternatively, you can replace germanium atoms by impurity atoms that have only 3 valence electrons. That creates holes that can accept valence band electrons with a bit of thermal energy. Therefore such impurity atoms are called "acceptors." The holes in the valence band from which the electrons were taken allow electrical conduction to occur. Because the holes act like positively charged particles, the doped semiconductor is called " $p$-type."

Silicon has 4 valence band electrons just like germanium. It can be doped similarly.

Now consider an $n$-type semiconductor in more detail. As the center of figure 6.31 indicates, the effect of the donor atoms is to add a spike of energy states just below the conduction band. At absolute zero temperature, these states are filled with electrons and the conduction band is empty. And at absolute
zero, the Fermi level is always in between filled and empty states. So the Fermi level is now in the narrow gap between the spike and the conduction band. It illustrates that the Fermi level of a semiconductor can jump around wildly at absolute zero.

But what happens at absolute zero is irrelevant to a room temperature semiconductor anyway. At room temperature the Fermi level is typically as shown by the tick mark in figure 6.31. The Fermi level has moved up a lot compared to the intrinsic semiconductor, but it still stays well below the donor states.

If the Fermi level would still be in the middle of the band gap like for the undoped material, then there would be very few electrons in the donor states. But all the electrons that are in the donor states at absolute zero temperature cannot just disappear into nothing. And they cannot go into the intrinsic states. If the Fermi level does not change, the intrinsic states still have the same number of electrons as before the doping.

So the Fermi level cannot be in the middle of the band gap. And the Fermi level going down makes the missing electron problem worse; then there are even less electrons in the donor states and conduction band, and even more holes in the valence band.

The Fermi level must go up, significantly. For one, that will reduce the number of holes in the valence band. However, since the number of such holes is so tiny compared to the nuber of donor electrons, that does not help much. Much more importantly, the Fermi level $\mu$ going up will increase the number of electrons not just in the donor states, but also and especially in the lowest conduction band states, (6.33). The missing electron problem gets resolved: the electrons missing from the donor states are now in conduction band states. (Or to be picky, a very few of them have gone in valence band holes.)

Do note that while the Fermi level must go up, it cannot move too close to the donor states either. For assume the contrary, that the Fermi level is really close to the donor states. Then the donor states will be largely filled with electrons. But at room temperature the gap between the donor states and the conduction band is comparable to $k_{\mathrm{B}} T$. Therefore, if the donor states are largely filled with electrons, then the states at the bottom of the conduction band contain significant numbers of electrons too. Since there are so many of these conduction states compared to a typical number of donor states, the number of electrons in the conduction states would dwarf the number of electrons missing from the donor states. And that would mean that now there would be far too many electrons. The Fermi level must go up but stay low enough that the number of electrons per state $\iota_{\mathrm{e}}$ stays small in both the donor states and conduction band. That is as sketched in figure 6.31.

If more donors are added, the Fermi level will move up more. Light doping may be on the order of 1 impurity atom in a 100 million, heavy doping 1 in 10,000 . If the donor atoms get too close together, their electrons start to
interact. If that happens the spike of donor states broadens into a band extending to the conduction band, and you end up with a metallic "degenerate" semiconductor. For example, low temperature measurements show that phosphor donors turn silicon metallic at about 1 phosphor atom per 15000 silicon ones. It may seem strange that impurity electrons at such a small concentration could interact at all. But note that 1 impurity in 15000 atoms means that each $25 \times 25 \times 25$ cube of silicon atoms has one phosphor atom. On average the phosphor atoms are only about 25 atom spacings apart. In addition, the orbit of the very loosely bound donor electron is really far from the positively charged donor atom compared to the crystal spacing.

The $p$-type material is analyzed pretty much the same as $n$-type, with holes taking the place of electrons and acceptors the place of donors.

As already mentioned, the upward shift in the Fermi level in the $n$-type material has another effect besides providing lots of electrons in the conduction band. It decimates the already miserably small number of holes in the valence band that the undoped semiconductor had. That means that virtually all electrical conduction will now be performed by electrons, not holes. The electrons in $n$-type material are therefore called the "majority carriers" and the holes the "minority carriers."

Figure 6.32: Relationship between conduction electron density and hole density. Intrinsic semiconductors have neither much conduction electrons nor holes.

The fact that raising the amount of conduction band electrons lowers the amount of valence band holes may be verified mathematically from (6.35). That equation implies that the product of the electron and hole densities is constant at a given temperature:

$$
\begin{equation*}
i_{\mathrm{e}} i_{\mathrm{h}}=4\left(\frac{\sqrt{m_{\mathrm{eff}, \mathrm{e}} m_{\mathrm{eff}, \mathrm{e}}} k_{\mathrm{B}} T}{2 \pi \hbar^{2}}\right)^{3} e^{-E_{\mathrm{gap}}^{\mathrm{p}} / k_{\mathrm{B}} T} \tag{6.36}
\end{equation*}
$$

This relationship is called the "law of mass action" since nonexperts would be able to make sense out of "electron-hole density relation." And if you come to think of it, what is wrong with the name? Doesn't pretty much everything in physics come down to masses performing actions? That includes semiconductors too!

The relationship is plotted in figure 6.32. It shows that a high number of conduction electrons implies a very low number of holes. Similarly a $p$-type material with a high number of holes will have very few conduction electrons.

The law of mass action can also be understood from more classical arguments. That is useful since band theory has its limits. The classical picture is as follows: In thermal equilibrium, the semiconductor is bathed in blackbody radiation. A very small but nonzero fraction of the photons of this radiation have energies above the band gap. These will move valence band electrons to the conduction band, thus creating electron-hole pairs. In equilibrium, this creation of electron-hole pairs must be balanced by the removal of an identical amount of electron-hole pairs. The removal of a pair occurs through "recombination," in which an conduction band electron drops back into a valence band hole, eliminating both. The rate of recombinations will be proportional to the product of the densities of electrons and holes. Indeed, for a given number of holes, the more electrons there are, the more will be able to find holes under suitable conditions for recombination. And vice-versa with electrons and holes swapped. Equating a creation rate of electron-hole pairs by photons, call it $A$, to a removal rate of the form $B i_{\mathrm{e}} i_{\mathrm{h}}$ shows that the product $i_{\mathrm{e}} i_{\mathrm{h}}$ equals the constant $A / B$. This constant will depend primarily on the Maxwell-Boltzmann factor $e^{-E_{\mathrm{gap}}^{\mathrm{p}} / k_{\mathrm{B}} T}$ that limits the number of photons that have sufficient energy to create pairs.

This classical picture also provides an intuitive explanation why adding both donors and acceptors to a semiconductor does not double the amount of current carriers over just one type of doping alone. Quite the opposite. As figure 6.32 shows, if the number of holes becomes comparable to the number of electrons, there are not many of either one. The semiconductor behaves again like an intrinsic one. The reason is that adding, say, some acceptors to an $n$-type material has the primary effect of making it much easier for the conduction band electrons to find valence band holes to recombine with. It is said that the added acceptors "compensate" for the donors.

## Key Points

$0-$ Doping a semiconductor with donor atoms greatly increases the number of electrons in the conduction band. It produces an $n$-type semiconductor.
$0-$ Doping a semiconductor with acceptor atoms greatly increases the number of holes in the valence band. It produces an $p$-type semiconductor.
$0-$ The minority carrier gets decimated.
$0-$ The Fermi level is in the band gap, and towards the side of the majority carrier.
$0-$ There is compensation in doping. In particular, if there are about the same numbers of electrons and holes, then there are not many of either.

### 6.24 The $P-N$ Junction

The $p-n$ junction is the work horse of semiconductor applications. This section explains its physical nature, and why it can act as a current rectifier, among other things.

Figure 6.33: The $p-n$ junction in thermal equilibrium. Top: energy spectra. Quantum states with electrons in them are in red. The mean electrostatic energy of the electrons is in green. Below: Physical schematic of the junction. The dots are conduction electrons and the small circles holes. The encircled plus signs are donor atoms, and the encircled minus signs acceptor atoms. (Donors and acceptors are not as regularly distributed, nor as densely, as this greatly simplified schematic suggests.)

A $p-n$ junction is created by doping one side of a semiconductor crystal $n$ type and the other side $p$ type. As illustrated at the bottom of figure 6.33, the $n$ side has a appreciable amount of conduction electrons, shown as black dots. These electrons have been provided by donor atoms. The donor atoms,
having given up one of their negatively charged electrons, have become positively charged and are shown as encircled plus signs.

The $p$ side has a appreciable number of holes, quantum states that have lost their electrons. The holes are shown as small circles in the figure. Since a negatively charged electron is missing at a hole, the hole behaves as a positively charged particle. The missing electrons have been absorbed by acceptor atoms. These atoms have therefore acquired a negative charge and are shown by encircled minus signs.

The atoms are stuck in the crystal and cannot move. Electrical conduction takes place by means of motion of the electrons and holes. But under normal conditions, significant electrical conduction can only occur in one direction. That makes the $p-n$ junction into a "diode," a current rectifier.

To see the basic reason is not difficult. In the so-called "forward" direction that allows a significant current, both the electrons in the $n$ side and the holes in the $p$ side flow towards the junction between the $n$ and $p$ sides. (Note that since electrons are negatively charged, they move in the direction opposite to the current.) In the vicinity of the junction, the incoming $n$-side electrons can drop into the incoming $p$-side holes. Phrased more formally, the electrons recombine with the holes. That can readily happen. A forward current flows freely if a suitable "forward-biased" voltage is applied.

However, if a "reverse-biased" voltage is applied, then normally very little current will flow. For a significant current in the reverse direction, both the electrons in the $n$ side and the holes in the $p$ side would have to flow away from the junction. So new conduction electrons and holes would have to be created near the junction to replace them. But random thermal motion can create only a few. Therefore there is negligible current.

While this simple argument explains why a $p-n$ junction can act as a diode, it is not sufficient. It does not explain the true response of the current to a voltage. It also does not explain other applications of $p$ - $n$ junctions, such as transistors, voltage stabilizers, light-emitting diodes, solar cells, etcetera.

It turns out that in the forward direction, the recombination of the incoming electrons and holes is severely hindered by an electrostatic barrier that develops at the contact surface between the $n$-type and $p$-type material. This barrier is known as the "built-in potential." It is shown in green in figure 6.33.

Consider first the $p-n$ junction in thermal equilibrium, when there is no current. The junction is shown in the lower part of figure 6.33. The $n$ side has an excess amount of conduction electrons. The negative charge of these electrons is balanced by the positively charged donor atoms. Similarly, the $p$ side has an excess amount of holes. The positive charge of these holes is balanced by the negatively charged acceptor atoms.

At the junction, due to random thermal motion the $n$-side electrons would want to diffuse into the $p$ side. Similarly the $p$-side holes would want to diffuse into the $n$ side. But that cannot go on indefinitely. These diffusion processes
cause a net negative charge to flow out of the $n$ side and a net positive charge out of the $p$ side. That produces the electrostatic barrier; it repels further $n$-side electrons from the $p$ side and $p$-side holes from the $n$ side.

The barrier takes the physical form of a double layer of positive charges next to negative charges. This layer is called the "space charge region." It is illustrated in figure 6.33. Double layers are common at contact surfaces between different solids. However, the one at the $p-n$ junction is somewhat unusual as it consists of ionized donor and acceptor atoms. There are preciously few electrons and holes in the space charge region, and therefore the charges of the donors and acceptors are no longer offset by the electrons, respectively holes.

The reason for the lack of electrons and holes in the space charge region may be understood from figure 6.32: when the numbers of electrons and holes become comparable, there are not many of either. The lack of electrons and holes explains why the space charge region is also known as the "depletion layer."

The double layer is relatively thick. It has to be, to compensate for the fact that the fraction of atoms that are donors or acceptors is quite small. A typical thickness is $10^{-6} \mathrm{~m}$, but this can vary greatly with doping level and any applied external voltage.

An $n$-side electron that tries to make it through the space charge region is strongly pulled back by the positive donors behind it and pushed back by the negative acceptors in front of it. Therefore there is a step-up in the electrostatic potential energy of an electron going through the region. This increase in potential energy is shown in green in figure 6.33. It raises the electron energy levels in the $p$ side relative to the $n$ side. In particular, it makes the chemical potentials, or Fermi levels, of the two sides equal. It has to do so; differences in chemical potential produce net electron diffusion, section 6.16. For the diffusion to stop, the chemical potential must become everywhere the same.

There is still some flow of electrons and holes through the junction, even in the absence of net current. It is due to random thermal motion. To simplify its description, it will be assumed that there is no significant recombination of electrons and holes while they pass through the space charge region, nor creation of new electrons and holes. That is a standard assumption, but by no means trivial. It requires great purification of the semiconductor. Crystal defects can act as "recombination centers," locations that help the electrons and holes recombine. For example, if you try to simply press separate $n$ and $p$ crystals together to create a $p-n$ junction, it will not work. It will have far too many defects where the crystals meet. A proper recombination of electrons and holes should take place near the junction, but mostly outside the space charge region.

Consider now first the thermal flow of electrons and holes through the junction when there is no net current. It is sketched in figure 6.34a. All those $n$-side electrons would love to diffuse into the $p$ side, but the electrostatic barrier is

holding them back. Only very few electrons have enough energy to make it through. The required amount of energy is the electrostatic energy increase over the junction. That energy will be called $V_{\mathrm{j}}$. For $n$-side electrons to make it through the barrier, they need to have at least that much energy above the bottom of the $n$-side conduction band. The relative amount of electrons at those energy levels is primarily determined by the Maxwell-Boltzmann factor (6.33). It implies that there are a factor $e^{-V_{\mathrm{j}} / k_{\mathrm{B}} T}$ less electrons per quantum state with the additional energy $V_{\mathrm{j}}$ than there are at the bottom of the conduction band.

The crossings of these few very lucky electrons produce a miniscule current through the junction. It is indicated as $j_{\mathrm{e}, \text { maj }}$ in figure 6.34a. The electrons are called the majority carriers in the $n$ side because there are virtually no holes in that side to carry current. Note also that the figure shows the negative currents for electrons, because that gives the direction that the electrons actually move. The currents in this discussion will be assumed to be per unit junction area, which explains why the symbol $j$ is used instead of $I$. A junction twice as large produces double the current, all else being the same. All else being the same includes ignoring edge effects.

The miniscule current of the $n$-side majority electrons is balanced by an equally miniscule but opposite current $j_{\mathrm{e}, \text { min }}$ produced by $p$-side minority electrons that cross into the $n$ side. Although the $p$ side has very few conduction band electrons, the number of electrons per state is still the same as that of $n$-side electrons with enough energy to cross the barrier. And note that for the $p$-side electrons, there is no barrier. If they diffuse into the space charge region, the electrostatic potential will instead help them along into the $n$ side.

For holes the story is equivalent. Because they have the opposite charge from the electrons, the same barrier that keeps the $n$-side electrons out of the $p$ side also keeps the $p$-side holes out of the $n$ side.

The bottom line is that there is no net current. And there should not be; otherwise you would have a battery that worked for free. Batteries must be powered by a chemical reaction.

But now suppose that a "forward-bias" external voltage $\varphi$ is applied that lowers the barrier by an amount $e \varphi_{j}$. What happens then is shown in figure 6.34b. The $n$-side majority electrons will now come pouring over the lowered barrier, and so will the $p$-side majority holes. Indeed, the Maxwell-Boltzmann factor for the majority carriers that can get through the barrier increases by a factor $e^{e \varphi_{\mathrm{j}} / k_{\mathrm{B}} T}$. That is a very large factor if the voltage change is bigger than about 0.025 volt, since $k_{\mathrm{B}} T$ is about 0.025 eV at normal temperatures. The currents of majority carriers explode, as sketched in the figure. And therefore, so does the net current.

The currents of minority carriers do not change appreciably. Whatever minority carriers diffuse into the space charge region still all pass through it. Note that the Fermi levels of the $n$ and $p$ sides do no longer match up when there is a current. If there is a current, the system is not in thermal equilibrium.

Figure $6.34 c$ shows the case that a reverse bias voltage is applied. The reverse voltage increases the barrier for the majority carriers. The number that still have enough energy to cross the junction gets decimated to essentially zero. All that remains is a residual small reverse current of minority carriers through the junction.

Based on this discussion, it is straightforward to write a ballpark expression for the net current through the junction:

$$
\begin{equation*}
j=j_{0} e^{e \varphi_{\mathrm{j}} / k_{\mathrm{B}} T}-j_{0} \tag{6.37}
\end{equation*}
$$

The final term is the net reverse current due to the minority carriers. According to the above discussion, that current does not change with the applied voltage. The other term is the net forward current due to the majority carriers. According to the above discussion, it differs from the minority current primarily by a Maxwell-Boltzmann exponential. The energy in the exponential is the electrostatic energy due to the external voltage difference across the junction.

For forward bias the exponential explodes, producing significant current. For reverse bias, the exponential is essentially zero and only the small reverse minority current is left.

Equation (6.37) is known as the "Shockley diode equation." It works well for germanium but not quite that well for silicon. Silicon has a much larger band gap. That makes the minority currents much smaller still, which is good. But the correspondingly small reversed-biased and slightly forward-biased currents are sensitive to depletion layer electron-hole generation, respectively recombination. A fudge factor called the "ideality factor" is often added to the argument of the exponential to improve agreement.

Even for germanium, the Shockley diode equation applies only over a limited range. The equation does not include the resistance of the semiconductor. If the current increases rapidly, the voltage drop due to resistance does too, and it should be added to the voltage $\operatorname{drop} \varphi_{\mathrm{j}}$ over the junction. That will eventually make the current versus voltage relation linear instead of exponential. And if the reverse voltage is too large, phenomena discussed in section 6.26 show up.

## Key Points

0 - The $p$ - $n$ junction is the interface between an $n$-type and a $p$-type side of a semiconductor crystal.
$0-$ Under normal conditions, it will only conduct a significant current in one direction, called the forward direction.
$0-$ In the forward direction both the $n$-side electrons and the $p$-side holes move towards the junction.
$0-$ The Shockley diode equation describes the current versus voltage relation of $p-n$ junctions, but only in a limited range.
$0-$ At the junction a space-charge region exists. It provides a barrier for the majority carriers. However, it accelerates the minority carriers passing through the junction.

### 6.25 The Transistor

A second very important semiconductor device besides the $p$ - $n$ diode is the transistor. While the $p-n$ diode allows currents to be blocked in one direction, the transistor allows currents to be regulated.

junction crossings by electrons:

$$

$$
\dot{j}_{\mathrm{h}, \text { maj }} \stackrel{j}{\mathrm{j}, \text { min }}^{j_{\mathrm{h}, \text { min }} \stackrel{j_{\mathrm{h}, \text { maj }}}{ } \text {. }}
$$

net currents:

Figure 6.35: Schematic of the operation of an $n-p-n$ transistor.
For example, an $n-p-n$ transistor allows the current of electrons through an $n$-type semiconductor to be controlled. A schematic is shown in figure 6.35. Electrons flow through the transistor from one side, called the "emitter," to the other side, called the "collector."

To control this current, a very narrow region of $p$-type doping is sandwiched in between the two sides of $n$-type doping. This $p$-type region is called the "base." If the voltage at the base is varied, it regulates the current between emitter and collector.

Of course, when used in a circuit, electrodes are soldered to the emitter and collector, and a third one to the base. The transistor then allows the current between the emitter and collector electrodes to be controlled by the voltage of the base electrode. At the same time, a well-designed transistor will divert almost none of the current being regulated to the base electrode.

The transistor works on the same principles as the $p-n$ junction of the previous section, with one twist. Consider first the flow of electrons through the device, as shown in figure 6.35. The junction between emitter and base is operated at a forward-bias voltage difference. Therefore, the majority electrons of the $n$-type emitter pour through it in great numbers. By the normal logic, these electrons should produce a current between the emitter and base electrodes.

But here comes the twist. The $p$ region is made extremely thin, much smaller than its transverse dimensions and even much smaller than the diffusion distance of the electrons. Essentially all electrons that pour through the junction blunder into the second junction, the one between base and collector. Now this second junction is operated at a reverse-bias voltage. That produces a strong electric field that sweeps the electrons forcefully into the collector. (Remember that since the electrons are considered to be minority carriers in the base, they get sweeped through the junction by the electric field rather than stopped by it.)

As a result, virtually all electrons leaving the emitter end up as an electron flow to the collector electrode instead of to the base one as they should have. The stupidity of these electrons explains why the base voltage can regulate the current between emitter and collector without diverting much of it. Further, as seen for the $p-n$ junction, the amount of electrons pouring through the junction from emitter to base varies very strongly with the base voltage. Small voltage changes at the base can therefore decimate or explode the electron flow, and almost all of it goes to the collector.

There is one remaining problem, however. The forward bias of the junction between emitter and base also means that the majority holes in the base pour through the junction towards the emitter. And that is strictly a current between the emitter and base electrodes. The holes cannot come from the collector, as the collector has virtually none. The hole current is therefore bad news. Fortunately, if you dope the $p$-type base only lightly, there are not that many majority holes, and virtually all current through the emitter to base junction will be carried by electrons.

A $p-n-p$ transistor works just like an $n-p-n$-one, but with holes taking the place of electrons. There are other types of semiconductor transistors, but they use similar ideas.

## Key Points

$0-$ A transistor allows current to be regulated.

### 6.26 Zener and Avalanche Diodes

Section 6.24 explained that normally no significant current will pass through a $p-n$ junction in the reverse direction. The basic reason can be readily explained
in terms of the schematic of the $p-n$ junction figure 6.33. A significant reverse current would require that the majority $n$-side conduction electrons and $p$-side holes both move away from the junction. That would require the creation of significant amounts of electron-hole pairs at the junction to replenish those that leave. Normally that will not happen.

But if the reverse voltage is increased enough, the diode can break down and a significant reverse current can indeed start to flow. That can be useful for voltage stabilization purposes.

Consider figure 6.33. One thing that can happen is that electrons in the valence band on the $p$ side end up in the conduction band on the $n$ side simply because of their quantum uncertainty in position. That process is called "tunneling." Diodes in which tunneling happens are called "Zener diodes."

The process requires that the energy spectrum at one location is raised sufficiently that its valence band reaches the level of the conduction band at another location. And the two locations must be extremely close together, as the quantum uncertainty in position is very small. Now it is the electrostatic potential, shown in green in figure 6.33, that raises the $p$-side spectra relative to the $n$-side ones. To raise a spectrum significantly relative to one very nearby requires a very steep slope to the electrostatic potential. And that in turn requires heavy doping and a sufficiently large reverse voltage to boost the builtin potential.

Once tunneling becomes a measurable effect, the current increases extremely rapidly with further voltage increases. That is a consequence of the fact that the strength of tunneling involves an exponential function, chapter 7.13 (7.74). The fast blow-up of current allows Zener diodes to provide a very stable voltage difference. The diode is put into a circuit that puts a nonzero tunneling current through the diode. Even if the voltage source in the circuit gets perturbed, the voltage drop across the Zener will stay virtually unchanged. Changes in voltage drops will remain restricted to other parts of the circuit; a corresponding change over the Zener would need a much larger change in current.

There is another way that diodes can break down under a sufficiently large reverse voltage. Recall that even under a reverse voltage there is still a tiny current through the junction. That current is due to the minority carriers, holes from the $n$ side and conduction electrons from the $p$ side. However, there are very few holes in the $n$ side and conduction electrons in the $p$ side. So normally this current can be ignored.

But that can change. When the minority carriers pass through the space charge region at the junction, they get accelerated by the strong electric field that exists there. If the reverse voltage is big enough, the space charge region can accelerate the minority carriers so much that they can knock electrons out of the valence band. The created electrons and holes will then add to the current.

Now consider the following scenario. A minority electron passes through the space charge region. Near the end of it, the electron has picked up enough
energy to knock a fellow electron out of the valence band. The two electrons continue on into the $n$ side. But the created hole is swept by the electric field in the opposite direction. It goes back into the space charge region. Traveling almost all the way through it, near the end the hole has picked up enough energy to knock an electron out of the valence band. The created conduction electron is swept by the electric field in the opposite direction of the two holes, back into the space charge region... The single original minority electron has set off an avalanche of new conduction electrons and holes. The current explodes.

A diode designed to survive this is an "avalanche diode." Avalanche diodes are often loosely called Zener diodes, because the current explodes in a similar way. However, the physics is completely different.

## Key Points

$0-$ Unlike the idealized theory suggests, under suitable conditions significant reverse currents can be made to pass through $p-n$ junctions.
$0-$ It allows voltage stabilization.

### 6.27 Optical Applications

This section gives a concise overview of optical physics ranging from the x-ray spectrum of solids to semiconductor devices such as solar cells and light-emitting diodes.

### 6.27.1 Atomic spectra

Lone atoms have discrete electron energy levels, figure 6.19. An electron can transition from one of these levels to another by emitting or absorbing a photon of light. The energy of the photon is given by the difference in energy between the levels. Therefore emitted and absorbed photons have very specific energies, and corresponding very specific frequencies and wave lengths.

If they are in the visible range, they have very specific colors. The visible range of light corresponds to photons with energies from about 1.6 eV (red) to 3.2 eV (violet). In terms of the wave length of the light, the range is from about 390 nm (violet) to 760 nm (red).

A basic example is the red photon emitted in an $E_{3}$ to $E_{2}$ Balmer transition of a hydrogen atom, figure 4.8. Its energy is 1.89 eV and its wave length is 656 nm . In general, when the light emitted by excited lone atoms is sent through a prism, it separates into a few discrete thin beams of specific colors. The colors are characteristic for the type of atom that emitted the light.

Lone atoms can also absorb photons from light that passes them by. The same wave lengths that they can emit, they can also absorb. Absorbing a photon
puts the atoms in an excited state of higher energy. They may then subsequently emit a photon identical to the absorbed one in a different direction. Or they may lose their excitation energy in a transition between different energy levels, producing a photon of a different wave length. Or they may lose the energy in collisions. Either one eliminates the original photon altogether. For example, an excited hydrogen atom in the $E_{2}$ state might absorb a 656 nm photon to reach the $E_{3}$ state. Then it may transition directly back to the $E_{1}$ ground state. One 656 nm photon has then been eliminated.

In 1817 Fraunhofer gave a list of dark lines in the spectrum of sunlight. His list included the red $E_{2}$ to $E_{3}$ Balmer line, as well as the blue-green $E_{2}$ to $E_{4}$ one. It was eventually discovered that light at these frequencies is absorbed by the hydrogen atoms in the solar atmosphere. Other lines were due to absorption by other atoms like helium, sodium, calcium, titanium, and iron. The atoms present in the solar atmosphere could be identified without having to actually go there in a space ship. Since the days of Fraunhofer, spectroscopy has become one of the most important sources of information about the large-scale universe.

A typical solar spectrum also includes absorption lines due to molecules like oxygen and water vapor in the atmosphere of the earth. Molecular spectra tend to be more complicated than atomic ones, especially in the infrared region. That is due to relative motion of the different nuclei. The spectra are also more complicated due to the larger number of electrons involved.

## Key Points

$0-$ Lone atoms and molecules emit and absorb light at specific wave lengths.
$0-$ It allows atoms and molecules to be recognized in the lab or far out in space.

### 6.27.2 Spectra of solids

Solids have electron energy levels arranged into continuous bands, figure 6.19. Therefore solids do not emit discrete wave lengths of light like lone atoms do. When light from solids is sent through a prism, the light will spread out into bands of gradually changing color. That is called "broadband" radiation.

To be sure, transitions involving the inner atomic electrons in solids still produce radiation at discrete wave lengths. The reason is that the energies of the inner electrons are not significantly different from the discrete values of the corresponding lone atoms. But because these energies are so much larger in magnitude, the produced radiation is in the X-ray range, not in the visible light range.

## Key Points

0 - Solids can emit and absorb electromagnetic radiation in continuous bands.
$0=$ The X-ray range of the inner electrons is still discrete.

### 6.27.3 Band gap effects

As noted above, the light from solids is not limited to discrete wave lengths like that of lone atoms. But it is not true that solids can emit and absorb all wave lengths. In particular, a perfect crystal of an insulator with a large-enough band gap will be transparent to visible light. Take diamond as an example. Its valence band is completely filled with electrons but its conduction band is empty, as sketched in figure 6.36. A photon of light with enough energy can use its energy to take take an electron out of the valence band and put it into the conduction band. That leaves a hole behind in the valence band and eliminates the photon. However, to do this requires that the photon has at least the band gap energy of diamond, which is 5.5 eV . The photons of visible light have energies from about 1.6 eV to 3.2 eV . That is not enough. Visible light simply does not have enough energy to be absorbed by diamond electrons. Therefore a perfect diamond is transparent. Visible light passes through it unabsorbed.

Figure 6.36: Vicinity of the band gap in the electron energy spectrum of an insulator. A photon of light with an energy greater than the band gap can take an electron from the valence band to the conduction band. The photon is absorbed in the process.

By this reasoning, all perfect crystals will be transparent if their band gap exceeds 3.2 eV . But actually, the energy of the photon can be somewhat less than the band gap and it may still be able to excite electrons. The model of energy states for noninteracting electrons that underlies spectra such as figure 6.36 is not perfect. The band gap in a spectrum is really the energy to create a conduction band electron and a valence band hole that do not interact. But the electron is negatively charged, and the hole acts as a positive particle. The two attract each other and can therefore form a bound state called an "exciton." The energy of the photon needed to create an exciton is less than the band gap
by the binding energy of the exciton. There is some additional slack due to variations in this binding energy. In the simplest model, the energy levels of lone excitons would be discrete like those of the hydrogen atom. However, they broaden considerably in the less than ideal environment of the solid.

If visible-light photons do not have enough energy to form electron-hole pairs nor excitons, the perfect crystal will be transparent. If the blue side of the visible spectrum has enough energy to excite electrons, the crystal will be colored reddish, since those components of light will remain unabsorbed.

## Key Points

$0-$ A perfect crystal of a solid with a large enough band gap will be transparent.
$0-$ An exciton is a bound state of an electron and a hole.

### 6.27.4 Effects of crystal imperfections

It should be pointed out that in real life, the colors of most nonmetals are caused by crystal imperfections. For example, in ionic materials there may be a vacancy where a negative ion is missing. Since the vacancy has a net positive charge, an electron can be trapped inside it. That is called an " $F$-center." Because its energy levels are relatively small, such a center can absorb light in the visible range. Besides vacancies, chemical impurities are another common cause of optical absorption. A complete description of all the different types of crystal imperfections and their effects is beyond the scope of this book.

## Key Points

$0-$ The colors of most nonmetals are caused by crystal imperfections.
0- An electron bound to a vacancy in a ionic crystal is a called an $F$ center.

### 6.27.5 Photoconductivity

For a nonmetal with a sufficiently narrow band gap, photons of light may have enough energy to take electrons to the conduction band. Then both the electrons in the conduction band, as well as the holes that they leave behind in the valence band, can participate in electrical conduction through the solid. Increased electrical conductivity due to light is called "photoconductivity." It is used for a variety of light sensing devices and for Xerox copiers.

Note that excitons cannot directly produce electrical conduction, as the complete exciton is electrically neutral. However, excitons can create charge carriers
by interacting with crystal imperfections. Or photons with energies less than the band gap can do so themselves. In general, the mechanisms underlying photoconductivity are highly complex and strongly affected by crystal imperfections.

## Key Points

$0-$ Photoconductivity is the increase in conductivity of nonmetals when photons of light create additional charge carriers.

### 6.27.6 Photovoltaic cells

In the vicinity of a $p-n$ junction in a semiconductor crystal, light can do much more than just increase conductivity. It can create electricity. That is the principle of the "photovoltaic cell." These cells are also known as solar cells if the source of light is sunlight.

To understand how they work, consider the schematic of a $p-n$ junction in figure 6.33. Suppose that the crystal is exposed to light. If the photons of light have more energy than the band gap, they can knock electrons out of the valence band. For example, silicon has a band gap of about 1.12 eV . And as noted above, the photons of visible light have energies from about 1.6 eV to 3.2 eV . So a typical photon of sunlight has plenty of energy to knock a silicon electron out of the valence band.

That produces a conduction band electron and a valence band hole. The two will move around randomly due to thermal motion. If they are close enough to the junction, they will eventually stumble into its space charge region, figure 6.33. The electric field in this region will forcefully sweep electrons to the $n$ side and holes to the $p$ side. Therefore, if the $p-n$ junction is exposed to a continuous stream of light, there will be a continuous flow of new electrons to the $n$ side and new holes to the $p$ side. This creates a usable electric voltage difference between the two sides: the excess $n$-side electrons are willing to pass through an external load to recombine with the $p$-side holes.

There are limitations for the efficiency of the creation of electricity. The excess energy that the absorbed photons have above the band gap ends up as heat instead of as electrical power. And photons with insufficient energy to create electron-hole pairs do not contribute. Having $p-n$ junctions with different band gaps absorb different wave lengths of the incoming light can significantly improve efficiency.

## Key Points

$0 \simeq$ Photovoltaics is the creation of electricity by photons. Solar cells are an important example.

### 6.27.7 Light-emitting diodes

In the photovoltaic effect, light creates electricity. But the opposite is also possible. A current across a $p-n$ junction can create light. That is the principle of the "light-emitting diode" (LED) and the "semiconductor laser."

Consider again the schematic of a $p-n$ junction in figure 6.33. When a forward voltage is applied across the junction, $n$-side electrons stream into the $p$ side. These electrons will eventually recombine with the prevailing holes in the $p$ side. Simply put, the conduction electrons drop into the valence band holes. Similarly, $p$-side holes stream into the $n$ side and eventually recombine with the prevailing electrons at that side. Each recombination releases a net amount of energy that is at least equal to the band gap energy. In a suitably chosen semiconductor, the energy can come out as light.

As section 6.22.4 discussed, silicon or germanium are not really suitable. They are what is called "indirect band gap" semiconductors. For these the energy is much more likely to come out as heat rather than light. Using various tricks, silicon can be made to emit some light, but the efficiency is low. LEDs normally use "direct band gap" semiconductors. The classical direct gap material is gallium arsenide, which produced the first patented infrared LED. To emit visible light, the band gap should exceed about 1.6 eV . Indeed, as noted earlier, the photons of visible light range from about 1.6 eV (red) to 3.2 eV (violet). That relates the band gap of the LED to its color. (For indirect gap semiconductors a phonon is involved, section 6.22.4, but its energy is small.) Gallium arsenide, with its 1.4 eV direct band gap emits infrared light with an average wave length of 940 nm . A 1.4 eV photon has a wave length of 885 nm . Diamond, with its 5.5 eV indirect band gap emits some ultraviolet light with an average wave length of 235 nm . A 5.5 eV photon has a wave length of 225 nm .

By the addition of a suitable optical cavity, a "diode laser" can be constructed that emits coherent light. The cavity lets the photons bounce a few times around through the region with the conduction electrons and holes. Now it is one of the peculiar symmetries of quantum mechanics that photons are not just good in taking electrons out of the valence band, they are also good at putting them back in. Because of energy conservation, the latter produces more photons than there were already; therefore it is called stimulated emission. Of course, bouncing the photons around might just get them absorbed again. But stimulated emission can win out over absorption if most electrons at the top of the valence band have been excited to the bottom of the conduction band. That is called a "population inversion." Such a situation can be achieved using a strong current across the junction. Under these conditions a photon may produce another photon through stimulated emission, then the two photons go on to stimulate the emission of still more photons, and so on in a runaway process. The result is coherent light because of the common origin of all the photons.

The idea of lasers is discussed in more detail in chapter 7.7.

## Key Points

$0-A$ LED creates light due to the recombination of electrons and holes near a $p-n$ junction. Normally, the semiconductor has a direct band gap.
$0-$ A laser diode adds an optical cavity to create coherent light.

### 6.28 Thermoelectric Applications

Thermoelectric effects can be used to make solid-state refrigeration devices, or to sense temperature differences, or to convert thermal energy directly into electricity. This section explains the underlying principles.

There are three different thermoelectric effects. They are named the Peltier, Seebeck, and Thomson effects after the researchers who first observed them. Thomson is better known as Kelvin.

These effects are not at all specific to semiconductors. However semiconductors are particularly suitable for thermoelectric applications. The reason is that the nature of the current carriers in semiconductors can be manipulated. That is done by doping the material as described in section 6.23. In an $n$-type doped semiconductor, currents are carried by mobile electrons. In a $p$-type doped semiconductor, the currents are carried by mobile holes, quantum states from which electrons are missing. Electrons are negatively charged particles, but holes act as positively charged ones. That is because a negatively charged electron is missing from a hole.

### 6.28.1 Peltier effect

Thermoelectric cooling can be achieved through what is called the "Peltier effect." The top part of figure 6.37 shows a schematic of a Peltier cooler. The typical device consists of blocks of a semiconductor like bismuth telluride that are alternately doped $n$-type and $p$-type. The blocks are electrically connected by strips of a metal like copper.

The connections are made such that when a current is passed through the device, both the $n$-type electrons and the $p$-type holes move towards the same side of the device. For example, in figure 6.37 both electrons and holes move to the top of the device. The current however is upward in the $p$-type blocks and downward in the $n$-type blocks. (Since electrons are negatively charged, their current is in the direction opposite to their motion.) The same current that enters a metal strip from one block leaves the strip again through the other block.

Figure 6.37: Peltier cooling. Top: physical device. Bottom: Electron energy spectra of the semiconductor materials. Quantum states filled with electrons are shown in red.

Consider now a metal strip at the top of the device in figure 6.37. Such a strip needs to take in a stream of conduction-band electrons from an $n$-type semiconductor block A. It must drop the same number of electrons into the valence-band holes coming in from a $p$-type semiconductor block B to eliminate them. As illustrated by the top arrow between the spectra at the bottom of figure 6.37, this lowers the energy of the electrons. Therefore energy is released, and the top strips get hot.

However, a bottom strip needs to take electrons out of the valence band of a $p$-type semiconductor B to create the outgoing holes. It needs to put these electrons into the conduction band of an $n$-type semiconductor A . That requires energy, so the bottom strips lose energy and cool down. You might think of it as evaporative cooling: the bottom strips have to give up their electrons with the highest thermal energy.

The net effect is that the Peltier cooler acts as a heat pump that removes
heat from the cold side and adds it to the hot side. It can therefore provide refrigeration at the cold side. At the time of writing, Peltier coolers use a lot more power to operate than a refrigerant-based device of the same cooling capability. However, the device is much simpler, and is therefore more suitable for various small applications. And it can easily regulate temperatures; a simple reversal of the current turns the cold side into the hot side.

Note that while the Peltier device connects $p$ and $n$ type semiconductors, it does not act as a diode. In particular, even in the bottom strips there is no need to raise electrons over the band gap of the semiconductor to create the new electrons and holes. Copper does not have a band gap.

It is true that the bottom strips must take electrons out of the $p$-type valence band and put them into the $n$-type conduction band. However, as the spectra at the bottom of figure 6.37 show, the energy needed to do so is much less than the band gap. The reason is that the $p$-type spectrum is raised relative to the $n$-type one. That is an effect of the electrostatic potential energies that are different in the two semiconductors. Even in thermal equilibrium, the spectra are at unequal levels. In particular, in equilibrium the electrostatic potentials adjust so that the chemical potentials, shown as red tick marks in the spectra, line up. The applied external voltage then decreases the energy difference even more.

The analysis of Peltier cooling can be phrased more generally in terms of properties of the materials involved. The "Peltier coefficient" $\mathcal{P}$ of a material is defined as the heat flow produced by an electric current, taken per unit current.

$$
\begin{equation*}
\mathcal{P} \equiv \frac{\dot{Q}}{I} \tag{6.38}
\end{equation*}
$$

Here $I$ is the current through the material and $\dot{Q}$ the heat flow it causes. Phrased another way, the Peltier coefficient is the thermal energy carried per unit charge. That gives it SI units of volts.

Now consider the energy balance of a top strip in figure 6.37. An electric current $I_{\mathrm{AB}}$ flows from material A to material B through the strip. (This current is negative as shown, but that is not important for the general formula.) The current brings along a heat flux $\dot{Q}_{\mathrm{A}}=\mathcal{P}_{\mathrm{A}} I_{\mathrm{AB}}$ from material A that flows into the strip. But a different heat flux $\dot{Q}_{\mathrm{B}}=\mathcal{P}_{\mathrm{B}} I_{\mathrm{AB}}$ leaves the strip through material B. The difference between what comes in and what goes out is what remains inside the strip to heat it:

$$
\begin{equation*}
\dot{Q}=-\left(\mathcal{P}_{\mathrm{B}}-\mathcal{P}_{\mathrm{A}}\right) I_{\mathrm{AB}} \tag{6.39}
\end{equation*}
$$

This equation is generally valid; A and B do not need to be semiconductors. The difference in material Peltier coefficients is called the Peltier coefficient of the junction.

For the top strips in figure $6.37, I_{\mathrm{AB}}$ is negative. Also, as discussed below, the $n$-type $\mathcal{P}_{\mathrm{A}}$ will be negative and the $p$-type $\mathcal{P}_{\mathrm{B}}$ positive. That makes the net heat flowing into the strip positive as it should be. Note also that the opposite signs of $n$-type and $p$-type Peltier coefficients really help to make the net heat flow as big as possible.

If there is a temperature gradient in the semiconductors in addition to the current, and there will be, it too will create a heat flow, \{A.11\}. This heat flow can be found using what is known as Fourier's law. It is bad news as it removes heat from the hot side and conducts it to the cold side.

A more quantitative understanding of the Peltier effect can be obtained using some ballpark Peltier coefficients. Consider again the spectra in figure 6.37. In the $n$-type semiconductor, each conduction electron has an energy per unit charge of about

$$
\mathcal{P}_{n \text { type }} \sim \frac{E^{\mathrm{p}}}{-e}=\frac{E_{\mathrm{c}}^{\mathrm{p}}+\frac{3}{2} k_{\mathrm{B}} T-\mu}{-e}
$$

Here $-e$ in the denominator is the charge of the electron, while $E_{\mathrm{c}}^{\mathrm{p}}$ in the numerator is the energy at the bottom of the conduction band. It has been assumed that a typical electron in the conduction band has an additional random thermal energy equal to the classical value $\frac{3}{2} k_{\mathrm{B}} T$. Further the chemical potential, or Fermi level, $\mu$ has been taken as the zero level of energy.

The reason for doing the latter has to do with the fact that in thermal equilibrium, all solids in contact have the same chemical potential. That makes the chemical potential a convenient reference level of energy. The idea can be described graphically in terms of the spectra of figure 6.37. In the spectra, the chemical potential is indicated by the red tick marks on the vertical axes. Now consider again the energy change in transferring electrons between the $n$ and $p$-type materials. What determines it is how much the $n$-type electrons are higher in energy than the chemical potential and how much electrons put in the $p$-type holes are lower than it. (This assumes that the current remains small enough that the chemical potentials in the two semiconductors stay level. Otherwise theoretical description would become much more difficult.)

As this picture suggests, for the holes in the $p$-type semiconductor, the energy should be taken to be increasing downwards in the electron spectrum. It takes more energy to create a hole by taking an electron up to the Fermi level if the hole is lower in the spectrum. Therefore the Peltier coefficient of the $p$-doped semiconductor is

$$
\mathcal{P}_{p \text { type }} \sim \frac{E^{\mathrm{p}}}{e}=\frac{\mu-E_{\mathrm{v}}^{\mathrm{p}}+\frac{3}{2} k_{\mathrm{B}} T}{e}
$$

where $E_{\mathrm{v}}^{\mathrm{p}}$ is the electron energy at the top of the valence band. Because holes act as positively charged particles, the Peltier coefficient of a $p$-type semiconductor
is positive. On the other hand, the Peltier coefficient of an $n$-type semiconductor is negative because of the negative charge in the denominator.

Note that both formulae are just ballparks. The thermal energy dragged along by a current is not simply the thermal equilibrium distribution of electron energy. The average thermal kinetic energy per current carrier to be used turns out to differ somewhat from $\frac{3}{2} k_{\mathrm{B}} T$. The current is also associated with a flow of phonons; their energy should be added to the thermal energy that is carried directly by the electrons or holes, $\{$ A. 11$\}$. Such issues are far beyond the scope of this book.

It is however interesting to compare the above semiconductor ballparks to one for metals:

$$
\mathcal{P}_{\text {metal }} \sim-\frac{2 \pi^{2}}{9} \frac{\frac{3}{2} k_{\mathrm{B}} T}{E_{\mathrm{F}}^{\mathrm{p}}} \frac{\frac{3}{2} k_{\mathrm{B}} T}{e}
$$

This ballpark comes from assuming the spectrum of a free-electron gas, \{A.11\}. The final ratio is easily understood as the classical thermal kinetic energy $\frac{3}{2} k_{\mathrm{B}} T$ per unit charge $e$. The ratio in front of it is the thermal energy divided by the Fermi energy $E_{\mathrm{F}}^{\mathrm{p}}$. As discussed in section 6.10, this fraction is much less than one. Its presence can be understood from the exclusion principle: as illustrated in figure 6.15 , only a small fraction of the electrons pick up thermal energy in a metal.

The ballpark above implies that the Peltier coefficient of a metal is very much less than that of a doped semiconductor. It should however be noted that while the ballpark does give the rough order of magnitude of the Peltier coefficients of metals, they tend to be noticeably larger. Worse, there are quite a few metals whose Peltier coefficient is positive, unlike the ballpark above says.

To some extent, the lower Peltier coefficients of metals are compensated for by their larger electrical conductivity. A nondimensional figure of merit can be defined for thermoelectric materials as, $\{$ A.11\}:

$$
\frac{\mathcal{P}^{2} \sigma}{T \kappa}
$$

where $T$ is a typical operating absolute temperature. This figure of merit shows that a large Peltier coefficient is good, quadratically so, but so is a large electrical conductivity $\sigma$ and a low thermal conductivity $\kappa$. Unfortunately, metals also conduct heat well.

## Key Points

$0-$ In the Peltier effect, a current produces cooling or heating when it passes through the contact area between two solids.
$0-$ The heat released is proportional to the current and the difference in Peltier coefficients of the materials.
$0-$ Connections between oppositely-doped semiconductors work well.

### 6.28.2 Seebeck effect

Thermoelectric temperature sensing and power generation can be achieved by what is known as the "Seebeck effect." It is in some sense the opposite of the Peltier effect of the previous subsection.

Consider the configuration shown in figure 6.38. Blocks of $n$-type and $p$-type doped semiconductors are electrically connected at their tops using a copper strip. Copper strips are also attached to the bottoms of the semiconductor blocks. Unlike for the Peltier device, no external voltage source is attached. In the pure Seebeck effect, the bottom strips are electrically not in contact at all. So there is no current through the device. It is what is called an open-circuit configuration.

- electron ( $n$-type semiconductor)
- hole ( $p$-type semiconductor)

Figure 6.38: An example Seebeck voltage generator.
To achieve the Seebeck effect, heat from an external heat source is added to the top copper strip. That heats it up. Heat is allowed to escape from the bottom strips to, say, cooling water. This heat flow pattern is the exact opposite of the one for the Peltier cooler. If heat went out of the strips of your Peltier cooler at the cold side, it would melt your ice cubes.

But the Peltier cooler requires an external voltage to be supplied to keep the device running. The opposite happens for the Seebeck generator of figure 6.38. The device itself turns into a electric power supply. A voltage difference develops spontaneously between the bottom two strips.

That voltage difference can be used to determine the temperature of the top copper strip, assuming that the bottom strips are kept at a known temperature. A device that measures temperatures this way is called a "thermocouple."

Alternatively, you can extract electrical power from the voltage difference between the two bottom terminals. In that case the Seebeck device acts as a
"thermoelectric generator." Of course, to extract power you need to allow some current to flow. That will reduce the voltage below the pure Seebeck value.

To describe why the device works physically is not that easy. To understand the basic idea, consider an arbitrary point P in the $n$-type semiconductor, as indicated in figure 6.38. Imagine yourself standing at this point, shrunk down to microscopic dimensions. Due to random heat motion, conduction electrons come at you randomly from both above and below. However, those coming from above are hotter and so they come towards you at a higher speed. Therefore, assuming that all else is the same, there is a net electron current downwards at your location. Of course, that cannot go on, because it moves negative charge down, charging the lower part of the device negative and the top positive. This will create an electric field that slows down the hot electrons going down and speeds up the cold electrons going up. The voltage gradient associated with this electric field is the Seebeck effect, $\{\mathrm{A} .11\}$.

In the Seebeck effect, an incremental temperature change $\mathrm{d} T$ in a material causes a corresponding change in voltage $\mathrm{d} \varphi$ given by:

$$
\mathrm{d} \varphi_{\mu}=-\mathcal{S} \mathrm{d} T
$$

The subscript on $\varphi_{\mu}$ indicates that the intrinsic chemical potential of the material must be included in addition to the electrostatic potential $\varphi$. In other words, $\varphi_{\mu}$ is the total chemical potential per unit electron charge. The constant $\mathcal{S}$ is a material coefficient depending on material and temperature.

This coefficient is sometimes called the "Seebeck coefficient." However, it is usually called the "thermopower" or "thermoelectric power." These names are much better, because the Seebeck coefficient describes an open-circuit voltage, in which no power is produced. It has units of $\mathrm{V} / \mathrm{K}$. It is hilarious to watch the confused faces of those hated nonspecialists when a physicist with a straight face describes something that is not, and cannot be, a power as the "thermopower."

The net voltage produced is the integrated total voltage change over the lengths of the two materials. If $T_{\mathrm{H}}$ is the temperature of the top strip and $T_{\mathrm{L}}$ that of the bottom ones, the net voltage can be written as:

$$
\begin{equation*}
\varphi_{\mathrm{B}}-\varphi_{\mathrm{A}}=\int_{T_{\mathrm{L}}}^{T_{\mathrm{H}}}\left(\mathcal{S}_{\mathrm{B}}-\mathcal{S}_{\mathrm{A}}\right) \mathrm{d} T \tag{6.40}
\end{equation*}
$$

This is the voltage that will show up on a voltmeter connected between the bottom strips. Note that there is no need to use the chemical potential $\varphi_{\mu}$ in this expression: since the bottom strips are both copper and at the same temperature, their intrinsic chemical potentials are identical.

The above equation assumes that the copper strips conduct heat well enough that their temperature is constant, (or alternatively, that materials A and B are in direct contact with each other at their top edges and with the voltmeter at
their bottom edges). Otherwise you would need to add an integral over the copper.

Note from the above equation that, given the temperature $T_{\mathrm{L}}$ of the bottom strips, the voltage only depends on the temperature $T_{\mathrm{H}}$ of the top strip. In terms of figure 6.38 , the detailed way that the temperature varies with height is not important, just that the end values are $T_{H}$ and $T_{L}$. That is great for your thermocouple application, because the voltage that you get only depends on the temperature at the tip of the thermocouple, the one you want to measure. It is not affected by whatever is the detailed temperature distribution in the two leads going to and from the tip. (As long as the material properties stay constant in the leads, that is. The temperature dependence of the Seebeck coefficients is not a problem.)

Figure 6.39: The Galvani potential jump over the contact surface does not produce a usable voltage.

It is sometimes suggested, even by some that surely know better like [22, p. 14-9], that the Seebeck potential is due to jumps in potential at the contact surfaces. To explain the idea, consider figure 6.39. In this figure materials A and B have been connected directly in order to simplify the ideas. It turns out that the mean electrostatic potential inside material A immediately before the contact surface with material B is different from the mean electrostatic potential inside material B immediately after the contact surface. The difference is called the Galvani potential. It is due to the charge double layer that exists at the contact surface between different solids. This charge layer develops to ensure that the chemical potentials are the same at both sides of the contact surface. Equality of chemical potentials across contact surfaces is a requirement for thermal equilibrium. Electrostatic potentials can be different.

If you try to measure this Galvani potential directly, like with the bottom voltmeter in figure 6.39, you fail. The reason is that there are also Galvani potential jumps between materials A and B and the leads of your voltmeter. Assume for simplicity that the leads of your voltmeter are both made of copper.

Because the chemical potentials are pairwise equal across the contact surfaces, all four chemical potentials are the same, including the two in the voltmeter leads. Therefore, the actual voltmeter can detect no difference between its two leads and gives a zero reading.

Now consider the top voltmeter in figure 6.39. This voltmeter does measure a voltage. Also in this case, the contact surfaces between the leads of the voltmeter and materials A and B are at a different temperature $T_{\mathrm{L}}$ than the temperature $T_{\mathrm{H}}$ of the contact surface between materials A and B . The suggestion is therefore sometimes made that changes in the Galvani potentials due to temperature differences produce the measured voltage. That would explain very neatly why the measured voltage only depends on the temperatures of the contact surfaces. Not on the detailed temperature distributions along the lengths of the materials.

It may be neat, but unfortunately it is also all wrong. The fact that the dependence on the temperature distribution drops out of the final result is just a mathematical coincidence. As long as the changes in intrinsic chemical potential can be ignored, the Galvani potential jumps still sum to zero. Not to the measured potential. After all, in that case the voltage changes over the lengths of the materials are the same as the chemical potential changes. And because they already sum to the measured voltage, there is nothing left for the Galvani jumps. Consider for example the free-electron gas model of metals. While its intrinsic chemical potential does change with temperature, $\{\mathrm{D} .62\}$, that change is only one third of the potential change produced by the Seebeck coefficient given in addendum $\{\mathrm{A} .11\}$. Galvani potential changes then sum to only a third of the measured potential. No, there is no partial credit.

Figure 6.40: The Seebeck effect is not directly measurable.
It should also be pointed out that the Seebeck effect of a material is not directly measurable. Figure 6.40 illustrates an attempt to directly measure the Seebeck effect of material A. Unfortunately, the only thing that changes compared to figure 6.39 is that the two leads of the voltmeter take over the place of material B. Unless the two leads are attached to points of equal temperature, they are an active part of the total Seebeck effect measured. (Superconductors should have their Seebeck coefficient zero. However, finding superconductors that still are superconductors if they are in thermal contact with real-life temperatures is an obvious issue.)

Kelvin discovered that you can find the Seebeck coefficient $\mathcal{S}$ from the Peltier coefficient $\mathcal{P}$ simply by dividing by the absolute temperature. Unfortunately, the Peltier coefficient is not directly measurable either. Its effect too requires a second material to be present to compare against. It does show, however, that good materials for the Peltier effect are also good materials for the Seebeck effect.

You might wonder where the charges that transfer between the hot and cold sides in the Seebeck effect end up. In thermal equilibrium, the interiors of solids need to stay free of net electric charge, or a current would develop to eliminated the charge difference. But in the Seebeck effect, the solids are not in thermal equilibrium. It is therefore somewhat surprising that the interiors do remain free of net charge. At least, they do if the temperature variations are small enough, $\{$ A. 11$\}$. So the charges that transfer between hot and cold, and so give rise to the Seebeck potential difference, end up at the surfaces of the solids. Not in the interior. Even in the Seebeck effect.

## Key Points

0- The Seebeck effect produces a usable voltage from temperature differences.
$0-$ It requires two different materials in electrical contact to span the temperature difference.

0- The voltage is the difference in the integrals of the Seebeck coefficients of the two materials with respect to temperature.
o- The Seebeck coefficient is usually called thermopower because it is not power.

### 6.28.3 Thomson effect

The "Thomson effect," or "Kelvin heat," describes the heat release in a material with a current through it. This heat release is directly measurable. That is unlike the Peltier and Seebeck effects, for which only the net effect of two different materials can be measured. Since the Peltier and Seebeck coefficients can be computed from the Thomson one, in principle the Thomson effect allows all three thermoelectric coefficients to be found without involving a second material.

Thomson, who later became lord Kelvin, showed that the net energy accumulation per unit volume in a bar of material with a current through it can be written as:

$$
\begin{equation*}
\dot{e}=\frac{\mathrm{d}}{\mathrm{~d} x}\left(\kappa \frac{\mathrm{~d} T}{\mathrm{~d} x}\right)+\frac{j^{2}}{\sigma}-\mathcal{K} j \frac{\mathrm{~d} T}{\mathrm{~d} x} \tag{6.41}
\end{equation*}
$$

Here $x$ is the position along the bar, $T$ is the temperature, $j$ is the current per unit area, and $\kappa$ and $\sigma$ are the thermal and electrical conductivities. The first term in the right hand side is heat accumulation due to Fourier's law of heat conduction. The second term is the Joule heating that keeps your resistance heater working. The final term is the thermoelectric Thomson effect or Kelvin heat. (The term "Kelvin effect" is not used because it is already in common use for something else.) The coefficient $\mathcal{K}$ is called the "Kelvin coefficient" or "Thomson coefficient." A derivation from the general equations of thermoelectrics is given in addendum \{A.11\}.

It may be noted that for devices in which the Thomson effect is important, the figure of merit introduced earlier becomes less meaningful. In such cases, a second nondimensional number based on the Kelvin coefficient will also affect device performance.

The other two thermoelectric coefficients can be computed from the Kelvin one using the Kelvin, or Thomson, relationships \{A.11\}:

$$
\begin{array}{|l|}
\hline \frac{\mathrm{dS}}{\mathrm{~d} \ln T}=\mathcal{K} \quad \mathcal{P}=\mathcal{S} T  \tag{6.42}\\
\hline
\end{array}
$$

By integrating $\mathcal{K}$ with respect to $\ln T$ you can find the Seebeck coefficient and from that the Peltier one.

That requires of course that you find the Kelvin coefficient over the complete temperature range. But you only need to do it for one material. As soon as you accurately know the thermoelectric coefficients for one material, you can use that as the reference material to find Peltier and Seebeck coefficients for every other material. Lead is typically used as the reference material, as it has relatively low thermoelectric coefficients.

Of course, if it turns out that the data on your reference material are not as accurate as you thought they were, it would be very bad news. It will affect the accuracy of the thermoelectric coefficients of every other material that you found using this reference material. A prediction on whether such a thing was likely to happen for lead could be derived from what is known as Murphy's law.

## Key Points

0- The Thomson effect, or Kelvin heat, describes the internal heating in a material with a current going through it. More precisely, it describes the part of this heating that is due to interaction of the current with the temperature changes.
$0-$ Unlike the Peltier and Seebeck coefficients, the Kelvin (Thomson) coefficient can be measured without involving a second material.
$0-$ The Kelvin (Thomson) relations allow you to compute the Peltier and Seebeck coefficients from the Kelvin one.

## Chapter 7

## Time Evolution

#### Abstract

The evolution of systems in time is less important in quantum mechanics than in classical physics, since in quantum mechanics so much can be learned from the energy eigenvalues and eigenfunctions. Still, time evolution is needed for such important physical processes as the creation and absorption of light and other radiation. And many other physical processes of practical importance are simplest to understand in terms of classical physics. To translate a typical rough classical description into correct quantum mechanics requires an understanding of unsteady quantum mechanics. The chapter starts with the introduction of the Schrödinger equation. This equation is as important for quantum mechanics as Newton's second law is for classical mechanics. A formal solution to the equation can be written immediately down for most systems of interest.

One direct consequence of the Schrödinger equation is energy conservation. Systems that have a definite value for their energy conserve that energy in the simplest possible way: they just do not change at all. They are stationary states. Systems that have uncertainty in energy do evolve in a nontrivial way. But such systems do still conserve the probability of each of their possible energy values. Of course, the energy of a system is only conserved if no devious external agent is adding or removing energy. In quantum mechanics that usually boils down to the condition that the Hamiltonian must be independent of time. If there is a nasty external agent that does mess things up, analysis may still be possible if that agent is a slowpoke. Since physicists do not know how to spell slowpoke, they call this the adiabatic approximation. More precisely, they call it adiabatic because they know how to spell adiabatic, but not what it means. The Schrödinger equation is readily used to describe the evolution of expectation values of physical quantities. This makes it possible to show

that Newton's equations are really an approximation of quantum mechanics valid for macroscopic systems. It also makes it possible to formulate the popular energy-time uncertainty relationship.

Next, the Schrödinger equation does not just explain energy conservation. It also explains where other conservation laws such as conservation of linear and angular momentum come from. For example, angular momentum conservation is a direct consequence of the fact that space has no preferred direction.

It is then shown how these various conservation laws can be used to better understand the emission of electromagnetic radiation by say an hydrogen atom. In particular, they provide conditions on the emission process that are called selection rules.

Next, the Schrödinger equation is used to describe the detailed time evolution of a simple quantum system. The system alternates between two physically equivalent states. That provides a model for how the fundamental forces of nature arise. It also provides a model for the emission of radiation by an atom or an atomic nucleus.
Unfortunately, the model for emission of radiation turns out to have some problems. These require the consideration of quantum systems involving two states that are not physically equivalent. That analysis then finally allows a comprehensive description of the interaction between atoms and the electromagnetic field. It turns out that emission of radiation can be stimulated by radiation that already exists. That allows for the operation of masers and lasers that dump out macroscopic amounts of monochromatic, coherent radiation.

The final sections discuss examples of the nontrivial evolution of simple quantum systems with infinite numbers of states. Before that can be done, first the so-far neglected eigenfunctions of position and linear momentum must be discussed. Position eigenfunctions turn out to be spikes, while linear momentum eigenfunctions turn out to be waves. Particles that have significant and sustained spatial localization can be identified as "packets" of waves. These ideas can be generalized to the motion of conduction electrons in crystals.

The motion of such wave packets is then examined. If the forces change slowly on quantum scales, wave packets move approximately like classical particles do. Under such conditions, a simple theory called the WKB approximation applies.
If the forces vary more rapidly on quantum scales, more weird effects are observed. For example, wave packets may be repelled by attractive forces. On the other hand, wave packets can penetrate through barriers even though classically speaking, they do not have enough energy to do so. That is called tunneling. It is important for various applications. A
simple estimate for the probability that a particle will tunnel through a barrier can be obtained from the WKB approximation.
Normally, a wave packet will be partially transmitted and partially reflected by a finite barrier. That produces the weird quantum situation that the same particle is going in two different directions at the same time. From a more practical point of view, scattering particles from objects is a primary technique that physicists use to examine nature.

### 7.1 The Schrödinger Equation

In Newtonian mechanics, Newton's second law states that the linear momentum changes in time proportional to the applied force; $\mathrm{d} m \vec{v} / \mathrm{d} t=m \vec{a}=\vec{F}$. The equivalent in quantum mechanics is the Schrödinger equation, which describes how the wave function evolves. This section discusses this equation, and a few of its immediate consequences.

### 7.1.1 The equation

The Schrödinger equation says that the time derivative of the wave function is obtained by applying the Hamiltonian on it. More precisely:

$$
\begin{equation*}
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=H \Psi \tag{7.1}
\end{equation*}
$$

An equivalent and earlier formulation of quantum mechanics was given by Heisenberg, $\{$ A. 12$\}$. However, the Schrödinger equation tends to be easier to deal with, especially in nonrelativistic applications. An integral version of the Schrödinger equation that is sometimes convenient is in \{A.13\}.

The Schrödinger equations is nonrelativistic. The simplest relativistic version is called the Klein-Gordon equation. A discussion is in addendum \{A.14\}. However, relativity introduces a fundamentally new issue: following Einstein's mass-energy equivalence, particles may be created out of pure energy or destroyed. To deal with that, you typically need a formulation of quantum mechanics called quantum field theory. A very brief introduction is in addendum \{A.15\}.

## Key Points

0- The Schrödinger equation describes the time evolution of the wave function.
0 - The time derivative is proportional to the Hamiltonian.

### 7.1.2 Solution of the equation

The solution to the Schrödinger equation can immediately be given for most cases of interest. The only condition that needs to be satisfied is that the Hamiltonian depends only on the state the system is in, and not explicitly on time. This condition is satisfied in all cases discussed so far, including the particle in a box, the harmonic oscillator, the hydrogen and heavier atoms, and the molecules, so the following solution applies to them all:

To satisfy the Schrödinger equation, write the wave function $\Psi$ in terms of whatever are the energy eigenfunctions $\psi_{\vec{n}}$ of the Hamiltonian,

$$
\begin{equation*}
\Psi=c_{\vec{n}_{1}}(t) \psi_{\vec{n}_{1}}+c_{\vec{n}_{2}}(t) \psi_{\vec{n}_{2}}+\ldots=\sum_{\vec{n}} c_{\vec{n}}(t) \psi_{\vec{n}} \tag{7.2}
\end{equation*}
$$

Then the coefficients $c_{\vec{n}}$ must evolve in time as complex exponentials:

$$
\begin{equation*}
c_{\vec{n}}(t)=c_{\vec{n}}(0) e^{-\mathrm{i} E_{\vec{n}} t / \hbar} \tag{7.3}
\end{equation*}
$$

for every combination of quantum numbers $\vec{n}$.
In short, you get the wave function for arbitrary times by taking the initial wave function and shoving in additional factors $e^{-\mathrm{i} E_{\bar{n}} t / \hbar}$. The initial values $c_{\vec{n}}(0)$ of the coefficients are not determined from the Schrödinger equation, but from whatever initial condition for the wave function is given. As always, the appropriate set of quantum numbers $\vec{n}$ depends on the problem.

Consider how this works out for the electron in the hydrogen atom. Here each spatial energy state $\psi_{n l m}$ is characterized by the three quantum numbers $n, l, m$, chapter 4.3. However, there is a spin-up version $\psi_{n l m} \uparrow$ of each state in which the electron has spin magnetic quantum number $m_{s}=\frac{1}{2}$, and a spin-down version $\psi_{n l m} \downarrow$ in which $m_{s}=-\frac{1}{2}$, chapter 5.5.1. So the states are characterized by the set of four quantum numbers

$$
\vec{n} \equiv\left(n, l, m, m_{s}\right)
$$

The most general wave function for the hydrogen atom is then:

$$
\begin{aligned}
& \Psi\left(r, \theta, \phi, S_{z}, t\right)= \\
& \quad \sum_{n=1}^{\infty} \sum_{l=0}^{n-1} \sum_{m=-l}^{l} c_{n l m \frac{1}{2}}(0) e^{-\mathrm{i} E_{n} t / \hbar} \psi_{n l m}(r, \theta, \phi) \uparrow+c_{n l m,-\frac{1}{2}}(0) e^{-\mathrm{i} E_{n} t / \hbar} \psi_{n l m}(r, \theta, \phi) \downarrow
\end{aligned}
$$

Note that each eigenfunction has been given its own coefficient that depends exponentially on time. (The summation limits come from chapter 4.3.)

The given solution in terms of eigenfunctions covers most cases of interest, but as noted, it is not valid if the Hamiltonian depends explicitly on time. That
possibility arises when there are external influences on the system; in such cases the energy does not just depend on what state the system itself is in, but also on what the external influences are like at the time.

## Key Points

$0-$ Normally, the coefficients of the energy eigenfunctions must be proportional to $e^{-\mathrm{i} E_{\bar{n}} t / \hbar}$.

### 7.1.2 Review Questions

1. The energy of a photon is $\hbar \omega$ where $\omega$ is the classical frequency of the electromagnetic field produced by the photon. So what is $e^{-\mathrm{i} E_{n} t / \hbar}$ for a photon? Are you surprised by the result?
Solution schrodsol-a
2. For the one-dimensional harmonic oscillator, the energy eigenvalues are

$$
E_{n}=\frac{2 n+1}{2} \omega
$$

Write out the coefficients $c_{n}(0) e^{-\mathrm{i} E_{n} t / \hbar}$ for those energies.
Now classically, the harmonic oscillator has a natural frequency $\omega$. That means that whenever $\omega t$ is a whole multiple of $2 \pi$, the harmonic oscillator is again in the same state as it started out with. Show that the coefficients of the energy eigenfunctions have a natural frequency of $\frac{1}{2} \omega$; $\frac{1}{2} \omega t$ must be a whole multiple of $2 \pi$ for the coefficients to return to their original values.
Solution schrodsol-b
3. Write the full wave function for a one-dimensional harmonic oscillator. Formulae are in chapter 4.1.2.

Solution schrodsol-c

### 7.1.3 Energy conservation

The Schrödinger equation implies that the energy of a system is conserved, assuming that there are no external influences on the system.

To see why, consider the general form of the wave function:

$$
\Psi=\sum_{\vec{n}} c_{\vec{n}}(t) \psi_{\vec{n}} \quad c_{\vec{n}}(t)=c_{\vec{n}}(0) e^{-\mathrm{i} E_{\vec{n}} t / \hbar}
$$

According to chapter 3.4 , the square magnitudes $\left|c_{\vec{n}}\right|^{2}$ of the coefficients of the energy eigenfunctions give the probability for the corresponding energy. While the coefficients vary with time, their square magnitudes do not:

$$
\left|c_{\vec{n}}(t)\right|^{2} \equiv c_{\vec{n}}^{*}(t) c_{\vec{n}}(t)=c_{\vec{n}}^{*}(0) e^{\mathrm{i} E_{\vec{n}} t / \hbar} c_{\vec{n}}(0) e^{-\mathrm{i} E_{\vec{n}} t / \hbar}=\left|c_{\vec{n}}(0)\right|^{2}
$$

So the probability of measuring a given energy level does not vary with time either. That means that energy is conserved.

For example, a wave function for a hydrogen atom at the excited energy level $E_{2}$ might be of the form:

$$
\Psi=e^{-\mathrm{i} E_{2} t / \hbar} \psi_{210} \uparrow
$$

(This corresponds to an assumed initial condition in which all coefficients $c_{n l m m_{s}}$ are zero except $c_{2101}=1$.) The square magnitude of the exponential is one, so the energy of this excited atom will stay $E_{2}$ with $100 \%$ certainty for all time. The energy of the atom is conserved.

This is an important example, because it also illustrates that an excited atom will stay excited for all time if left alone. That is an apparent contradiction because, as discussed in chapter 4.3, the above excited atom will eventually emit a photon and transition back to the ground state. Even if you put it in a sealed box whose interior is at absolute zero temperature, it will still decay.

The explanation for this apparent contradiction is that an atom is never truly left alone. Simply put, even at absolute zero temperature, quantum uncertainty in energy allows an electromagnetic photon to pop up that perturbs the atom and causes the decay. (To describe more precisely what happens is a major objective of this chapter.)

Returning to the unperturbed atom, you may wonder what happens to energy conservation if there is uncertainty in energy. In that case, what does not change with time are the probabilities of measuring the possible energy levels. As an arbitrary example, the following wave function describes a case of an unperturbed hydrogen atom whose energy has a $50 / 50$ chance of being measured as $E_{1},(-13.6 \mathrm{eV})$, or as $E_{2},(-3.4 \mathrm{eV})$ :

$$
\Psi=\frac{1}{\sqrt{2}} e^{-\mathrm{i} E_{1} t / \hbar} \psi_{100} \downarrow+\frac{1}{\sqrt{2}} e^{-\mathrm{i} E_{2} t / \hbar} \psi_{210} \uparrow
$$

The 50/50 probability applies regardless how long the wait is before the measurement is done.

You can turn the observations of this subsection also around. If an external effect changes the energy of a system, then clearly the probabilities of the individual energies must change. So then the coefficients of the energy eigenfunctions cannot be simply vary exponentially with time as they do for the unperturbed systems discussed above.

## Key Points

$0-$ Energy conservation is a fundamental consequence of the Schrödinger equation.
$0-$ An isolated system that has a given energy retains that energy.
$0-$ Even if there is uncertainty in the energy of an isolated system, still the probabilities of the various energies do not change with time.

### 7.1.4 Stationary states

The quest for the dynamical implications of the Schrödinger equation must start with the simplest case. That is the case in which there is only a single energy eigenfunction involved. Then the wave function is of the form

$$
\Psi=c_{\vec{n}}(0) e^{-\mathrm{i} E_{\vec{n}} t / \hbar} \psi_{\vec{n}}
$$

Such states are called "stationary states." Systems in their ground state are of this type.

To see why these states are called stationary, note first of all that the energy of the state is $E_{\vec{n}}$ for all time, with no uncertainty.

But energy is not the only thing that does not change in time. According to the Born interpretation, chapter 3.1, the square magnitude of the wave function of a particle gives the probability of finding the particle at that position and time. Now the square magnitude of the wave function above is

$$
|\Psi|^{2}=\left|\psi_{\vec{n}}\right|^{2}
$$

Time has dropped out in the square magnitude; the probability of finding the particle is the same for all time.

For example, consider the case of the particle in a pipe of chapter 3.5. If the particle is in the ground state, its wave function is of the form

$$
\Psi=c_{111}(0) e^{-\mathrm{i} E_{111} t / \hbar} \psi_{111}
$$

The precise form of the function $\psi_{111}$ is not of particular interest here, but it can be found in chapter 3.5.

The relative probability for where the particle may be found can be shown as grey tones:

Figure 7.1: The ground state wave function looks the same at all times.

The bottom line is that this picture is the same for all time.
If the wave function is purely the first excited state $\psi_{211}$, the corresponding picture looks for all time like:

And it is not just position that does not change. Neither do linear or angular momentum, kinetic energy, etcetera. That can be easily checked. The probability for a specific value of any physical quantity is given by

$$
|\langle\alpha \mid \Psi\rangle|^{2}
$$

where $\alpha$ is the eigenfunction corresponding to the value. (If there is more than one eigenfunction with that value, sum their contributions.) The exponential drops out in the square magnitude. So the probability does not depend on time.

And if probabilities do not change, then neither do expectation values, uncertainties, etcetera. No physically meaningful quantity changes with time.

Hence it is not really surprising that none of the energy eigenfunctions derived so far had any resemblance to the classical Newtonian picture of a particle moving around. Each energy eigenfunction by itself is a stationary state. There is no change in the probability of finding the particle regardless of the time that you look. So how could it possibly resemble a classical particle that is at different positions at different times?

To get time variations of physical quantities, states of different energy must be combined. In other words, there must be uncertainty in energy.

## Key Points

$0-$ States of definite energy are stationary states.
$0-$ To get nontrivial time variation of a system requires uncertainty in energy.

### 7.1.5 The adiabatic approximation

The previous subsections discussed the solution for systems in which the Hamiltonian does not explicitly depend on time. Typically that means isolated systems, unaffected by external effects, or systems for which the external effects are relatively simple. If the external effects produce a time-dependent Hamiltonian, things get much messier. You cannot simply make the coefficients of the eigenfunctions vary exponentially in time as done in the previous subsections.

However, dealing with systems with time-dependent Hamiltonians can still be relatively easy if the Hamiltonian varies sufficiently slowly in time. Such systems are quasi-steady ones.

So physicists cannot call these systems quasi-steady; that would give the secret away to these hated nonspecialists and pesky students. Fortunately, physicists were able to find a much better name. They call these systems "adiabatic." That works much better because the word "adiabatic" is a well-known term in thermodynamics: it indicates systems that evolve fast enough that heat conduction with the surroundings can be ignored. So, what better name to use also for quantum systems that evolve slowly enough that they stay in equilibrium with their surroundings? No one familiar with even the most basic thermodynamics will ever guess what it means.

As a simple example of an adiabatic system, assume that you have a particle in the ground state in a box. Now you change the volume of the box by a significant amount. The question is, will the particle still be in the ground state after the volume change? Normally there is no reason to assume so; after all, either way the energy of the particle will change significantly. However, the "adiabatic theorem" says that if the change is performed slowly enough, it will. The particle will indeed remain in the ground state, even though that state slowly changes into a completely different form.

If the system is in an energy state other than the ground state, the particle will stay in that state as it evolves during an adiabatic process. The theorem does assume that the energy is nondegenerate, so that the energy state is unambiguous. More sophisticated versions of the analysis exist to deal with degeneracy and continuous spectra.

A derivation of the theorem can be found in $\{\mathrm{D} .34\}$. Some additional implications are in addendum $\{$ A. 16\}. The most important practical application of the adiabatic theorem is without doubt the Born-Oppenheimer approximation, which is discussed separately in chapter 9.2.

## Key Points

$0=$ If the properties of a system in its ground state are changed, but slowly, the system will remain in the changing ground state.
$0-$ More generally, the "adiabatic" approximation can be used to analyze slowly changing systems.
$0-$ No, it has nothing to do with the normal use of the word "adiabatic."

### 7.2 Time Variation of Expectation Values

The time evolution of systems may be found using the Schrödinger equation as described in the previous section. However, that requires the energy eigenfunctions to be found. That might not be easy.

For some systems, especially for macroscopic ones, it may be sufficient to figure out the evolution of the expectation values. An expectation value of a
physical quantity is the average of the possible values of that quantity, chapter 4.4. This section will show how expectation values may often be found without finding the energy eigenfunctions. Some applications will be indicated.

The Schrödinger equation requires that the expectation value $\langle a\rangle$ of any physical quantity $a$ with associated operator $A$ evolves in time as:

$$
\begin{equation*}
\frac{\mathrm{d}\langle a\rangle}{\mathrm{d} t}=\frac{\mathrm{i}}{\hbar}\langle[H, A]\rangle+\left\langle\frac{\partial A}{\partial t}\right\rangle \tag{7.4}
\end{equation*}
$$

A derivation is in $\{\mathrm{D} .35\}$. The commutator $[H, A]$ of $A$ with the Hamiltonian was defined in chapter 4.5 as $H A-A H$. The final term in (7.4) is usually zero, since most (simple) operators do not explicitly depend on time.

The above evolution equation for expectation values does not require the energy eigenfunctions, but it does require the commutator.

Note from (7.4) that if an operator $A$ commutes with the Hamiltonian, i.e. $[H, A]=0$, then the expectation value of the corresponding quantity $a$ will not vary with time. Actually, that is just the start of it. Such a quantity has eigenfunctions that are also energy eigenfunctions, so it has the same timeconserved statistics as energy, section 7.1.4. The uncertainty, probabilities of the individual values, etcetera, do not change with time either for such a variable.

One application of equation (7.4) is the so-called "virial theorem" that relates the expectation potential and kinetic energies of energy eigenstates, \{A.17\}. For example, it shows that harmonic oscillator states have equal potential and kinetic energies. And that for hydrogen states, the potential energy is minus two times the kinetic energy.

Two other important applications are discussed in the next two subsections.

## Key Points

$0-$ A relatively simple equation that describes the time evolution of expectation values of physical quantities exists. It is fully in terms of expectation values.
$0-$ Variables which commute with the Hamiltonian have the same timeindependent statistics as energy.
$0-$ The virial theorem relates the expectation kinetic and potential energies for important systems.

### 7.2.1 Newtonian motion

The purpose of this section is to show that even though Newton's equations do not apply to very small systems, they are correct for macroscopic systems.

The trick is to note that for a macroscopic particle, the position and momentum are very precisely defined. Many unavoidable physical effects, such as
incident light, colliding air atoms, earlier history, etcetera, will narrow down position and momentum of a macroscopic particle to great accuracy. Heisenberg's uncertainty relationship says that they must have uncertainties big enough that $\Delta p_{x} \Delta x \geqslant \frac{1}{2} \hbar$, but $\hbar$ is far too small for that to be noticeable on a macroscopic scale. Normal light changes the momentum of a rocket ship in space only immeasurably little, but it is quite capable of locating it to excellent accuracy.

With little uncertainty in position and momentum, both can be approximated accurately by their expectation values. So the evolution of macroscopic systems can be obtained from the evolution equation (7.4) for expectation values given in the previous subsection. Just work out the commutator that appears in it.

Consider one-dimensional motion of a particle in a potential $V(x)$ (the threedimensional case goes exactly the same way). The Hamiltonian $H$ is:

$$
H=\frac{\widehat{p}_{x}^{2}}{2 m}+V(x)
$$

where $\widehat{p}_{x}$ is the linear momentum operator and $m$ the mass of the particle.
Now according to evolution equation (7.4), the expectation position $\langle x\rangle$ changes at a rate:

$$
\begin{equation*}
\frac{\mathrm{d}\langle x\rangle}{\mathrm{d} t}=\left\langle\frac{\mathrm{i}}{\hbar}[H, \widehat{x}]\right\rangle=\left\langle\frac{\mathrm{i}}{\hbar}\left[\frac{\widehat{p}_{x}^{2}}{2 m}+V(x), \widehat{x}\right]\right\rangle \tag{7.5}
\end{equation*}
$$

Recalling the properties of the commutator from chapter 4.5, $[V(x), \widehat{x}]=0$, since multiplication commutes. Further, according to the rules for manipulation of products and the canonical commutator

$$
\left[\widehat{p}_{x}^{2}, \widehat{x}\right]=\widehat{p}_{x}\left[\widehat{p}_{x}, \widehat{x}\right]+\left[\widehat{p}_{x}, \widehat{x}\right] \widehat{p}_{x}=-\widehat{p}_{x}\left[\widehat{x}, \widehat{p}_{x}\right]-\left[\widehat{x}, \widehat{p}_{x}\right] \widehat{p}_{x}=-2 \mathrm{i} \hbar \widehat{p}_{x}
$$

So the rate of change of expectation position becomes:

$$
\begin{equation*}
\frac{\mathrm{d}\langle x\rangle}{\mathrm{d} t}=\left\langle\frac{p_{x}}{m}\right\rangle \tag{7.6}
\end{equation*}
$$

This is exactly the Newtonian expression for the change in position with time, because Newtonian mechanics defines $p_{x} / m$ to be the velocity. However, it is in terms of expectation values.

To figure out how the expectation value of momentum varies, the commutator $\left[H, \widehat{p}_{x}\right]$ is needed. Now $\widehat{p}_{x}$ commutes, of course, with itself, but just like it does not commute with $\widehat{x}$, it does not commute with the potential energy $V(x)$. The generalized canonical commutator (4.62) says that $\left[V, \widehat{p}_{x}\right]$ equals $-\hbar \partial V / \mathrm{i} \partial x$. As a result, the rate of change of the expectation value of linear momentum becomes:

$$
\begin{equation*}
\frac{\mathrm{d}\left\langle p_{x}\right\rangle}{\mathrm{d} t}=\left\langle-\frac{\partial V}{\partial x}\right\rangle \tag{7.7}
\end{equation*}
$$

This is Newton's second law in terms of expectation values: Newtonian mechanics defines the negative derivative of the potential energy to be the force, so the right hand side is the expectation value of the force. The left hand side is equivalent to mass times acceleration.

The fact that the expectation values satisfy the Newtonian equations is known as "Ehrenfest's theorem."

For a quantum-scale system, however, it should be cautioned that even the expectation values do not truly satisfy Newtonian equations. Newtonian equations use the force at the expectation value of position, instead of the expectation value of the force. If the force varies nonlinearly over the range of possible positions, it makes a difference.

There is a alternative formulation of quantum mechanics due to Heisenberg that is like the Ehrenfest theorem on steroids, $\{\mathrm{A} .12\}$. Here the operators satisfy the Newtonian equations.

### 7.2.2 Energy-time uncertainty relation

The Heisenberg uncertainty relationship provides an intuitive way to understand the various weird features of quantum mechanics. The relationship says $\Delta p_{x} \Delta x \geqslant \frac{1}{2} \hbar$, chapter 4.5.3. Here $\Delta p_{x}$ is the uncertainty in a component of the momentum of a particle, and $\Delta x$ is the uncertainty in the corresponding component of position.

Now special relativity considers the energy $E$ divided by the speed of light $c$ to be much like a zeroth momentum coordinate, and $c t$ to be much like a zeroth position coordinate, chapter 1.2.4 and 1.3.1. Making such substitutions transforms Heisenberg's relationship into the so-called "energy-time uncertainty relationship:"

$$
\begin{equation*}
\Delta E \Delta t \geqslant \frac{1}{2} \hbar \tag{7.8}
\end{equation*}
$$

There is a difference, however. In Heisenberg's original relationship, the uncertainties in momentum and positions are mathematically well defined. In particular, they are the standard deviations in the measurable values of these quantities. The uncertainty in energy in the energy-time uncertainty relationship can be defined similarly. The problem is what to make of that "uncertainty in time" $\Delta t$. The Schrödinger equation treats time fundamentally different from space.

One way to address the problem is to look at the typical evolution time of the expectation values of quantities of interest. Using careful analytical arguments along those lines, Mandelshtam and Tamm succeeded in giving a meaningful definition of the uncertainty in time, $\{\mathrm{A} .18\}$. Unfortunately, its usefulness is limited.

Ignore it. Careful analytical arguments are for wimps! Take out your pen and cross out " $\Delta t$." Write in "any time difference you want." Cross out " $\Delta E$ " and write in "any energy difference you want." As long as you are at it anyway, also cross out " $\geqslant$ " and write in " $=$." This can be justified because both are mathematical symbols. And inequalities are so vague anyway. You have now obtained the popular version of the Heisenberg energy-time uncertainty equality:

$$
\begin{equation*}
\text { any energy difference you want } \times \text { any time difference you want }=\frac{1}{2} \hbar \tag{7.9}
\end{equation*}
$$

This is an extremely powerful equation that can explain anything in quantum physics involving any two quantities that have dimensions of energy and time. Be sure, however, to only publicize the cases in which it gives the right answer.

## Key Points

$0-$ The energy-time uncertainty relationship is a generalization of the Heisenberg uncertainty relationship. It relates uncertainty in energy to uncertainty in time. What uncertainty in time means is not obvious.
0 - If you are not a wimp, the answer to that problem is easy.

### 7.3 Conservation Laws and Symmetries

Physical laws like conservation of linear and angular momentum are important. For example, angular momentum was key to the solution of the hydrogen atom in chapter 4.3. More generally, conservation laws are often the central element in the explanation for how simple systems work. And conservation laws are normally the most trusted and valuable source of information about complex, poorly understood, systems like atomic nuclei.

It turns out that conservation laws are related to fundamental "symmetries" of physics. A symmetry means that you can do something that does not make a difference. For example, if you place a system of particles in empty space, far from anything that might affect it, it does not make a difference where exactly you put it. There are no preferred locations in empty space; all locations are equivalent. That symmetry leads to the law of conservation of linear momentum. A system of particles in otherwise empty space conserves its total amount of linear momentum. Similarly, if you place a system of particles in empty space, it
does not make a difference under what angle you put it. There are no preferred directions in empty space. That leads to conservation of angular momentum. See addendum $\{$ A. 19$\}$ for the details.

Why is the relationship between conservation laws and symmetries important? One reason is that it allows for other conservation laws to be formulated. For example, for conduction electrons in solids all locations in the solid are not equivalent. For one, some locations are closer to nuclei than others. Therefore linear momentum of the electrons is not conserved. (The total linear momentum of the complete solid is conserved in the absence of external forces. In other words, if the solid is in otherwise empty space, it conserves its total linear momentum. But that does not really help for describing the motion of the conduction electrons.) However, if the solid is crystalline, its atomic structure is periodic. Periodicity is a symmetry too. If you shift a system of conduction electrons in the interior of the crystal over a whole number of periods, it makes no difference. That leads to a conserved quantity called "crystal momentum," \{A.19\}. It is important for optical applications of semiconductors.

Even in empty space there are additional symmetries that lead to important conservation laws. The most important example of all is that it does not make a difference at what time you start an experiment with a system of particles in empty space. The results will be the same. That symmetry with respect to time shift gives rise to the law of conservation of energy, maybe the most important conservation law in physics.

In a sense, time-shift symmetry is already "built-in" into the Schrödinger equation. The equation does not depend on what time you take to be zero. Any solution of the equation can be shifted in time, assuming a Hamiltonian that does not depend explicitly on time. So it is not really surprising that energy conservation came rolling out of the Schrödinger equation so easily in section 7.1.3. The time shift symmetry is also evident in the fact that states of definite energy are stationary states, section 7.1.4. They change only trivially in time shifts. Despite all that, the symmetry of nature with respect to time shifts is a bit less self-evident than that with respect to spatial shifts, $\{\mathrm{A} .19\}$.

As a second example of an additional symmetry in empty space, physics works, normally, the same when seen in the mirror. That leads to a very useful conserved quantity called "parity." Parity is somewhat different from momentum. While a component of linear or angular momentum can have any value, parity can only be 1 , called "even," or -1 , called "odd." Also, while the contributions of the parts of a system to the total momentum components add together, their contributions to parity multiply together, \{A.19\}. That is why the $\pm 1$ parities of the parts of a system can combine together into a corresponding system parity that is still either 1 or -1 .
(Of course, there can be uncertainty in parity just like there can be uncertainty in other quantities. But the measurable values are either 1 or -1 .)

Despite having only two possible values, parity is still very important. In the
emission and absorption of electromagnetic radiation by atoms and molecules, parity conservation provides a very strong restriction on which electronic transitions are possible. And in nuclear physics, it greatly restricts what nuclear decays and nuclear reactions are possible.

Another reason why the relation between conservation laws and symmetries is important is for the information that it produces about physical properties. For example, consider a nucleus that has zero net angular momentum. Because of the relationship between angular momentum and angular symmetry, such a nucleus looks the same from all directions. It is spherically symmetric. Therefore such a nucleus does not respond in magnetic resonance imaging. That can be said without knowing all the complicated details of the motion of the protons and neutrons inside the nucleus. So-called spin $1 / 2$ nuclei have the smallest possible nonzero net angular momentum allowed by quantum mechanics, with components that can be $\pm \frac{1}{2} \hbar$ in a given direction. These nuclei do respond in magnetic resonance imaging. But because they depend in a relatively simple way on the direction from which they are viewed, their response is relatively simple.

Similar observations apply for complete atoms. The hydrogen atom is spherically symmetric in its ground state, figure 4.9. Although that result was derived ignoring the motion and spin of the proton and the spin of the electron, the hydrogen atom remains spherically symmetric even if these effects are included. Similarly, the normal helium atom, with two electrons, two protons, and two neutrons, is spherically symmetric in its ground state. That is very useful information if you want, say, an ideal gas that is easy to analyze. For heavier noble gases, the spherical symmetry is related to the "Ramsauer effect" that makes the atoms almost completely transparent to electrons of a certain wave length.

As you may guess from the fact that energy eigenstates are stationary, conserved quantities normally have definite values in energy eigenstates, $\{\mathrm{A} .19 .3\}$. (An exception may occur when the energy does not depend on the value of the conserved quantity.) For example, nuclei, lone atoms, and lone molecules normally have definite net angular momentum and parity in their ground state. Excited states too will have definite angular momentum and parity, although the values may be different from the ground state.

It is also possible to derive physical properties of particles from their symmetry properties. As an example, addendum \{A.20\} derives the spin and parity of an important class of particles, including photons, that way.

Finally, the relation between conservation laws and symmetries gives more confidence in the conservation laws. For example, as mentioned nuclei are still poorly understood. It might therefore seem reasonable enough to conjecture that maybe the nuclear forces do not conserve angular momentum. And indeed, the force between the proton and neutron in a deuteron nucleus does not conserve orbital angular momentum. But it is quite another matter to suppose that the forces do not conserve the net angular momentum of the nucleus, in-
cluding the spins of the proton and neutron. That would imply that empty space has some inherent preferred direction. That is much harder to swallow. Such a preferred direction has never been observed, and there is no known mechanism or cause that would give rise to it. So physicists are in fact quite confident that nuclei do conserve angular momentum just like everything else does. The deuteron conserves its net angular momentum if you include the proton and neutron spins in the total.

It goes both ways. If there is unambiguous evidence that a supposedly conserved quantity is not truly conserved, then nature does not have the corresponding symmetry. That says something important about nature. This happened for the mirror symmetry of nature. If you look at a person in a mirror, the heart is on the other side of the chest. On a smaller scale, the molecules that make up the person change in their mirror images. But physically the person in the mirror would function just fine. (As long as you do not try to mix mirror images of biological molecules with nonmirror images, that is.) In principle, evolution could have created the mirror image of the biological systems that exist today. Maybe it did on a different planet. The electromagnetic forces that govern the mechanics of biological systems obey the exact same laws when nature is seen in the mirror. So does the force of gravity that keeps the systems on earth. And so does the so-called strong force that keeps the atomic nuclei together.

Therefore it was long believed that nature behaved in exactly the same way when seen in the mirror. That then leads to the conserved quantity called parity. But eventually, in 1956, Lee and Yang realized that the decay of a certain nuclear particle by means of the so-called weak force does not conserve parity. As a result, it had to be accepted also that nature does not always behave in exactly the same way when seen in the mirror. That was confirmed experimentally by Wu and her coworkers in 1957. (In fact, while other experimentalists like Lederman laughed at the ideas of Lee and Yang, Wu spend eight months of hard work on the risky proposition of confirming them. If she had been a man, she would have been given the Nobel Prize along with Lee and Yang. However, Nobel Prize committees have usually recognized that giving Nobel Prizes to women might interfere with their domestic duties.)

Fortunately, the weak force is not important for most applications, not even for many involving nuclei. Therefore conservation of parity usually remains valid to an excellent approximation.

Mirroring corresponds mathematically to an inversion of a spatial coordinate. But it is mathematically much cleaner to invert the direction of all three coordinates, replacing every position vector $\vec{r}$ by $-\vec{r}$. That is called "spatial inversion." Spatial inversion is cleaner since no choice of mirror is required. That is why many physicists reserve the term "parity transformation" exclusively to spatial inversion. (Mathematicians do not, since inversion does not work in strictly two-dimensional systems, \{A.19\}.) A normal mirroring is equivalent to spatial inversion followed by a rotation of $180^{\circ}$ around the axis normal to the

## chosen mirror.

Inversion of the time coordinate is called "time reversal." That can be thought of as making a movie of a physical process and playing the movie back in reverse. Now if you make a movie of a macroscopic process and play it backwards, the physics will definitely not be right. However, it used to be generally believed that if you made a movie of the microscopic physics and played it backwards, it would look fine. The difference is really not well understood. But presumably it is related to that evil demon of quantum mechanics, the collapse of the wave function, and its equally evil macroscopic alter ego, called the second law of thermodynamics. In any case, as you might guess it is somewhat academic. If physics is not completely symmetric under reversal of a spatial coordinate, why would it be under reversal of time? Special relativity has shown the close relationship between spatial and time coordinates. And indeed, it was found that nature is not completely symmetric under time reversal either, even on a microscopic scale.

There is a third symmetry involved in this story of inversion. It involves replacing every particle in a system by the corresponding antiparticle. For every elementary particle, there is a corresponding antiparticle that is its exact opposite. For example, the electron, with electric charge $-e$ and lepton number 1 , has an antiparticle, the positron, with charge $e$ and lepton number -1 . (Lepton number is a conserved quantity much like charge is.) Bring an electron and a positron together, and they can totally annihilate each other, producing two photons. The net charge was zero, and is still zero. Photons have no charge. The net lepton number was zero, and is still zero. Photons are not leptons and have zero lepton number.

All particles have antiparticles. Protons have antiprotons, neutrons antineutrons, etcetera. Replacing every particle in a system by its antiparticle produces almost the same physics. You can create an antihydrogen atom out of an antiproton and a positron that seems to behave just like a normal hydrogen atom does.

Replacing every particle by its antiparticle is not called particle inversion, as you might think, but "charge conjugation." That is because physicists recognized that "charge inversion" would be all wrong; a lot more changes than just the charge. And the particle involved might not even have a charge, like the neutron, with no net charge but a baryon number that inverts, or the neutrino, with no charge but a lepton number that inverts. So physicists figured that if "charge inversion" is wrong anyway, you may as well replace "inversion" by "conjugation." That is not the same as inversion, but it was wrong anyway, and conjugation sounds much more sophisticated and it alliterates.

The bottom line is that physics is almost, but not fully, symmetric under spatial inversion, time inversion, and particle inversion. However, physicists currently believe that if you apply all three of these operations together, then the resulting physics is indeed truly the same. There is a theorem called the CPT
theorem, (charge, parity, time), that says so under relatively mild assumptions. One way to look at it is to say that systems of antiparticles are the mirror images of systems of normal particles that move backwards in time.

At the time of writing, there is a lot of interest in the possibility that nature may in fact not be exactly the same when the CPT transformations are applied. It is hoped that this may explain why nature ended up consisting almost exclusively of particles, rather than antiparticles.

Symmetry transformations like the ones discussed above form mathematical "groups." There are infinitely many different angles that you can rotate a system over or distances that you can translate it over. What is mathematically particularly interesting is how group members combine together into different group members. For example, a rotation followed by another rotation is equivalent to a single rotation over a combined angle. You can even eliminate a rotation by following it by one in the opposite direction. All that is nectar to mathematicians.

The inversion transformations are somewhat different in that they form finite groups. You can either invert or not invert. These finite groups provide much less detailed constraints on the physics. Parity can only be 1 or -1 . On the other hand, a component of linear or angular momentum must maintain one specific value out of infinitely many possibilities. But even these constraints remain restricted to the total system. It is the complete system that must maintain the same linear and angular momentum, not the individual parts of it. That reflects that the same rotation angle or translation distance applies for all parts of the system.

Advanced relativistic theories of quantum mechanics postulate symmetries that apply on a local (point by point) basis. A simple example relevant to quantum electrodynamics can be found in addendum \{A.19\}. Such symmetries narrow down what the physics can do much more because they involve separate parameters at each individual point. Combined with the massive antisymmetrization requirements for fermions, they allow the physics to be deduced in terms of a few remaining numerical parameters. The so-called "standard model" of relativistic quantum mechanics postulates a combination of three symmetries of the form

$$
\mathrm{U}(1) \times \mathrm{SU}(2) \times \mathrm{SU}(3)
$$

In terms of linear algebra, these are complex matrices that describe rotations of complex vectors in 1,2 , respectively 3 dimensions. The " S " on the latter two matrices indicates that they are special in the sense that their determinant is 1. The first matrix is characterized by 1 parameter, the angle that the single complex numbers are rotated over. It gives rise to the photon that is the single carrier of the electromagnetic force. The second matrix has 3 parameters, corresponding to the 3 so-called "vector bosons" that are the carriers of the weak nuclear force. The third matrix has 8 parameters, corresponding to the 8
"gluons" that are the carriers of the strong nuclear force.
There is an entire branch of mathematics, "group theory," devoted to how group properties relate to the solutions of equations. It is essential to advanced quantum mechanics, but far beyond the scope of this book.

$0-$ There are kinks in the armor of the symmetries under spatial inversion, time reversal, and "charge conjugation." However, it is believed that nature is symmetric under the combination of all three.

### 7.4 Conservation Laws in Emission

Conservation laws are very useful for understanding emission or absorption of radiation of various kinds, as well as nuclear reactions, collision processes, etcetera. As an example, this section will examine what conservation laws say about the spontaneous emission of a photon of light by an excited atom. While this example is relatively simple, the concepts discussed here apply in essentially the same way to more complex systems.

Figure 7.3: Crude concept sketch of the emission of an electromagnetic photon by an atom. The initial state is left and the final state is right.

Figure 7.3 gives a sketch of the emission process. The atom is initially in an high energy, or excited, state that will be called $\psi_{\mathrm{H}}$. After some time, the atom releases a photon and returns a lower energy state that will be called $\psi_{\mathrm{L}}$. As a simple example, take an hydrogen atom. Then the excited atomic state
could be the " $2 \mathrm{p}_{z}$ " $\psi_{210}$ state, chapter 4.3. The final atomic state will then be the " 1 s " ground state $\psi_{100}$.

The emitted photon has an energy given by the Planck-Einstein relation

$$
E_{\gamma}=\hbar \omega
$$

where $\omega$ is the frequency of the electromagnetic radiation corresponding to the photon. Note that $\gamma$ (gamma, think gamma decay) is the standard symbol used to indicate a photon.

## Key Points

$0-$ Atoms can transition to a lower electronic energy level while emitting a photon of electromagnetic radiation.
$0-$ The Planck-Einstein relation gives the energy of a photon in terms of its frequency.

### 7.4.1 Conservation of energy

The first conservation law that is very useful for understanding the emission process is conservation of energy. The final atom and photon should have the exact same energy as the initial excited atom. So the difference between the atomic energies $E_{\mathrm{H}}$ and $E_{\mathrm{L}}$ must be the energy $\hbar \omega$ of the photon. Therefore, the emitted photon must have a very precise frequency $\omega$. That means that it has a very precise color. For example, for the $2 \mathrm{p}_{z}$ to 1 s transition of a hydrogen atom, the emitted photon is a very specific ultraviolet color.

It should be pointed out that the frequency of the emitted photon does have a very slight variation. The reason can be understood from the fact that the excited state decays at all. Energy eigenstates should be stationary, section 7.1.4.

> The very fact that a state decays shows that it is not truly an energy eigenstate.

The big problem with the analysis of the hydrogen atom in chapter 4.3 was that it ignored any ambient radiation that the electron might be exposed to. It turns out that there is always some perturbing ambient radiation, even if the atom is inside a black box at absolute zero temperature. This is related to the fact that the electromagnetic field has quantum uncertainty. Advanced quantum analysis is needed to take that into account, $\{\mathrm{A} .23\}$. Fortunately, the uncertainty in energy is extremely small for the typical applications considered here.

As a measure of the uncertainty in energy of a state, physicists often use the so-called "natural width"

$$
\begin{equation*}
\Gamma=\frac{\hbar}{\tau} \tag{7.10}
\end{equation*}
$$

Here $\tau$ is the mean lifetime of the state, the average time it takes for the photon to be emitted.

The claim that this width gives the uncertainty in energy of the state is usually justified using the all-powerful energy-time uncertainty equality (7.9). A different argument will be given at the end of section 7.6.1. In any case, the bottom line is that $\Gamma$ does indeed give the observed uncertainty in energy for isolated atoms, [52, p. 139], and for nuclei, [31, p. 40, 167].

As an example, the hydrogen atom $2 \mathrm{p}_{z}$ state has a lifetime of 1.6 nanoseconds. (The lifetime can be computed using the data in addendum \{A.25.8\}.) That makes its width about $410^{-7} \mathrm{eV}$. Compared to the 10 eV energy of the emitted photon, that is obviously extremely small. Energy conservation in atomic transitions may not be truly exact, but it is definitely an excellent approximation.

Still, since a small range of frequencies can be emitted, the observed line in the emission spectrum is not going to be a mathematically exact line, but will have a small width. Such an effect is known as "spectral line broadening."

The natural width of a state is usually only a small part of the actual line broadening. If the atom is exposed to an incoherent ambient electromagnetic field, it will increase the uncertainty in energy. (The evolution of atoms in an incoherent electromagnetic field will be analyzed in \{D.41\}.) Frequent interactions with surrounding atoms or other perturbations will also increase the uncertainty in energy, in part for reasons discussed at the end of section 7.6.1. And anything else that changes the atomic energy levels will of course also change the emitted frequencies.

An important further effect that causes spectral line deviations is atom motion, either thermal motion or global gas motion. It produces a Doppler shift in the radiation. This is not necessarily bad news in astronomy; line broadening can provide an hint about the temperature of the gas you are looking at, while line displacement can provide a hint of its overall motion away from you.

It may also be mentioned that the natural width is not always small. If you start looking at excited nuclear particles, the uncertainty in energy can be enormous. Such particles may have an uncertainty in energy that is of the order of $10 \%$ of their relativistic rest mass energy. And as you might therefore guess, they are hardly stationary states. Typically, they survive for only about $10^{-23}$ seconds after they are created. Even moving at a speed comparable to the speed of light, such particles will travel only a distance comparable to the diameter of a proton before disintegrating.

Generally speaking, the shorter the lifetime of a state, the larger its uncertainty in energy, and vice-versa.
(To be fair, physicists do not actually manage to see these particles during their infinitesimal lifetime. Instead they infer the lifetime from the variation in energy of the resulting state.)

## Key Points

$0-$ In a transition, the difference in atomic energy levels gives the energy, and so the frequency, of the emitted photon.
$0-$ Unstable states have some uncertainty in energy, but it is usually very small. For extremely unstable particles, the uncertainty can be a lot.

0 - The width of a state is $\Gamma=\hbar / \tau$ with $\tau$ the mean lifetime. It is a measure for the minimum observed variation in energy of the final state.

### 7.4.2 Combining angular momenta and parities

Conservation of angular momentum and parity is easily stated:
The angular momentum and parity of the initial atomic state must be the same as the combined angular momentum and parity of the final atomic state and photon.

The question is however, how do you combine angular momenta and parity values? Even combining angular momenta is not trivial, because angular momenta are quantized.

Figure 7.4: Addition of angular momenta in classical physics.
To get an idea of how angular momenta combine, first consider what would happen in classical physics. Conservation of angular momentum would say that

$$
\vec{J}_{\mathrm{H}}=\vec{J}_{\mathrm{L}}+\vec{J}_{\gamma}
$$

is usually taken to be the $z$-component. Also, the component cannot have any arbitrary value; it must have a value of the form $m \hbar$. Here the "magnetic quantum number" $m$ can only have values that range from $-j$ to $j$ in increments of 1 .

If you can add and subtract components of angular momentum, then you can also add and subtract magnetic quantum numbers. After all, they are only different from components by a factor $\hbar$. Therefore, the conservation of angular momentum in the $z$-direction becomes

$$
m_{\mathrm{L}}=m_{\mathrm{H}}-m_{\gamma}
$$

Putting in the possible values of the magnetic quantum number of the photon gives for the final atomic magnetic quantum number:

$$
\begin{equation*}
m_{\mathrm{L}}=m_{\mathrm{H}}-j_{\gamma}, m_{\mathrm{H}}-j_{\gamma}+1, \ldots, m_{\mathrm{H}}+j_{\gamma}-1, \text { or } m_{\mathrm{H}}+j_{\gamma} \tag{7.12}
\end{equation*}
$$

To be sure, $m_{\mathrm{L}}$ is also constrained by the fact that its magnitude cannot exceed $j_{\mathrm{L}}$.

Next consider conservation of parity. Recall from section 7.3 that parity is the factor by which the wave function changes when the positive direction of all three coordinate axes is inverted. That replaces every position vector $\vec{r}$ by $-\vec{r}$. Parity can have only two values, 1 or -1 . Parity is commonly indicated by $\pi$, which is the Greek letter for "p." Parity starts with a p and may well be Greek. Also, the symbol avoids confusion, assuming that $\pi$ is not yet used for anything else in science.

Conservation of parity means that the initial and final parities must be equal. The parity of the initial high energy atom must be the same as the combined parity of the final low energy atom and photon:

$$
\pi_{\mathrm{H}}=\pi_{\mathrm{L}} \pi_{\gamma}
$$

Note that parity is a multiplicative quantity. You get the combined parity of the final state by multiplying the parities of atom and photon; you do not add them.
(Just think of the simplest possible wave function of two particles, $\Psi=$ $\psi_{1}\left(\vec{r}_{1}\right) \psi_{2}\left(\vec{r}_{2}\right)$. If $\psi_{1}$ changes by a factor $\pi_{1}$ when $\vec{r}_{1} \rightarrow-\vec{r}_{1}$ and $\psi_{2}$ changes by a factor $\pi_{2}$ when $\vec{r}_{2} \rightarrow-\vec{r}_{2}$, then the total wave function $\Psi$ changes by a factor $\pi_{1} \pi_{2}$. Actually, it is angular momentum, not parity, that is the weird case. The reason that angular momenta must be added together instead of multiplied together is because angular momentum is defined by taking a logarithm of the "natural" conserved quantity. For details, see addendum \{A.19\}.)

The parity of the atom is related to the orbital angular momentum of the electron, and in particular to its azimuthal quantum number $l$. If you check out the example spherical harmonics in table 4.3, you see that those with even
values of $l$ only contain terms that are square in the position coordinates. So these states do not change when $\vec{r}$ is replaced by $-\vec{r}$. In other words, they change by a trivial factor 1 . That makes the parity 1 , or even, or positive. The spherical harmonics for odd $l$ change sign when $\vec{r}$ is replaced by $-\vec{r}$. In other words, they get multiplied by a factor -1 . That makes the parity -1 , or odd, or negative. These observations apply for all values of $l,\{\mathrm{D} .14\}$.

The parity can therefore be written for any value of $l$ as

$$
\begin{equation*}
\pi=(-1)^{l} \tag{7.13}
\end{equation*}
$$

This is just the parity due to orbital angular momentum. If the particle has negative intrinsic parity, you need to multiply by another factor -1 . However, an electron has positive parity, as does a proton. (Positrons and antiprotons have negative parity. That is partly a matter of convention. Conservation of parity would still work if it was the other way around.)

It follows that parity conservation in the emission process can be written as

$$
\begin{equation*}
(-1)^{l_{\mathrm{H}}}=(-1)^{l_{\mathrm{L}}} \pi_{\gamma} \tag{7.14}
\end{equation*}
$$

Therefore, if the parity of the photon is even, (i.e. 1 ), then $l_{\mathrm{H}}$ and $l_{\mathrm{L}}$ are both even or both odd. In other words, the atomic parity stays unchanged. If the parity of the photon is odd, (i.e. -1 ), then one of $l_{\mathrm{H}}$ and $l_{\mathrm{L}}$ is even and the other odd. The atomic parity flips over.

To apply the obtained conservation laws, the next step must be to figure out the angular momentum and parity of the photon.

### 7.4.3 Transition types and their photons

The conservation laws of angular momentum and parity restrict the emission of a photon by an excited atom. But for these laws to be useful, there must be information about the spin and parity of the photon.

This section will just state various needed photon properties. Derivations are given in $\{\mathrm{A} .21 .7\}$ for the brave. In any case, the main conclusions reached about the photons associated with atomic transitions will be verified by more detailed analysis of transitions in later sections.

There are two types of transitions, electric ones and magnetic ones. In electric transitions, the electromagnetic field produced by the photon at the atom is primarily electric, $\{\mathrm{A} .21 .7\}$. In magnetic transitions, it is primarily magnetic. Electric transitions are easiest to understand physically, and will be discussed first.

A photon is a particle with spin $s_{\gamma}=1$ and intrinsic parity -1 . Also, assuming that the size of the atom is negligible, in the simplest model the photon will have zero orbital angular momentum around the center of the atom. That is most easily understood using classical physics: a particle that travels along a line that comes out of a point has zero angular momentum around that point. For equivalent quantum arguments, see $\{\mathrm{N} .10\}$ or $\{\mathrm{A} .21 .7\}$. It means in terms of quantum mechanics that the photon has a quantum number $l_{\gamma}$ of orbital angular momentum that is zero. That makes the total angular momentum quantum number $j_{\gamma}$ of the photon equal to the spin $s_{\gamma}, 1$.

The normal, efficient kind of atomic transition does in fact produce a photon like that. Since the term "normal" is too normal, such a transition is called "allowed." For reasons that will eventually be excused for in section 7.7.2, allowed transitions are also more technically called "electric dipole" transitions. According to the above, then, the photon net angular momentum and parity are:

$$
\begin{array}{|lll}
\hline \text { for electric dipole transitions: } & j_{\gamma}=1 & \pi_{\gamma}=-1  \tag{7.15}\\
\hline
\end{array}
$$

Transitions that cannot happen according to the electric dipole mechanism are called "forbidden." That does not mean that these transitions cannot occur at all; just forbid your kids something. But they are much more awkward, and therefore normally very much slower, than allowed transitions.

One important case of a forbidden transition is one in which the atomic angular momentum changes by 2 or more units. Since the photon has only 1 unit of spin, in such a transition the photon must have nonzero orbital angular momentum. Transitions in which the photon has more than 1 unit of net angular momentum are called "multipole transitions." For example, in a "quadrupole" transition, the net angular momentum of the photon $j_{\gamma}=2$. In an "octupole" transition, $j_{\gamma}=3$ etcetera. In all these transitions, the photon has at least $j_{\gamma}-1$ units of orbital angular momentum.

To roughly understand how orbital angular momentum arises, reconsider the sketch of the emission process in figure 7.3. As shown, the photon has no orbital angular momentum around the center of the atom, classically speaking. But the photon does not have to come from exactly the center of the atom. If the atom has a typical radius $R$, then the photon could come from a point at a distance comparable to $R$ away from the center. That will give it an orbital angular momentum of order $R p$ around the center, where $p$ is the linear momentum of the photon. And according to relativity, (1.2), the photon's momentum is related to its energy, which is in turn related to its frequency by the Planck-

Einstein relation. That makes the classical orbital angular momentum of the photon of order $R \hbar \omega / c$. But $c / \omega$ is the wave length $\lambda$ of the photon, within a factor $2 \pi$. That factor is not important for a rough estimate. So the typical classical orbital angular momentum of the photon is

$$
L \sim \frac{R}{\lambda} \hbar
$$

The fraction is typically small. For example, the wave length $\lambda$ of visible light is about $5000 \AA$ and the size $R$ of an atom is about an $\AA$. So the orbital angular momentum above is a very small fraction of $\hbar$.

But according to quantum mechanics, the orbital angular momentum cannot be a small fraction of $\hbar$. If the quantum number $l_{\gamma}$ is zero, then so is the orbital angular momentum. And if $l_{\gamma}$ is 1 , then the orbital angular momentum is $\sqrt{2} \hbar$. There is nothing in between. The above classical orbital angular momentum should be understood to mean that there is quantum uncertainty in orbital angular momentum. That the photon has almost certainly zero orbital angular momentum, but that there remains a small probability of $l_{\gamma}=1$. In particular, if you take the ratio $R / \lambda$ to be the coefficient of the $l_{\gamma}=1$ state, then the probability of the photon coming out with $l_{\gamma}=1$ is the square of that, $(R / \lambda)^{2}$. That will be a very small probability. But still, there is a slight probability that the net photon angular momentum $j_{\gamma}$ will be increased from 1 to 2 by a unit's worth of orbital angular momentum. That will then produce a quadrupole transition. And of course, two units of orbital angular momentum can increase the net photon angular momentum to $j_{\gamma}=3$, the octupole level. But that reduces the probability by another factor $(R \lambda)^{2}$, so don't hold you breath for these higher order multipole transitions to occur.
(If the above random mixture of unjustified classical and quantum arguments is too unconvincing, there is a quantum argument in $\{\mathrm{N} .10\}$ that may be more believable. If you are brave, see \{A.21.7\} for a precise analysis of the relevant photon momenta and their probabilities in an interaction with an atom or nucleus. But the bottom line is that the above ideas do describe what happens in transition processes. That follows from a complete analysis of the transition process, as discussed in later sections and notes like $\{$ A. 25$\}$ and $\{\mathrm{D} .39\}$.)

So far, only electric multipole transitions have been discussed, in which the electromagnetic field at the atom is primarily electric. In magnetic multipole transitions however, it is primarily magnetic. In a "magnetic dipole" transition, the photon comes out with one unit of net angular momentum just like in an electric dipole one. However, the parity of the photon is now even:

$$
\begin{array}{|lll|}
\hline \text { for magnetic dipole transitions: } & j_{\gamma}=1 & \pi_{\gamma}=1  \tag{7.16}\\
\hline
\end{array}
$$

You might wonder how the positive parity is possible if the photon has negative intrinsic parity and no orbital angular momentum. The reason is that
in a magnetic dipole transition, the photon does have a unit of orbital angular momentum. Recall from the previous subsection that it is quite possible for one unit of spin and one unit of orbital angular momentum to combine into still only one unit of net angular momentum.

In view of the crude discussion of orbital angular momentum given above, this may still seem weird. How come that an atom of vanishing size does suddenly manage to readily produce a unit of orbital angular momentum in a magnetic dipole transition? The basic reason is that the magnetic field acts in some way as if it has one unit of orbital angular momentum less than the photon, \{A.21.7\}. It is unpexpectedly strong at the atom. This allows a magnetic atom state to "get a solid grip" on a photon state of unit orbital angular momentum. It is somewhat like hitting a rapidly spinning ball with a bat in baseball; the resulting motion of the ball can be weird. And in a sense the orbital angular momentum comes at the expense of the spin; the net angular momentum $j_{\gamma}$ of a photon in a magnetic dipole transition will not be 2 despite the orbital angular momentum.

Certainly this sort of complications would not arise if the photon had no spin. Without discussion, the photon is one of the most basic particles in physics. But it is surprisingly complex for such an elementary particle. This also seems the right place to confess to the fact that electric multipole photons have uncertainty in orbital angular momentum. For example, an electric dipole photon has a probability for $l_{\gamma}=2$ in addition to $l_{\gamma}=0$. However, this additional orbital angular momentum comes courtesy of the internal mechanics, and especially the spin, of the photon. It does not give the photon a probability for net angular momentum $j_{\gamma}=2$. So it does not really change the given discussion.

All else being the same, the probability of a magnetic dipole transition is normally much smaller than an electric dipole one. The principal reason is that the magnetic field is really a relativistic effect. That can be understood, for example, from how the magnetic field popped up in the description of the relativistic motion of charged particles, chapter 1.3.2. So you would expect the effect of the magnetic field to be minor unless the atomic electron or nucleon involved in the transition has a kinetic energy comparable to its rest mass energy. Indeed, it turns out that the probability of a magnetic transition is smaller than an electric one by a factor of order $T / m c^{2}$, where $T$ is the kinetic energy of the particle and $m c^{2}$ its rest mass energy, $\{\mathrm{A} .25 .4\}$. For the electron in a hydrogen atom, and for the outer electrons in atoms in general, this ratio is very much less than one. The same holds for the nucleons in nuclei. It follows that magnetic dipole transitions will normally take place much slower than electric dipole ones.

In magnetic multipole transitions, the photon receives additional angular momentum. Like for electric multipole transitions, there is one additional unit of angular momentum for each additional multipole order. And there is a corresponding slow down of the transitions.

Table 7.1 gives a summary of the photon properties in multipole transitions.

|  | $j_{\gamma}$ | $\pi_{\gamma}$ | slow down |
| :---: | :---: | :--- | :---: |
| $\mathrm{E} \ell:$ | $\ell$ | $(-1)^{\ell}$ | $(R / \lambda)^{2 \ell-2}$ |
| $\mathrm{M} \ell:$ | $\ell$ | $(-1)^{\ell-1}$ | $\left(T / m c^{2}\right)(R / \lambda)^{2 \ell-2}$ |

photons do not have zero net angular momentum; $\ell=j_{\gamma} \geqslant 1$

Table 7.1: Properties of photons emitted in electric and magnetic multipole transitions.

It is conventional to write electric multipole transitions as $\mathrm{E} \ell$ and magnetic ones as $\mathrm{M} \ell$ where $\ell$, (or L , but never $j$ ), is the net photon angular momentum $j_{\gamma}$. So an electric dipole transition is E1 and a magnetic dipole one M1. In agreement with the previous section, each unit increase in the orbital angular momentum produces an additional factor -1 in parity.

The column "slow down" gives an order of magnitude estimate by what factor a transition is slower than an electric dipole one, all else being equal. Note however that all else is definitely not equal, so these factors should not be used even for ballparks.

There are some official ballparks for atomic nuclei based on a more detailed analysis. These are called the Weisskopf and Moszkowski estimates, chapter 14.20 .4 and in particular addendum \{A.25.8\}. But even there you should not be surprised if the ballpark is off by orders of magnitude. These estimates do happen to work fine for the nonrelativistic hydrogen atom, with appropriate adjustments, \{A.25.8\}.

The slow down factors $T / m c^{2}$ and $(R / \lambda)^{2}$ are often quite comparable. That makes the order of slow down of magnetic dipole transitions similar to that of electric quadrupole transitions. To see the equivalence of the slow-down factors, rewrite them as

$$
\left(\frac{R}{\lambda}\right)^{2}=\frac{1}{\hbar^{2} c^{2}} R^{2}(\hbar \omega)^{2} \quad \Longleftrightarrow \quad \frac{T}{m c^{2}}=\frac{1}{\hbar^{2} c^{2}} R^{2} T \frac{\hbar^{2}}{m R^{2}}
$$

where the $2 \pi$ in the wave length was again put back. For an atom, the energy of the emitted photon $\hbar \omega$ is often comparable to the kinetic energy $T$ of the outer electrons, and the final ratio in the equations above is a rough estimate for that kinetic energy. It follows that the two slow down factors are comparable. Another way of looking at the similarity between magnetic dipole and electric quadrupole transitions will be given in $\{\mathrm{D} .39\}$.

Note from the table that electric quadrupole and magnetic dipole transitions have the same parity. That means that they may compete directly with each
other on the same transition, provided that the atomic angular momentum does not change more than one unit in that transition.

For nuclei, the photon energy tends to be significantly less than the nucleon kinetic energy. That is one reason that the Weisskopf estimates have the electric quadrupole transitions a lot slower than magnetic dipole ones for typical transitions. Also note that the kinetic energy estimate above does not include the effect of the exclusion principle. Exclusion raises the true kinetic energy if there are multiple identical particles in a given volume.

There is another issue that should be mentioned here. Magnetic transitions have a tendency to underperform for simple systems like the hydrogen atom. For these systems, the magnetic field has difficulty making effective use of spin in changing the atomic or nuclear structure. That is discussed in more detail in the next subsection.

One very important additional property must still be mentioned. The photon cannot have zero net angular momentum. Normally it is certainly possible for a particle with spin $s=1$ and orbital angular momentum quantum number $l$ $=1$ to be in a state that has zero net angular momentum, $j=0$. However, a photon is not a normal particle; it is a relativistic particle with zero rest mass that can only move at the speed of light. It turns out that for a photon, spin and orbital angular momentum are not independent, but intrinsically linked. This limitation prevents a state where the photon has zero net angular momentum, \{A.21.3\}.

There are some effects in classical physics that are related to this limitation. First of all, consider a photon with definite linear momentum. That corresponds to a light wave propagating in a particular direction. Now linear and angular momentum do not commute, so such a photon will not have definite angular momentum. However, the angular momentum component in the direction of motion is still well defined. The limitation on photons is in this case that the photon must either have angular momentum $\hbar$ or $-\hbar$ along the direction of motion. A normal particle of spin 1 could also have zero angular momentum in the direction of motion, but a photon cannot. The two states of definite angular momentum in the direction of motion are called "right- and left-circularly polarized" light, respectively.

Second, for the same type of photon, there are two equivalent states that have definite directions of the electric and magnetic fields. These states have uncertainty in angular momentum in the direction of motion. They are called "linearly polarized" light. These states illustrate that there cannot be an electric or magnetic field component in the direction of motion. The electric and magnetic fields are normal to the direction of motion, and to each other.

More general photons of definite linear momentum may have uncertainty in both of the mentioned properties. But still there is zero probability for zero angular momentum in the direction of motion, and zero probability for a field in the direction of motion.

Third, directly related to the previous case. Suppose you have a charge distribution that is spherically symmetric, but pulsating in the radial direction. You would expect that you would get a fluctuating radial electrical field outside this pulsating charge. But you do not, it does not radiate energy. Such radiation would have the electric field in the direction of motion, and that does not happen. Now consider the transition from the spherically symmetric " 2 s " state of a hydrogen atom to the spherical symmetric " 1 s " state. Because of the lack of spherically symmetric radiation, you might guess that this transition is in trouble. And it is; that is discussed in the next subsection.

In fact, the last example is directly related to the missing state of zero angular momentum of the photon. Recall from section 7.3 that angular momentum is related to angular symmetry. In particular, a state of zero angular momentum (if exact to quantum accuracy) looks the same when seen from all directions. The fact that there is no spherically symmetric radiation is then just another way of saying that the photon cannot have zero angular momentum.

## Key Points

$0-$ Normal atomic transitions are called allowed or electric dipole ones. All others are called forbidden but can occur just fine.
0- In electric dipole transitions the emitted photon has angular momentum quantum number $j_{\gamma}=1$ and negative parity $\pi_{\gamma}=-1$.
$0-$ In the slower magnetic dipole transitions the photon parity is positive, $\pi_{\gamma}=1$.
$0-$ Each higher multipole order adds a unit to the photon angular momentum quantum number $j_{\gamma}$ and flips over the parity $\pi_{\gamma}$.
0- The higher the multipole order, the slower the transition will be.

### 7.4.4 Selection rules

As discussed, a given excited atomic state may be able to transition to a lower energy state by emitting a photon. But many transitions from a higher energy state to a lower one simply do not happen. There are so-called "selection rules" that predict whether or not a given transition process is possible. This subsection gives a brief introduction to these rules.

The primary considered system will be the hydrogen atom. However, some generally valid rules are given at the end. It will usually be assumed that the effect of the spin of the electron on its motion can be ignored. That is the same approximation as used in chapter 4.3, and it is quite accurate. Basically, the model system studied is a spinless charged electron going around a stationary proton. Spin will be tacked on after the fact.

The selection rules result from the conservation laws and photon properties as discussed in the previous two subsections. Since the conservation laws are applied to a spinless electron, the angular momentum of the electron is simply its orbital angular momentum. That means that for the atomic states, the angular momentum quantum number $j$ becomes the orbital angular momentum quantum number $l$. For the emitted photon, the true net angular momentum quantum number $\ell$ must be used.

Now suppose that the initial high-energy atomic state has an orbital angular momentum quantum number $l_{\mathrm{H}}$ and that it emits a photon with angular momentum quantum number $\ell$. The question is then what can be said about the orbital angular momentum $l_{\mathrm{L}}$ of the atomic state of lower energy after the transition. The answer is given by subsection 7.4.2 (7.11):

$$
\begin{equation*}
l_{\mathrm{L}}=\left|l_{\mathrm{H}}-\ell\right|,\left|l_{\mathrm{H}}-\ell\right|+1, \ldots, l_{\mathrm{H}}+\ell-1, \text { or } l_{\mathrm{H}}+\ell \tag{7.17}
\end{equation*}
$$

That leads immediately to a stunning conclusion for the decay of the hydrogen $\psi_{200}$ " 2 s " state. This state has angular momentum $l_{\mathrm{H}}=0$, as any s state. So the requirement above simplifies to $l_{\mathrm{L}}=\ell$. Now recall from the previous subsection that a photon must have $\ell$ at least equal to 1 . So $l_{\mathrm{L}}$ must be at least 1. But $l_{\mathrm{L}}$ cannot be at least 1 . The only lower energy state that exists is the $\psi_{100}$ " 1 s " ground state. It has $l_{\mathrm{L}}=0$. So the 2 s state cannot decay!

Never say never, of course. It turns out that if left alone, the 2 s state will eventually decay through the emission of two photons, rather than a single one. This takes forever on quantum scales; the 2s state survives for about a tenth of a second rather than maybe a nanosecond for a normal transition. Also, to actually observe the two-photon emission process, the atom must be in high vacuum. Otherwise the 2 s state would be messed up by collisions with other particles long before it could decay. Now you see why the introduction to this section gave a 2 p state, and not the seemingly more simple 2 s one, as a simple example of an atomic state that decays by emitting a photon.

Based on the previous subsection, you might wonder why a second photon can succeed where a unit of photon orbital angular momentum cannot. After all, photons have only two independent spin states, while a unit of orbital angular momentum has the full set of three. The explanation is that in reality you cannot add a suitable unit of orbital angular momentum to a photon; the orbital and spin angular momentum of a photon are intrinsically linked. But photons do have complete sets of states with angular momentum $\ell=1,\{\mathrm{~A} .21 .7\}$. For two photons, these can combine into zero net angular momentum.

It is customary to "explain" photons in terms of states of definite linear momentum. That is in fact what was done in the final paragraphs of the previous subsection. But it is simplistic. It is definitely impossible to understand how two photons, each missing the state of zero angular momentum along their direction of motion, could combine into a state of zero net angular momentum. In fact, they simply cannot. Linear and orbital angular momentum do not
commute. But photons do not have to be in quantum states of definite linear momentum. They can be, and often are, in quantum superpositions of such states. The states of definite angular momentum are quantum superpositions of infinitely many states of linear momentum in all directions. To make sense out of that, you need to switch to a description in terms of photon states of definite angular, rather than linear, momentum. Those states are listed in $\{\mathrm{A} .21 .7\}$. Unfortunately, they are much more difficult to describe physically than states of definite linear momentum.

It should also be noted that if you include relativistic effects, the 2s state can actually decay to the 2 p state that has net angular momentum (spin plus orbital) $1 / 2$. This 2 p state has very slightly lower energy than the 2 s state due to a tiny relativistic effect called "Lamb shift," \{A.39.4\}. But because of the negligible difference in energy, such a transition is even slower than two-photon emission. It takes over 100 years to have a $50 / 50$ probability for the transition.

Also, including relativistic efects, a magnetic dipole transition is possible. An atomic state with net angular momentum $1 / 2$ (due to the spin) can decay to a state with again net angular momentum $1 / 2$ by emitting a photon with angular momentum $\ell=1$, subsection 7.4.2. A magnetic M1 transition is needed in order that the parity stays the same. Unfortunately, in the nonrelativistic approximation an M1 transition does not change the orbital motion; it just flips over the spin. Also, without any energy change the theoretical transition rate will be zero, section 7.6.1.

Relativistic effects remove these obstacles. But since these effects are very small, the one-photon transition does take several days, so it is again much slower than two-photon emission. In this case, it may be useful to think in terms of the complete atom, including the proton spin. The electron and proton can combine their spins into a singlet state with zero net angular momentum or a triplet state with one unit of net momentum. The photon takes one unit of angular momentum away, turning a triplet state into a singlet state or viceversa. If the atom ends up in a 1 s triplet state, it will take another 10 million year or so to decay to the singlet state, the true ground state.

For excited atomic states in general, different types of transitions may be possible. As discussed in the previous subsection, the normal type is called an "allowed," "electric dipole," or E1 transition.

Yes, every one of these three names is confusing. Nonallowed transitions, called "forbidden" transitions, are perfectly allowed and they do occur. They are typically just a lot slower. The atomic states between which the transitions occur do not have electric dipole moments. And how many people really know what an electric dipole is? And E1 is just cryptic. E0 would have been more intuitive, as it indicates the level to which the transition is forbidden. Who cares about photon angular momentum?

The one good thing that can be said is that in the electric dipole approximation, the atom does indeed respond to the electric part of the electromagnetic
field. In such transitions the photon comes out with one unit of angular momentum, i.e. $\ell=1$, and negative parity. Then the selection rules are:

$$
\begin{equation*}
\text { E1: } \quad l_{\mathrm{L}}=l_{\mathrm{H}} \pm 1 \quad m_{l, \mathrm{~L}}=m_{l, \mathrm{H}} \text { or } m_{l, \mathrm{H}} \pm 1 \quad m_{s, \mathrm{~L}}=m_{s, \mathrm{H}} \tag{7.18}
\end{equation*}
$$

The first rule reflects the possible orbital angular momentum values as given above. To be sure, these values also allow $l$ to stay the same. However, since the parity of the photon is negative, parity conservation requires that the parity of the atom must change, subsection 7.4.2. And that means that the orbital angular momentum quantum number $l$ must change from odd to even or viceversa. It cannot stay the same.

The second rule gives the possible magnetic quantum numbers. Recall that these are a direct measure for the angular momentum in the chosen $z$-direction. Since the photon momentum $\ell=1$, the photon $z$ momentum $m_{\gamma}$ can be -1 , 0 , or 1 . So the photon can change the atomic $z$ momentum by up to one unit, as the selection rule says. Note that while the photon angular momentum cannot be zero in the direction of its motion, the direction of motion is not necessarily the $z$-direction. In essence the photon may be coming off sideways. (The better way of thinking about this is in terms of photon states of definite angular momentum. These can have the angular momentum zero in the $z$ direction, while the direction of photon motion is uncertain.)

The final selection rule says that the electron spin in the $z$-direction does not change. That reflects the fact that the electron spin does not respond to an electric field in a nonrelativistic approximation. (Of course, you might argue that in a nonrelativistic approximation, the electron should not have spin in the first place, chapter 12.12.)

Note that ignoring relativistic effects in transitions is a tricky business. Even a small effect, given enough time to build up, might produce a transition where one was not possible before. In a more sophisticated analysis of the hydrogen atom, addendum \{A.39\}, there is a slight interaction between the orbital angular momentum of the electron and its spin. That is known as spin-orbit interaction. Note that the s states have no orbital angular momentum for the spin to interact with.

As a result of spin-orbit interaction the correct energy eigenfunctions, except the s states, develop uncertainty in the values of both $m_{l}$ and $m_{s}$. In other words, the $z$ components of both the orbital and the spin angular momenta have uncertainty. That implies that the above rules are no longer really right. The energy eigenfunctions do keep definite values for $l$, representing the magnitude of orbital angular momentum, for $j$, representing the magnitude of net angular momentum, orbital plus spin, and $m_{j}$ representing the net angular momentum in the $z$-direction. In those terms the modified selection rules become
$\mathrm{E} 1_{\mathrm{so}}: \quad l_{\mathrm{L}}=l_{\mathrm{H}} \pm 1 \quad j_{\mathrm{L}}=j_{\mathrm{H}}$ or $j_{\mathrm{H}} \pm 1 \quad m_{j, \mathrm{~L}}=m_{j, \mathrm{H}}$ or $m_{j, \mathrm{H}} \pm 1$

The last two selection rules above are a direct consequence of angular momentum conservation; since the photon has $\ell=1$, it can change each atomic quantum number by at most one unit. In the first selection rule, angular momentum conservation could in principle allow a change in $l$ by 2 units. A change in electron spin could add to the photon angular momentum. But parity conservation requires that $l$ changes by an odd amount and 2 is not odd.

If the selection rules are not satisfied, the transition is called forbidden. However, the transition may still occur through a different mechanism. One possibility is a slower magnetic dipole transition, in which the electron interacts with the magnetic part of the electromagnetic field. That interaction occurs because an electron has spin and orbital angular momentum. A charged particle with angular momentum behaves like a little electromagnet and wants to align itself with an ambient magnetic field, chapter 13.4. The selection rules in this case are

M1: $\quad l_{\mathrm{L}}=l_{\mathrm{H}} \quad m_{l, \mathrm{~L}}=m_{l, \mathrm{H}}$ or $m_{l, \mathrm{H}} \pm 1 \quad m_{s, \mathrm{~L}}=m_{s, \mathrm{H}}$ or $m_{s, \mathrm{H}} \pm 1$
The reasons are similar to the electric dipole case, taking into account that the photon comes out with positive parity rather than negative. Also, the electron spin definitely interacts with a magnetic field. A more detailed analysis will show that exactly one of the two magnetic quantum numbers $m_{l}$ and $m_{s}$ must change, $\{\mathrm{D} .39\}$.

It must be pointed out that an M1 transition is trivial for an hydrogen atom in the nonrelativistic approximation. All the transition does is change the direction of the orbital or spin angular momentum vector, $\{\mathrm{D} .39\}$. Not only is this ho-hum, the rate of transitions will be vanishingly small since it depends on the energy release in the transition. The same problem exists more generally for charged particles in radial potentials that only depend on position, $\{\mathrm{A} .25 .8\}$.

Relativistic effects can change this. In particular, in the presence of spinorbit coupling, the selection rules become

$$
\begin{equation*}
\mathrm{M} 1_{\mathrm{so}}: \quad l_{\mathrm{L}}=l_{\mathrm{H}} \quad j_{\mathrm{L}}=j_{\mathrm{H}} \text { or } j_{\mathrm{H}} \pm 1 \quad m_{j, \mathrm{~L}}=m_{j, \mathrm{H}} \text { or } m_{j, \mathrm{H}} \pm 1 \tag{7.21}
\end{equation*}
$$

In this case, it is less obvious why $l$ could not change by 2 units. The basic reason is that the magnetic field wants to rotate the orbital angular momentum vector, rather than change its magnitude, $\{\mathrm{D} .39\}$. (Note however that that derivation, and this book in general, uses a nonrelativistic Hamiltonian for the interaction between the spin and the magnetic field.) Similar limitations apply for magnetic transitions of higher multipole order, \{A.25.5\} (A.175).

In higher-order multipole transitions the photon comes out with angular momentum $\ell$ greater than 1 . As the previous subsection noted, this slows down the transitions. The fastest multipole transitions are the electric quadrupole ones. In these transitions the emitted photon has $\ell=2$ and positive parity.

The selection rules are then

In addition $l_{\mathrm{H}}=l_{\mathrm{L}}=0$ is not possible for such transitions. Neither is $l_{\mathrm{H}}=1$ and $l_{\mathrm{L}}=0$ or vice-versa. Including electron spin, $j_{\mathrm{H}}=j_{\mathrm{L}}=\frac{1}{2}$ is not possible. The reasons are similar to the ones before.

Magnetic transitions at higher multipole orders have similar problems as the magnetic dipole one. In particular, consider the orbital angular momentum selection rule (7.17) above. The lowest possible multipole order in the nonrelativistic case is

$$
\ell_{\min }=\left|l_{\mathrm{H}}-l_{\mathrm{L}}\right|
$$

Because of parity, that is always an electric multipole transition. (This excludes the case that the orbital angular momenta are equal, in which case the lowest transition is the already discussed trivial magnetic dipole one.)

The bottom line is that magnetic transitions simply cannot compete. Of course, conservation of net angular momentum might forbid the electric transition to a given final state. But in that case there will be an equivalent state that differs only in spin to which the electric transition can proceed just fine.

However, for a multi-electron atom or nucleus in an independent-particle model, that equivalent state might already be occupied by another particle. Or there may be enough spin-orbit interaction to raise the energy of the equivalent state to a level that transition to it becomes impossible. In that case, the lowest possible transition will be a magnetic one.

Consider now more general systems than hydrogen atoms. General selection rules for electric $\mathrm{E} \ell$ and magnetic $\mathrm{M} \ell$ transitions are:

$$
\begin{equation*}
\mathrm{E} \ell: \quad\left|j_{\mathrm{H}}-\ell\right| \leqslant j_{\mathrm{L}} \leqslant j_{\mathrm{H}}+\ell \quad \text { and } \quad \pi_{\mathrm{L}}=\pi_{\mathrm{H}}(-1)^{\ell} \quad(\ell \geqslant 1) \tag{7.23}
\end{equation*}
$$

$$
\begin{equation*}
\mathrm{M} \ell: \quad\left|j_{\mathrm{H}}-\ell\right| \leqslant j_{\mathrm{L}} \leqslant j_{\mathrm{H}}+\ell \quad \text { and } \quad \pi_{\mathrm{L}}=\pi_{\mathrm{H}}(-1)^{\ell-1} \quad(\ell \geqslant 1) \tag{7.24}
\end{equation*}
$$

These rules rely only on the spin and parity of the emitted photon. So they are quite generally valid for one-photon emission.

If a normal electric dipole transition is possible for an atomic or nuclear state, it will most likely decay that way before any other type of transition can occur. But if an electric dipole transition is forbidden, other types of transitions may appear in significant amounts. If both electric quadrupole and magnetic dipole transitions are possible, they may be competitive. And electric quadrupole transitions can produce two units of change in the atomic angular momentum, rather than just one like the magnetic dipole ones.

Given the initial state, often the question is not what final states are possible, but what transition types are possible given the final state. In that case, the
general selection rules can be written as

$$
\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right| \leqslant \ell \leqslant j_{\mathrm{H}}+j_{\mathrm{L}} \quad \text { and } \quad \ell \geqslant 1 \quad \text { and } \quad \pi_{\mathrm{L}} \pi_{\mathrm{H}}(-1)^{\ell}=\left\{\begin{array}{c}
1: \text { electric }  \tag{7.25}\\
-1: \text { magnetic }
\end{array}\right.
$$

Since transition rates decrease rapidly with increasing multipole order $\ell$, normally the lowest value of $\ell$ allowed will be the important one. That is

$$
\ell_{\min }=\left|j_{\mathrm{H}}-j_{\mathrm{L}}\right| \quad \text { or } \quad 1 \text { if } j_{\mathrm{H}}=j_{\mathrm{L}} \quad \text { and } \quad j_{\mathrm{H}}=j_{\mathrm{L}}=0 \text { is not possible. }
$$

If parity makes the corresponding transition magnetic, the next-higher order electric transition may well be of importance too.

## Key Points

$0-$ Normal atomic transitions are called electric dipole ones, or allowed ones, or E1 ones. Unfortunately.
$0-$ The quantum numbers of the initial and final atomic states in transitions must satisfy certain selection rules in order for transitions of a given type to be possible.
0 - If a transition does not satisfy the rules of electric dipole transitions, it will have to proceed by a slower mechanism. That could be a magnetic dipole transition or an electric or magnetic multipole transition.
$0=$ A state of zero angular momentum cannot decay to another state of zero angular momentum through any of these mechanisms. For such transitions, two-photon emission is an option.

### 7.5 Symmetric Two-State Systems

This section will look at the simplest quantum systems that can have nontrivial time variation. They are called symmetric two-state systems. Despite their simplicity, a lot can be learned from them.

Symmetric two-state systems were encountered before in chapter 5.3. They describe such systems as the hydrogen molecule and molecular ion, chemical bonds, and ammonia. This section will show that they can also be used as a model for the fundamental forces of nature. And for the spontaneous emission of radiation by say excited atoms or atomic nuclei.

Two-state systems are characterized by just two basic states; these states will be called $\psi_{1}$ and $\psi_{2}$. For symmetric two-state systems, these two states must be physically equivalent. Or at least they must have the same expectation energy. And the Hamiltonian must be independent of time.

For example, for the hydrogen molecular ion $\psi_{1}$ is the state where the electron is in the ground state around the first proton. And $\psi_{2}$ is the state in which it is in the ground state around the second proton. Since the two protons are identical in their properties, there is no physical difference between the two states. So they have the same expectation energy.

The interesting quantum mechanics arises from the fact that the two states $\psi_{1}$ and $\psi_{2}$ are not energy eigenstates. The ground state of the system, call it $\psi_{\mathrm{gs}}$, is a symmetric combination of the two states. And there is also an excited energy eigenstate $\psi_{\text {as }}$ that is an antisymmetric combination, chapter $5.3,\{\mathrm{~N} .11\}$ :

$$
\psi_{\mathrm{gs}}=\frac{\psi_{1}+\psi_{2}}{\sqrt{2}} \quad \psi_{\mathrm{as}}=\frac{\psi_{1}-\psi_{2}}{\sqrt{2}}
$$

The above expressions may be inverted to give the states $\psi_{1}$ and $\psi_{2}$ in terms of the energy states:

$$
\psi_{1}=\frac{\psi_{\mathrm{gs}}+\psi_{\mathrm{as}}}{\sqrt{2}} \quad \psi_{2}=\frac{\psi_{\mathrm{gs}}-\psi_{\mathrm{as}}}{\sqrt{2}}
$$

It follows that $\psi_{1}$ and $\psi_{2}$ are a 50/50 mixture of the low and high energy states. That means that they have uncertainty in energy. In particular they have a $50 \%$ chance for the ground state energy $E_{\mathrm{gs}}$ and a $50 \%$ chance for the elevated energy $E_{\text {as }}$.

That makes their expectation energy $\langle E\rangle$ equal to the average of the two energies, and their uncertainty in energy $\Delta E$ equal to half the difference:

$$
\langle E\rangle=\frac{E_{\mathrm{gs}}+E_{\mathrm{as}}}{2} \quad \Delta E=\frac{E_{\mathrm{as}}-E_{\mathrm{gs}}}{2}
$$

The question in this section is how the system evolves in time. In general the wave function is, section 7.1,

$$
\Psi=c_{\mathrm{gs}} e^{-\mathrm{i} E_{\mathrm{gs}} t / \hbar} \psi_{\mathrm{gs}}+c_{\mathrm{as}} e^{-\mathrm{i} E_{\mathrm{as}} t / \hbar} \psi_{\mathrm{as}}
$$

Here $c_{\mathrm{gs}}$ and $c_{\mathrm{as}}$ are constants that are arbitrary except for the normalization requirement.

However, this section will be more concerned with what happens to the basic states $\psi_{1}$ and $\psi_{2}$, rather than to the energy eigenstates. So, it is desirable to rewrite the wave function above in terms of $\psi_{1}$ and $\psi_{2}$ and their properties. That produces:

$$
\Psi=e^{-\mathrm{i}\langle E\rangle t / \hbar}\left[c_{\mathrm{gs}} e^{\mathrm{i} \Delta E t / \hbar} \frac{\psi_{1}+\psi_{2}}{\sqrt{2}}+c_{\mathrm{as}} e^{-\mathrm{i} \Delta E t / \hbar} \frac{\psi_{1}-\psi_{2}}{\sqrt{2}}\right]
$$

This expression is of the general form

$$
\Psi=c_{1} \psi_{1}+c_{2} \psi_{2}
$$

According to the ideas of quantum mechanics, $\left|c_{1}\right|^{2}$ gives the probability that the system is in state $\psi_{1}$ and $\left|c_{2}\right|^{2}$ that it is in state $\psi_{2}$.

The most interesting case is the one in which the system is in the state $\psi_{1}$ at time zero. In that case the probabilities of the states $\psi_{1}$ and $\psi_{2}$ vary with time as

$$
\begin{equation*}
\left|c_{1}\right|^{2}=\cos ^{2}(\Delta E t / \hbar) \quad\left|c_{2}\right|^{2}=\sin ^{2}(\Delta E t / \hbar) \tag{7.27}
\end{equation*}
$$

To verify this, first note from the general wave function that if the system is in state $\psi_{1}$ at time zero, the coefficients $c_{\mathrm{gs}}$ and $c_{\text {as }}$ must be equal. Then identify what $c_{1}$ and $c_{2}$ are and compute their square magnitudes using the Euler formula (2.5).

At time zero, the above probabilities produce state $\psi_{1}$ with $100 \%$ probability as they should. And so they do whenever the sine in the second expressions is zero. However, at times at which the cosine is zero, the system is fully in state $\psi_{2}$. It follows that the system is oscillating between the states $\psi_{1}$ and $\psi_{2}$.

## Key Points

0- Symmetric two-state systems are described by two quantum states $\psi_{1}$ and $\psi_{2}$ that have the same expectation energy $\langle E\rangle$.
$0-$ The two states have an uncertainty in energy $\Delta E$ that is not zero.
$0-$ The probabilities of the two states are given in (7.27). This assumes that the system is initially in state $\psi_{1}$.
$0-$ The system oscillates between states $\psi_{1}$ and $\psi_{2}$.

### 7.5.1 A graphical example

Consider a simple example of the oscillatory behavior of symmetric two-state systems. The example system is the particle inside a closed pipe as discussed in chapter 3.5. It will be assumed that the wave function is of the form

$$
\Psi=\sqrt{\frac{4}{5}} e^{-\mathrm{i} E_{111} t / \hbar} \psi_{111}+\sqrt{\frac{1}{5}} e^{-\mathrm{i} E_{211} t / \hbar} \psi_{211}
$$

Here $\psi_{111}$ and $\psi_{211}$ are the ground state and the second lowest energy state, and $E_{111}$ and $E_{211}$ are the corresponding energies, as given in chapter 3.5.

The above wave function is a valid solution of the Schrödinger equation since the two terms have the correct exponential dependence on time. And since the two terms have different energies, there is uncertainty in energy.

The relative probability to find the particle at a given position is given by the square magnitude of the wave function. That works out to

$$
|\Psi|^{2}=\Psi^{*} \Psi=\frac{4}{5}\left|\psi_{111}\right|^{2}+\frac{4}{5} \cos \left(\left(E_{111}-E_{211}\right) t / \hbar\right) \psi_{111} \psi_{211}+\frac{1}{5}\left|\psi_{211}\right|^{2}
$$

Note that this result is time dependent. If there was no uncertainty in energy, which would be true if $E_{111}=E_{211}$, the square wave function would be independent of time.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/pipemv.gif
Figure 7.6: A combination of two energy eigenfunctions seen at some typical times.

The probability for finding the particle is plotted at four representative times in figure 7.6. After time (d) the evolution repeats at (a). The wave function blob is sloshing back and forth in the pipe. That is much like a classical frictionless particle with kinetic energy would bounce back and forth between the ends of the pipe.

In terms of symmetric two-state systems, you can take the state $\psi_{1}$ to be the one in which the blob is at its leftmost position, figure 7.6(a). Then $\psi_{2}$ is the state in which the blob is at its rightmost position, figure 7.6(c). Note from the figure that these two states are physically equivalent. And they have uncertainty in energy.

### 7.5.2 Particle exchange and forces

An important two-state system very similar to the simple example in the previous subsection is the hydrogen molecular ion. This ion consists of two protons and one electron.

The molecular ion can show oscillatory behavior very similar to that of the example. In particular, assume that the electron is initially in the ground state around the first proton, corresponding to state $\psi_{1}$. In that case, after some time interval $\Delta t$, the electron will be found in the ground state around the second
proton, corresponding to state $\psi_{2}$. After another time interval $\Delta t$, the electron will be back around the first proton, and the cycle repeats. In effect, the two protons play catch with the electron!

That may be fun, but there is something more serious that can be learned. As is, there is no (significant) force between the two protons. However, there is a second similar play-catch solution in which the electron is initially around the second proton instead of around the first. If these two solutions are symmetrically combined, the result is the ground state of the molecular ion. In this state of lowered energy, the protons are bound together. In other words, there is now a force that holds the two protons together:

> If two particles play catch, it can produce forces between these two particles.

A "play catch" mechanism as described above is used in more advanced quantum mechanics to explain the forces of nature. For example, consider the correct, relativistic, description of electromagnetism, given by "quantum electrodynamics". In it, the electromagnetic interaction between two charged particles comes about largely through processes in which one particle creates a photon that the other particle absorbs and vice versa. Charged particles play catch using photons.

That is much like how the protons in the molecular ion get bound together by exchanging the electron. Note however that the solution for the ion was based on the Coulomb potential. This potential implies instantaneous interaction at a distance: if, say, the first proton is moved, the electron and the other proton notice this instantaneously in the force that they experience. Classical relativity, however, does not allow effects that propagate at infinite speed. The highest possible propagation speed is the speed of light. In classical electromagnetics, charged particles do not really interact instantaneously. Instead charged particles interact with the electromagnetic field at their location. The electromagnetic field then communicates this to the other charged particles, at the speed of light. The Coulomb potential is merely a simple approximation, for cases in which the particle velocities are much less than the speed of light.

In a relativistic quantum description, the electromagnetic field is quantized into photons. (A concise introduction to this advanced topic is in addendum \{A.23\}.) Photons are bosons with spin 1. Similarly to classical electrodynamics, in the quantum description charged particles interact with photons at their location. They do not interact directly with other charged particles.

These are three-particle interactions, a boson and two fermions. For example, if an electron absorbs a photon, the three particles involved are the photon, the electron before the absorption, and the electron after the absorption. (Since in relativistic applications particles may be created or destroyed, a particle after an interaction should be counted separately from an identical particle that may exist before it.)

The ideas of quantum electrodynamics trace back to the early days of quantum mechanics. Unfortunately, there was the practical problem that the computations came up with infinite values. A theory that got around this problem was formulated in 1948 independently by Julian Schwinger and Sin-Itiro Tomonaga. A different theory was proposed that same year by Richard Feynman based on a more pictorial approach. Freeman Dyson showed that the two theories were in fact equivalent. Feynman, Schwinger, and Tomonaga received the Nobel prize in 1965 for this work, Dyson was not included. (The Nobel prize in physics is limited to a maximum of three recipients.)

Following the ideas of quantum electrodynamics and pioneering work by Sheldon Glashow, Steven Weinberg and Abdus Salam in 1967 independently developed a particle exchange model for the so called "weak force." All three received the Nobel prize for that work in 1979. Gerardus 't Hooft and Martinus Veltman received the 1999 Nobel Prize for a final formulation of this theory that allows meaningful computations.

The weak force is responsible for the beta decay of atomic nuclei, among other things. It is of key importance for such nuclear reactions as the hydrogen fusion that keeps our sun going. In weak interactions, the exchanged particles are not photons, but one of three different bosons of spin 1: the negatively charged $\mathrm{W}^{-}$, (think W for weak force), the positively charged $\mathrm{W}^{+}$, and the neutral $Z^{0}$ (think Z for zero charge). You might call them the "massives" because they have a nonzero rest mass, unlike the photons of electromagnetic interactions. In fact, they have gigantic rest masses. The $\mathrm{W}^{ \pm}$have an experimental rest mass energy of about 80 GeV (giga-electron-volt) and the $\mathrm{Z}^{0}$ about 91 GeV . Compare that with the rest mass energy of a proton or neutron, less than a GeV , or an electron, less than a thousandth of a GeV . However, a memorable name like "massives" is of course completely unacceptable in physics. And neither would be "weak-force carriers," because it is accurate and to the point. So physicists call them the "intermediate vector bosons." That is also three words, but completely meaningless to most people and almost meaningless to the rest, $\{A .20\}$. It meets the requirements of physics well.

A typical weak interaction might involve the creation of say a $\mathrm{W}^{-}$by a quark inside a neutron and its absorption in the creation of an electron and an antineutrino. Now for massive particles like the intermediate vector bosons to be created out of nothing requires a gigantic quantum uncertainty in energy. Following the idea of the energy-time equality (7.9), such particles can only exist for extremely short times. And that makes the weak force of extremely short range.

The theory of "quantum chromedynamics" describes the so-called "strong force" or "color force." This force is responsible for such things as keeping atomic nuclei together.

The color force acts between "quarks." Quarks are the constituents of "baryons" like the proton and the neutron, and of "mesons" like the pions.

In particular, baryons consist of three quarks, while mesons consist of a quark and an antiquark. For example, a proton consists of two so-called "up quarks" and a third "down quark." Since up quarks have electric charge $\frac{2}{3} e$ and down quarks $-\frac{1}{3} e$, the net charge of the proton $\frac{2}{3} e+\frac{2}{3} e-\frac{1}{3} e$ equals $e$. Similarly, a neutron consists of one up quark and two down quarks. That makes its net charge $\frac{2}{3} e-\frac{1}{3} e-\frac{1}{3} e$ equal to zero. As another example, a so-called $\pi^{+}$meson consists of an up quark and an antidown quark. An antiparticle has the opposite charge from the corresponding particle, so the charge of the $\pi^{+}$meson $\frac{2}{3} e+\frac{1}{3} e$ equals $e$, the same as the proton. Three antiquarks make up an antibaryon. That gives an antibaryon the opposite charge of the corresponding baryon. More exotic baryons and mesons may involve the strange, charm, bottom, and top flavors of quarks. (Yes, there are six of them. You might well ask, "Who ordered that?" as the physicist Rabi did in 1936 upon the discovery of the muon, a heavier version of the electron. He did not know the least of it.)

Quarks are fermions with spin $1 / 2$ like electrons. However, quarks have an additional property called "color charge." (This color charge has nothing to do with the colors you can see. There are just a few superficial similarities. Physicists love to give complete different things identical names because it promotes such hilarious confusion.) There are three quark "colors" called, you guessed it, red, green and blue. There are also three corresponding "anticolors" called cyan, magenta, and yellow.

Now the electric charge of quarks can be observed, for example in the form of the charge of the proton. But their color charge cannot be observed in our macroscopic world. The reason is that quarks can only be found in "colorless" combinations. In particular, in baryons each of the three quarks takes a different color. (For comparison, on a video screen full-blast red, green and blue produces a colorless white.) Similarly, in antibaryons, each of the antiquarks takes on a different anticolor. In mesons the quark takes on a color and the antiquark the corresponding anticolor. (For example on a video screen, if you define antigreen as magenta, i.e. full-blast red plus blue, then green and antigreen produces again white.)

Actually, it is a bit more complicated still than that. If you had a green and magenta flag, you might call it color-balanced, but you would definitely not call it colorless. At least not in this book. Similarly, a green-antigreen meson would not be colorless, and such a meson does not exist. An actual meson is an quantum superposition of the three possibilities red-antired, green-antigreen, and blue-antiblue. The meson color state is

$$
\frac{1}{\sqrt{3}}(r \bar{r}+g \bar{g}+b \bar{b})
$$

where a bar indicates an anticolor. Note that the quark has equal probabilities of being observed as red, green, or blue. Similarly the antiquark has equal
probabilities of being observed antired, antigreen, or antiblue, but always the anticolor of the quark.

In addition, the meson color state above is a one-of-a-kind, or "singlet" state. To see why, suppose that, say, the final $b \bar{b}$ term had a minus sign instead of a plus sign. Then surely, based on symmetry arguments, there should also be states where the $g \bar{g}$ or $r \bar{r}$ has the minus sign. And that cannot be true because linear combinations of such states would produce states like the green-antigreen meson that are not colorless. So the only true colorless possibility is the state above, where all three color-anticolor states have the same coefficient. (Do recall that a constant of magnitude one is indeterminate in quantum states. So if all three color-anticolor states had a minus sign, it would still be the same state.)

Similarly, an "rgb" baryon with the first quark red, the second green, and the third blue would be color-balanced but not colorless. So such a baryon does not exist. For baryons there are six different possible color combinations: there are three possibilities for which of the three quarks is red, times two possibilities which of the remaining two quarks is green. An actual baryon is a quantum superposition of these six possibilities. Moreover, the combination is antisymmetric under color exchange:

$$
\frac{1}{\sqrt{6}}(r g b-r b g+g b r-g r b+b r g-b g r)
$$

Equivalently, the combination is antisymmetric under quark exchange. That explains why the so-called $\Delta^{++}$delta baryon can exist. This baryon consists of three up quarks in a symmetric spatial ground state and a symmetric spin $3 / 2$ state, like $\uparrow \uparrow \uparrow$. Because of the antisymmetric color state, the antisymmetrization requirements for the three quarks can be satisfied. The color state above is again a singlet one. In terms of chapter 5.7, it is the unique Slater determinant that can be formed from three states for three particles.

It is believed that baryons and mesons cannot be taken apart into separate quarks to study quarks in isolation. In other words, quarks are subject to "confinement" inside colorless baryons and mesons. The problem with trying to take these apart is that the force between quarks does not become zero with distance like other forces. If you try to take a quark out of a baryon or meson, presumably eventually you will put in enough energy to create a quark-antiquark pair in between. That kills off the quark separation that you thought you had achieved.

The color force between quarks is due to the exchange of so-called "gluons." Gluons are massless bosons with spin 1 like photons. However, photons do not carry electric charge. Gluons do carry color/anticolor combinations. That is one reason that quantum chromedynamics is enormously more difficult than quantum electrodynamics. Photons cannot move electric charge from one fermion to the next. But gluons allow the interchange of colors between quarks.

Also, because photons have no charge, they do not interact with other photons. But since gluons themselves carry color, gluons do interact with other gluons. In fact, both three-gluon and four-gluon interactions are possible. In principle, this makes it conceivable that "glueballs," colorless combinations of gluons, might exist. However, at the time of writing, 2012, only baryons, antibaryons, and mesons have been solidly established.

Gluon-gluon interactions are related to an effective strengthening of the color force at larger distances. Or as physicists prefer to say, to an effective weakening of the interactions at short distances called "asymptotic freedom." This helps a bit because it allows some analysis to be done at very short distances, i.e. at very high energies.

Normally you would expect nine independent color/anticolor gluon states: there are three colors times three anticolors. But in fact only eight independent gluon states are believed to exist. Recall the colorless meson state described above. If a gluon could be in such a colorless state, it would not be subject to confinement. It could then be exchanged between distant protons and neutrons, giving rise to a long-range nuclear force. Since such a force is not observed, it must be concluded that gluons cannot be in the colorless state. So if the nine independent orthonormal color states are taken to be the colorless state plus eight more states orthogonal to it, then only the latter eight states can be observable. In terms of section 7.3 , the relevant symmetry of the color force must be $\operatorname{SU}(3)$, not $\mathrm{U}(3)$.

Many people contributed to the theory of quantum chromedynamics. However Murray Gell-Mann seemed to be involved in pretty much every stage. He received the 1969 Nobel Prize at least in part for his work on quantum chromedynamics. It is also he who came up with the name "quark." The name is really not bad compared to many other terms in physics. However, Gell-Mann is also responsible for not spelling "color" as "qolor." That would have saved countless feeble explanations that, "No, this color has absolutely nothing to do with the color that you see in nature." So far nobody has been able to solve that problem, but David Gross, David Politzer and Frank Wilczek did manage to discover the asymptotic freedom mentioned above. For that they were awarded the 2004 Nobel Prize in Physics.

It may be noted that Gell-Mann initially called the three colors red, white, and blue. Just like the colors of the US flag, in short. Or of the Netherlands and Taiwan, to mention a few others. Huang, [27, p. 167], born in China, with a red and yellow flag, claims red, yellow and green are now the conventional choice. He must live in a world different from ours. Sorry, but the honor of having the color-balanced, (but not colorless), flag goes to Azerbaijan.

The force of gravity is supposedly due to the exchange of particles called "gravitons." They should be massless bosons with spin 2. However, it is hard to experiment with gravity because of its weakness on human scales. The graviton remains unconfirmed. Worse, the exact place of gravity in quantum mechanics
remains very controversial.

## Key Points

$0-$ The fundamental forces are due to the exchange of particles.
$0-$ The particles are photons for electromagnetism, intermediate vector bosons for the weak force, gluons for the color force, and presumably gravitons for gravity.

### 7.5.3 Spontaneous emission

Symmetric two state systems provide the simplest model for spontaneous emission of radiation by atoms or atomic nuclei. The general ideas are the same whether it is an atom or nucleus, and whether the radiation is electromagnetic (like visible light) or nuclear alpha or beta radiation. But to be specific, this subsection will use the example of an excited atomic state that decays to a lower energy state by releasing a photon of electromagnetic radiation. The conservation laws applicable to this process were discussed earlier in section 7.4. This subsection wants to examine the actual mechanics of the emission process.

First, there are some important terms and concepts that must be mentioned. You will encounter them all the time in decay processes.

The big thing is that decay processes are random. A typical atom in an excited state $\psi_{\mathrm{H}}$ will after some time transition to a state of lower energy $\psi_{\mathrm{L}}$ while releasing a photon. But if you take a second identical atom in the exact same excited state, the time after which this atom transitions will be different.

Still, the decay process is not completely unpredictable. Averages over large numbers of atoms have meaningful values. In particular, suppose that you have a very large number $I$ of identical excited atoms. Then the "decay rate" is by definition

$$
\begin{equation*}
\lambda=-\frac{1}{I} \frac{\mathrm{~d} I}{\mathrm{~d} t} \tag{7.28}
\end{equation*}
$$

It is the relative fraction $-\mathrm{d} I / I$ of excited atoms that disappears per unit time through transitions to a lower energy state. The decay rate has a precise value for a given atomic state. It is not a random number.

To be precise, the above decay rate is better called the specific decay rate. The actual decay rate is usually defined to be simply $-\mathrm{d} I / \mathrm{d} t$. But anyway, decay rate is not a good term to use in physics. It is much too clear. Sometimes the term "spontaneous emission rate" or "transition rate" is used, especially in the context of atoms. But that is even worse. A better and very popular choice is "decay constant." But, while "constant" is a term that can mean anything, it really is still far too transparent. How does "disintegration constant" sound? Especially since the atom hardly disintegrates in the transition? Why not call
it the [specific] "activity," come to think of it? Activity is another of these vague terms. Another good one is "transition probability," because a probability should be nondimensional and $\lambda$ is per unit time. May as well call it "radiation probability" then. Actually, many references will use a bunch of these terms interchangeably on the same page.

In fact, would it not be a good thing to take the inverse of the decay rate? That allows another term to be defined for essentially the same thing: the [mean] "lifetime" of the excited state:

$$
\begin{equation*}
\tau \equiv \frac{1}{\lambda} \tag{7.29}
\end{equation*}
$$

Do remember that this is not really a lifetime. Each individual atom has its own lifetime. (However, if you average the lifetimes of a large number of identical atoms, you will in fact get the mean lifetime above.)

Also, remember, if more than one decay process occurs for the excited state,

## Add decay rates, not lifetimes.

The sum of the decay rates gives the total decay rate of the atomic state. The reciprocal of that total is the correct lifetime.

Now suppose that initially there is a large number $I_{0}$ of excited atoms. Then the number of excited atoms $I$ left at a later time $t$ is

$$
\begin{equation*}
I=I_{0} e^{-\lambda t} \tag{7.30}
\end{equation*}
$$

So the number of excited atoms left decays exponentially in time. To check this expression, just check that it is right at time zero and plug it into the definition for the decay rate.

A quantity with a clearer physical meaning than lifetime is the time for about half the nuclei in a given large sample of excited atoms to decay. This time is called the "half-life" $\tau_{1 / 2}$. From (7.30) and (7.29) above, it follow that the half-life is shorter than the lifetime by a factor $\ln 2$ :

$$
\begin{equation*}
\tau_{1 / 2}=\tau \ln 2 \tag{7.31}
\end{equation*}
$$

Note that $\ln 2$ is less than one.
The purpose in this subsection is now to understand some of the above concepts in decays using the model of a symmetric two-state system.

The initial state $\psi_{1}$ of the system is taken to be an atom in a high-energy atomic state $\psi_{\mathrm{H}}$, figure 7.3. The state seems to be an state of definite energy. That would make it a stationary state, section 7.1.4, and hence it would not decay. However, $\psi_{1}$ is not really an energy eigenstate, because an atom is always perturbed by a certain amount of ambient electromagnetic radiation. The actual state $\psi_{1}$ has therefore some uncertainty in energy $\Delta E$.

The decayed state $\psi_{2}$ consists of an atomic state of lowered energy $\psi_{\mathrm{L}}$ plus an emitted photon. This state seems to have the same combined energy as the
initial state $\psi_{1}$. It too, however, is not really an energy eigenstate. Otherwise it would always have existed. In fact, it has the same expectation energy and uncertainty in energy as the initial state, section 7.1.3.

The probabilities of the two states were given at the start of this section. They were:

$$
\begin{equation*}
\left|c_{1}\right|^{2}=\cos ^{2}(\Delta E t / \hbar) \quad\left|c_{2}\right|^{2}=\sin ^{2}(\Delta E t / \hbar) \tag{7.32}
\end{equation*}
$$

At time zero, the system is in state $\psi_{1}$ for sure, but after a time interval $\Delta t$ it is in state $\psi_{2}$ for sure. The atom has emitted a photon and decayed. An expression for the time that this takes can be found by setting the angle in the sine equal to $\frac{1}{2} \pi$. That gives:

$$
\Delta t=\frac{1}{2} \pi \hbar / \Delta E
$$

But note that there is a problem. According to (7.32), after another time interval $\Delta t$ the probabilities of the two states will revert back to the initial ones. That means that the low energy atomic state absorbs the photon again and so returns to the excited state!

Effects like that do occur in nuclear magnetic resonance, chapter 13.6, or for atoms in strong laser light and high vacuum, [52, pp. 147-152]. But normally, decayed atoms stay decayed.

To explain that, it must be assumed that the state of the system is "measured" according to the rules of quantum mechanics, chapter 3.4. The macroscopic surroundings "observes" that a photon is released well before the original state can be restored. In the presence of such significant interaction with the macroscopic surroundings, the two-state evolution as described above is no longer valid. In fact, the macroscopic surroundings will have become firmly committed to the fact that the photon has been emitted. Little chance for the atom to get it back under such conditions.

In an improved model of the transition process, section 7.6.1, the need for measurement remains. However, the reasons get more complex.

Interactions with the surroundings are generically called "collisions." For example, a real-life atom in a gas will periodically collide with neighboring atoms and other particles. If a process is fast enough that no interactions with the surroundings occur during the time interval of interest, then the process takes place in the so-called "collisionless regime." Nuclear magnetic resonance and atoms in strong laser light and high vacuum may be in this regime.

However, normal atomic decays take place in the so-called "collision-dominated regime." Here collisions with the surroundings occur almost immediately.

To model that, take the time interval between collisions to be $t_{\mathrm{c}}$. Assume that the atom evolves as an unperturbed two-state system until time $t_{c}$. At that time however, the atom is "measured" by its surroundings and it is either found to be in the initial excited state $\psi_{1}$ or in the decayed state with photon $\psi_{2}$. According to the rules of quantum mechanics the result is random. However,
they are not completely random. The probability $P_{1 \rightarrow 2}$ for the atom to be found to be decayed is the square magnitude $\left|c_{2}\right|^{2}$ of the state $\psi_{2}$.

That square magnitude was given in (7.32). But it may be approximated to:

$$
P_{1 \rightarrow 2}=\frac{|\Delta E|^{2}}{\hbar^{2}} t_{\mathrm{c}}^{2}
$$

This approximated the sine in (7.32) by its argument, since the time $t_{\mathrm{c}}$ is assumed small enough that the argument is small.

Note that the decay process has become probabilistic. You cannot say for sure whether the atom will be decayed or not at time $t_{\mathrm{c}}$. You can only give the chances. See chapter 8.6 for a further discussion of that philosophical issue.

However, if you have not just one excited atom, but a large number $I$ of them, then $P_{1 \rightarrow 2}$ above is the relative fraction that will be found to be decayed at time $t_{\mathrm{c}}$. The remaining atoms, which are found to be in the excited state, (or rather, have been pushed back into the excited state), start from scratch. Then at time $2 t_{\mathrm{c}}$, a fraction $P_{1 \rightarrow 2}$ of these will be found to be decayed. And so on. Over time the number $I$ of excited atoms decreases to zero.

As mentioned earlier, the relative fraction of excited atoms that disappears per unit time is called the decay rate $\lambda$. That can be found by simply dividing the decay probability $P_{1 \rightarrow 2}$ above by the time $t_{\mathrm{c}}$ that the evolution took. So

$$
\lambda_{1 \rightarrow 2}=\frac{\left|H_{21}\right|^{2}}{\hbar^{2}} t_{\mathrm{c}} \quad H_{21}=\Delta E=\left\langle\psi_{2}\right| H\left|\psi_{1}\right\rangle
$$

Here the uncertainty in energy $\Delta E$ was identified in terms of the Hamiltonian $H$ using the analysis of chapter 5.3.

Physicists call $H_{21}$ the "matrix element." That is well below their usual form, because it really is a matrix element. But before you start seriously doubting the capability of physicists to invariably come up with confusing terms, note that there are lots of different matrices in any advanced physical analysis. So the name does not give its secret away to nonspecialists. To enforce that, many physicists write matrix elements in the form $M_{21}$, because, hey, the word matrix starts with an m . That hides the fact that it is an element of a Hamiltonian matrix pretty well.

The good news is that the assumption of collisions has solved the problem of decayed atoms undecaying again. Also, the decay process is now probabilistic. And the decay rate $\lambda_{1 \rightarrow 2}$ above is a normal number, not a random one.

Unfortunately, there are a couple of major new problems. One problem is that the state $\psi_{2}$ has one more particle than state $\psi_{1}$; the emitted photon. That makes it impossible to evaluate the matrix element using nonrelativistic quantum mechanics as covered in this book. Nonrelativistic quantum mechanics does not allow for new particles to be created or old ones to be destroyed. To evaluate the matrix element, you need relativistic quantum mechanics. Section 7.8 will eventually manage to work around that limitation using a dirty trick.

Addendum \{A.24\} gives the actual relativistic derivation of the matrix element. However, to really understand that addendum, you may have to read a couple of others.

An even bigger problem is that the decay rate above is proportional to the collision time $t_{\mathrm{c}}$. That makes it completely dependent on the details of the surroundings of the atom. But that is wrong. Atoms have very specific decay rates. These rates are the same under a wide variety of environmental conditions.

The basic problem is that in reality there is not just a single decay process for an excited atom; there are infinitely many. The derivation above assumed that the photon has an energy exactly given by the difference between the atomic states. However, there is uncertainty in energy one way or the other. Decays that produce photons whose frequency is ever so slightly different will occur too. To deal with that complication, asymmetric two-state systems must be considered. That is done in the next section.

Finally, a few words should probably be said about what collisions really are. Darn. Typically, they are pictured as atomic collisions. But that may be in a large part because atomic collisions are quite well understood from classical physics. Atomic collisions do occur, and definitely need to be taken into account, like later in the derivations of $\{\mathrm{D} .41\}$. But in the above description, collisions take on a second role as doing quantum mechanical "measurements." In that second role, a collision has occurred if the system has been "measured" to be in one state or the other. Following the analysis of chapter 8.6, measurement should be taken to mean that the surroundings has become firmly committed that the system has decayed. In principle, that does not require any actual collision with the atom; the surroundings could simply observe that the photon is present. The bad news is that the entire process of measurement is really not well understood at all. In any case, the bottom line to remember is that collisions do not necessarily represent what you would intuitively call collisions. Their dual role is to represent the typical moment that the surroundings commits itself that a transition has occurred.

## Key Points

$0-$ The two-state system provides a model for the decay of excited atoms or nuclei.
$0-$ Interaction with the surroundings is needed to make the decay permanent. That makes decays probabilistic.
$0-$ The [specific] decay rate, $\lambda$ is the relative fraction of particles that decays per unit time. Its inverse is the mean lifetime $\tau$ of the particles. The half-life $\tau_{1 / 2}$ is the time it takes for half the particles in a big sample to decay. It is shorter than the mean lifetime by a factor $\ln 2$.
$0-$ Always add decay rates, not lifetimes.

### 7.6 Asymmetric Two-State Systems

Two-state systems are quantum systems for which just two states $\psi_{1}$ and $\psi_{2}$ are relevant. If the two states have different expectation energy, or if the Hamiltonian depends on time, the two-state system is asymmetric. Such systems must be considered to fix the problems in the description of spontaneous emission that turned up in the previous section.

The wave function of a two state system is of the form

$$
\begin{equation*}
\Psi=c_{1} \psi_{1}+c_{2} \psi_{2} \tag{7.33}
\end{equation*}
$$

where $\left|c_{1}\right|^{2}$ and $\left|c_{2}\right|^{2}$ are the probabilities that the system is in state $\psi_{1}$, respectively $\psi_{2}$.

The coefficients $c_{1}$ and $c_{2}$ evolve in time according to

$$
\begin{equation*}
\mathrm{i} \hbar \dot{c}_{1}=\left\langle E_{1}\right\rangle c_{1}+H_{12} c_{2} \quad \mathrm{i} \hbar \dot{C}_{2}=H_{21} c_{1}+\left\langle E_{2}\right\rangle c_{2} \tag{7.34}
\end{equation*}
$$

where

$$
\left\langle E_{1}\right\rangle=\left\langle\psi_{1} \mid H \psi_{1}\right\rangle, \quad H_{12}=\left\langle\psi_{1} \mid H \psi_{2}\right\rangle, \quad H_{21}=\left\langle\psi_{2} \mid H \psi_{1}\right\rangle, \quad\left\langle E_{2}\right\rangle=\left\langle\psi_{2} \mid H \psi_{2}\right\rangle
$$

with $H$ the Hamiltonian. The Hamiltonian coefficients $\left\langle E_{1}\right\rangle$ and $\left\langle E_{2}\right\rangle$ are the expectation energies of states $\psi_{1}$ and $\psi_{2}$. The Hamiltonian coefficients $H_{12}$ and $H_{21}$ are complex conjugates. Either one is often referred to as the "matrix element." To derive the above evolution equations, plug the two-state wave function $\Psi$ into the Schrödinger equation and take inner products with $\left\langle\psi_{1}\right|$ and $\left\langle\psi_{2}\right|$, using orthonormality of the states.

It will be assumed that the Hamiltonian is independent of time. In that case the evolution equations can be solved analytically. To do so, the analysis of chapter 5.3 can be used to find the energy eigenstates and then the solution is given by the Schrödinger equation, section 7.1.2. However, the final solution is messy. The discussion here will restrict itself to some general observations about it.

It will be assumed that the solution starts out in the state $\psi_{1}$. That means that initially $\left|c_{1}\right|^{2}=1$ and $\left|c_{2}\right|^{2}=0$. Then in the symmetric case discussed in the previous section, the system oscillates between the two states. But that requires that the states have the same expectation energy.

This section addresses the asymmetric case, in which there is a nonzero difference $E_{21}$ between the two expectation energies:

$$
\begin{equation*}
E_{21} \equiv\left\langle E_{2}\right\rangle-\left\langle E_{1}\right\rangle \tag{7.35}
\end{equation*}
$$

In the asymmetric case, the system never gets into state $\psi_{2}$ completely. There is always some probability for state $\psi_{1}$ left. That can be seen from energy conservation: the expectation value of energy must stay the same during the evolution, and it would not if the system went fully into state 2 . However, the system will periodically return fully to the state $\psi_{1}$. That is all that will be said about the exact solution here.

The remainder of this section will use an approximation called "time-dependent perturbation theory." It assumes that the system stays close to a given state. In particular, it will be assumed that the system starts out in state $\psi_{1}$ and stays close to it.

That assumption results in the following probability for the system to be in the state $\psi_{2},\{$ D. 38$\}$ :

$$
\begin{equation*}
\left|c_{2}\right|^{2} \approx\left(\frac{\left|H_{21}\right| t}{\hbar}\right)^{2} \frac{\sin ^{2}\left(E_{21} t / 2 \hbar\right)}{\left(E_{21} t / 2 \hbar\right)^{2}} \tag{7.36}
\end{equation*}
$$

For this expression to be a valid approximation, the parenthetical ratio must be small. Note that the final factor shows the effect of the asymmetry of the two state system; $E_{21}$ is the difference in expectation energy between the states. For a symmetric two-state system, the final factor would be 1, (using l'Hôpital).

## Key Points

0 - If the states in a two-state system have different expectation energies, the system is asymmetric.
0- If the system is initially in the state $\psi_{1}$, it will never fully get into the state $\psi_{2}$.
$0-$ If the system is initially in the state $\psi_{1}$ and remains close to it, then the probability of the state $\psi_{2}$ is given by (7.36)

### 7.6.1 Spontaneous emission revisited

Decay of excited atomic or nuclear states was addressed in the previous section using symmetric two-state systems. But there were some issues. They can now be addressed.

The example is again an excited atomic state that transitions to a lower energy state by emitting a photon. The state $\psi_{1}$ is the excited atomic state. The state $\psi_{2}$ is the atomic state of lowered energy plus the emitted photon. These states seem states of definite energy, but if they really were, there would not be any decay. Energy states are stationary. There is a slight uncertainty in energy in the states.

Since there is, clearly it does not make much sense to say that the initial and final expectation energies must be the same exactly.

In decay processes, a bit of energy slop $E_{21}$ must be allowed between the initial and final expectation values of energy.

In practical terms, that means that the energy of the emitted photon can vary a bit. So its frequency can vary a bit.

Now in infinite space, the possible photon frequencies are infinitely close together. So you are now suddenly dealing with not just one possible decay process, but infinitely many. That would require messy, poorly justified mathematics full of so-called delta functions.

Instead, in this subsection it will be assumed that the atom is not in infinite space, but in a very large periodic box, chapter 6.17. The decay rate in infinite space can then be found by taking the limit that the box size becomes infinite. The advantage of a finite box is that the photon frequencies, and so the corresponding energies, are discrete. So you can sum over them rather than integrate.

Each possible photon state corresponds to a different final state $\psi_{2}$, each with its own coefficient $c_{2}$. The square magnitude of that coefficient gives the probability that the system can be found in that state $\psi_{2}$. And in the approximation of time-dependent perturbation theory, the coefficients $c_{2}$ do not interact; the square magnitude of each is given by (7.36). The total probability that the system can be found in some decayed state at a time $t_{\mathrm{c}}$ is then

$$
P_{1 \rightarrow \text { all 2 }}=\sum_{\text {all states 2 }}\left(\frac{\left|H_{21}\right| t_{\mathrm{c}}}{\hbar}\right)^{2} \frac{\sin ^{2}\left(E_{21} t_{\mathrm{c}} / 2 \hbar\right)}{\left(E_{21} t_{\mathrm{c}} / 2 \hbar\right)^{2}}
$$

The time $t_{\mathrm{c}}$ will again model the time between "collisions," interactions with the surroundings that "measure" whether the atom has decayed or not. The decay rate, the number of transitions per unit time, is found from dividing by the time:

$$
\lambda=\sum_{\text {all states } 2} \frac{\left|H_{21}\right|^{2}}{\hbar^{2}} t_{\mathrm{c}} \frac{\sin ^{2}\left(E_{21} t_{\mathrm{c}} / 2 \hbar\right)}{\left(E_{21} t_{\mathrm{c}} / 2 \hbar\right)^{2}}
$$

The final factor in the sum for the decay rate depends on the energy slop $E_{21}$. This factor is plotted graphically in figure 7.7. Notice that only a limited range around the point of zero slop contributes much to the decay rate. The spikes in the figure are intended to qualitatively indicate the discrete photon frequencies that are possible in the box that the atom is in. If the box is extremely big, then these spikes will be extremely close together.

Now suppose that you plot the energy slop diagram against the actual photon energy instead of the scaled energy slop $E_{21} t_{\mathrm{c}} / 2 \hbar$. Then the center of the diagram will be at the nominal energy of the emitted photon and $E_{21}$ will be the deviation from that nominal energy. The spike at the center then represents the transition of atoms where the photon comes out with exactly the nominal energy. And those surrounding spikes whose height is not negligible represent

Figure 7.7: Energy slop diagram.
slightly different photon energies that have a reasonable probability of being observed. So the energy slop diagram, plotted against photon energy, graphically represents the uncertainty in energy of the final state that will be observed.

Normally, the observed uncertainty in energy is very small in physical terms. The energy of the emitted photon is almost exactly the nominal one; that allows spectral analysis to identify atoms so well. So the entire diagram figure 7.7 is extremely narrow horizontally when plotted against the photon energy.

Figure 7.8: Schematized energy slop diagram.
That suggests that you can simplify things by replacing the energy slop diagram by the schematized one of figure 7.8. This diagram is zero if the energy slop is greater than $\pi \hbar / t_{\mathrm{c}}$, and otherwise it is one. And it integrates to the same value as the original function. So, if the spikes are very closely spaced, they still sum to the same value as before. To be sure, if the square matrix element $\left|H_{21}\right|^{2}$ varied nonlinearly over the typical width of the diagram, the transition rate would now sum to something else. But it should not; if the variation in photon energy is negligible, then so should the one in the matrix element be.

Using the schematized energy slop diagram, you only need to sum over the states whose spikes are equal to 1 . That are the states 2 whose expectation energy is no more than $\pi \hbar / t_{\mathrm{c}}$ different from the initial expectation energy. And inside this summation range, the final factor can be dropped because it is now 1. That gives:

$$
\begin{equation*}
\lambda=\sum_{\substack{\text { all states } 2 \text { with } \\\left|\left\langle E_{2}\right\rangle-\left\langle E_{1}\right\rangle\right|<\pi \hbar / t_{\mathrm{c}}}} \frac{\left|H_{21}\right|^{2}}{\hbar^{2}} t_{\mathrm{c}} \tag{7.37}
\end{equation*}
$$

This can be cleaned up further, assuming that $H_{21}$ is constant and can be taken out of the sum:

$$
\begin{equation*}
\lambda=2 \pi \frac{\left|H_{21}\right|^{2}}{\hbar} \frac{\mathrm{~d} N}{\mathrm{~d}\left\langle E_{2}\right\rangle} \tag{7.38}
\end{equation*}
$$

This formula is known as "Fermi's golden rule." The final factor is the number of photon states per unit energy range. It is to be evaluated at the nominal photon energy. The formula simply observes that the number of terms in the sum is the number of photon states per unit energy range times the energy range. The equation is considered to originate from Dirac, but Fermi is the one who named it "golden rule number two."

Actually, the original sum (7.37) may be easier to handle in practice since the number of photon states per unit energy range is not needed. But Fermi's rule is important because it shows that the big problem of the previous section with decays has been resolved. The decay rate does no longer depend on the time between collisions $t_{\mathrm{c}}$. Atoms can have specific values for their decay rates despite the minute details of their surroundings. Shorter collision times do produce less transitions per unit time for a given state. But they also allow more slop in energy, so the number of states that achieve a significant amount of transitions per unit time goes up. The net effect is that the decay rate stays the same, though the uncertainty in energy goes up.

The other problem remains; the evaluation of the matrix element $H_{21}$ requires relativistic quantum mechanics. But it is not hard to guess the general ideas. When the size of the periodic box that holds the system increases, the electromagnetic field of the photons decreases; they have the same energy in a larger volume. That results in smaller values for the matrix element $H_{21}$. On the other hand, the number of photons per unit energy range $\mathrm{d} N / \mathrm{d}\left\langle E_{2}\right\rangle$ increases, chapter 6.3. The net result will be that the decay rate remains finite when the box becomes infinite.

That is verified by the relativistic analysis in addendum \{A.24\}. That addendum completes the analysis in this section by computing the matrix element using relativistic quantum mechanics. Using a description in terms of photon states of definite linear momentum, the matrix element is inversely proportional to the volume of the box, but the density of states is directly proportional to it. (It is somewhat different using a description in terms of photon states of definite angular momentum, $\{\mathrm{A} .25\}$. But the idea remains the same.)

One problem of section 7.5.3 that has now disappeared is the photon being reabsorbed again. For each individual transition process, the interaction is too weak to produce a finite reversal time. But quantum "measurement" remains required to explain the experiments. The time-dependent perturbation theory used does not apply if the quantum system is allowed to evolve undisturbed over a time long enough for a significant transition probability (to any state) to evolve, $\{\mathrm{D} .38\}$. That would affect the specific decay rate. If you are merely
interested in the average emission and absorption of a large number of atoms, it is not a big problem. Then you can substitute a classical description in terms of random collisions for the quantum measurement process. That will be done in derivation \{D.41\}. But to describe what happens to individual atoms one at a time, while still explaining the observed statistics of many of such individual atoms, is another matter.

So far it has been assumed that there is only one atomic initial state of interest and only one final state. However, either state might have a net angular momentum quantum number $j$ that is not zero. In that case, there are $2 j+$ 1 atomic states that differ only in magnetic quantum number. The magnetic quantum number describes the component of the angular momentum in the chosen $z$-direction. Now if the atom is in empty space, the direction of the $z$ axis should not make a difference. Then these $2 j+1$ states will have the same energy. So you cannot include one and not the other. If this happens to the initial atomic state, you will need to average the decay rates over the magnetic states. The physical reason is that if you have a large number $I$ of excited atoms in the given energy state, their magnetic quantum numbers will be randomly distributed. So the average decay rate of the total sample is the average over the initial magnetic quantum numbers. But if it happens to the final state, you have to sum over the final magnetic quantum numbers. Each final magnetic quantum number gives an initial excited atom one more state that it can decay to. The general rule is:

## Sum over the final atomic states, then average over the initial atomic

 states.The averaging over the initial states is typically trivial. Without a preferred direction, the decay rate will not depend on the initial orientation.

It is interesting to examine the limitations of the analysis in this subsection. First, time-dependent perturbation theory has to be valid. It might seem that the requirement of (7.36) that $H_{21} t_{\mathrm{c}} / \hbar$ is small is automatically satisfied, because the matrix element $H_{21}$ goes to zero for infinite box size. But then the number of states 2 goes to infinity. And if you look a bit closer at the analysis, $\{\mathrm{D} .38\}$, the requirement is really that there is little probability of any transition in time interval $t_{\mathrm{c}}$. So the time between collisions must be small compared to the lifetime of the state. With typical lifetimes in the range of nanoseconds, atomic collisions are typically a few orders of magnitude more rapid. However, that depends on the relative vacuum.

Second, the energy slop diagram figure 7.7 has to be narrow on the scale of the photon energy. It can be seen that this is true if the time between collisions $t_{\mathrm{c}}$ is large compared to the inverse of the photon frequency. For emission of visible light, that means that the collision time must be large when expressed in femtoseconds. Collisions between atoms will easily meet that requirement.

The width of the energy slop diagram figure 7.7 should give the observed variation $E_{21}$ in the energy of the final state. The diagram shows that roughly

$$
E_{21} t_{\mathrm{c}} \sim \pi \hbar
$$

Note that this takes the form of the all-powerful energy-time uncertainty equality (7.9). To be sure, the equality above involves the artificial time between collisions, or "measurements," $t_{\mathrm{c}}$. But you could assume that this time is comparable to the mean lifetime $\tau$ of the state. Essentially that supposes that interactions with the surroundings are infrequent enough that the atomic evolution can evolve undisturbed for about the typical decay time. But that nature will definitely commit itself whether or not a decay has occurred as soon as there is a fairly reasonable probability that a photon has been emitted.

That argument then leads to the definition of the typical uncertainty in energy, or "width," of a state as $\Gamma=\hbar / \tau$, as mentioned in section 7.4.1. In addition, if there are frequent interactions between the atom and its surroundings, the shorter collision time $t_{\mathrm{c}}$ should be expected to increase the uncertainty in energy to more than the width.

Note that the wavy nature of the energy slop diagram figure 7.7 is due to the assumption that the time between "collisions" is always the same. If you start averaging over a more physical random set of collision times, the waves will smooth out. The actual energy slop diagram as usually given is of the form

$$
\begin{equation*}
\frac{1}{1+\left(E_{21} / \Gamma\right)^{2}} \tag{7.39}
\end{equation*}
$$

That is commonly called a [Cauchy] "Lorentz[ian] profile" or distribution or function, or a "Breit-Wigner distribution." Hey, don't blame the messenger. In any case, it still has the same inverse quadratic decay for large energy slop as the diagram figure 7.7. That means that if you start computing the standard deviation in energy, you end up with infinity. That would be a real problem for versions of the energy-time relationship like the one of Mandelshtam and Tamm. Such versions take the uncertainty in energy to be the standard deviation in energy. But it is no problem for the all-powerful energy-time uncertainty equality (7.9), because the standard deviation in energy is not needed.

### 7.7 Absorption and Stimulated Emission

This section will address the basic physic of absorption and emission of radiation by a gas of atoms in an electromagnetic field. The next section will give practical formulae.
(a) Spontaneous emission:

Figure 7.9: Emission and absorption of radiation by an atom.

Figure 7.9 shows the three different processes of interest. The previous sections already discussed the process of spontaneous emission. Here an atom in a state $\psi_{\mathrm{H}}$ of high energy emits a photon of electromagnetic radiation and returns to an atomic state $\psi_{\mathrm{L}}$ of lower energy. For example, for a hydrogen atom the excited state $\psi_{\mathrm{H}}$ might be the $\psi_{210}$ " $2 \mathrm{p}_{z}$ " state, and the lower energy state $\psi_{\mathrm{L}}$ the $\psi_{100}$ " 1 s " ground state, as defined in chapter 4.3.

To a superb approximation, the photon carries off the difference in energy between the atomic states. In view of the Planck-Einstein relation, that means that its frequency $\omega$ is given by

$$
\hbar \omega=E_{\mathrm{H}}-E_{\mathrm{L}}
$$

Unfortunately, the discussion of spontaneous emission in the previous sections had to remain incomplete. Nonrelativistic quantum mechanics as covered in this book cannot accommodate the creation of new particles like the photon in this case. The number of particles has to stay the same.

The second process of interest in figure 7.9 is absorption. Here an atom in a low energy state $\psi_{\mathrm{L}}$ interacts with an external electromagnetic field. The atom picks up a photon from the field, which allows it to enter an excited energy state $\psi_{\mathrm{H}}$. Unlike spontaneous emission, this process can reasonably be described using nonrelativistic quantum mechanics. The trick is to ignore the photon absorbed from the electromagnetic field. In that case, the electromagnetic field can be
approximated as a known one, using classical electromagnetics. After all, if the field has many photons, one more or less is not going to make a difference.

The third process is stimulated emission. In this case an atom in an excited state $\psi_{\mathrm{H}}$ interacts with an electromagnetic field. And now the atom does not do the logical thing; it does not pick up a photon to go to a still more excited state. Instead it uses the presence of the electromagnetic field as an excuse to dump a photon and return to a lower energy state $\psi_{\mathrm{L}}$.

This process is the operating principle of lasers. Suppose that you bring a large number of atoms into a relatively stable excited state. Then suppose that one of the atoms performs a spontaneous emission. The photon released by that atom can stimulate another excited atom to release a photon too. Then there are two coherent photons, which can go on to stimulate still more excited atoms to release still more photons. And so on in an avalanche effect. It can produce a runaway process of photon release in which a macroscopic amount of monochromatic, coherent light is created.

Masers work on the same principle, but the radiation is of much lower energy than visible light. It is therefore usually referred to as microwaves instead of light. The ammonia molecule is one possible source of such low energy radiation, chapter 5.3.

The analysis in this section will illuminate some of the details of stimulated emission. For example, it turns out that photon absorption by the lower energy atoms, figure $7.9(b)$, competes on a perfectly equal footing with stimulated emission, figure 7.9 (c). If you have a $50 / 50$ mixture of atoms in the excited state $\psi_{\mathrm{H}}$ and the lower energy state $\psi_{\mathrm{L}}$, just as many photons will be created by stimulated emission as will be absorbed. So no net light will be produced. To get a laser to work, you must initially have a "population inversion;" you must have more excited atoms than lower energy ones.
(Note that the lower energy state is not necessarily the same as the ground state. All else being the same, it obviously helps to have the lower energy state itself decay rapidly to a state of still lower energy. To a considerable extent, you can pick and choose decay rates, because decay rates can vary greatly depending on the amount to which they are forbidden, section 7.4.)

## Key Points

$0-$ An electromagnetic field can cause atoms to absorb photons.
$0-$ However, it can also cause excited atoms to release photons. That is called stimulated emission.
$0-$ In lasers and masers, an avalanche effect of stimulated emission produces coherent, monochromatic light.

### 7.7.1 The Hamiltonian

To describe the effect of an electromagnetic field on an atom using quantum mechanics, as always the Hamiltonian operator is needed.

The atom will be taken to be a hydrogen atom for simplicity. Since the proton is heavy, the electromagnetic field interacts mainly with the electron. The proton will be assumed to be at rest.

It is also necessary to simplify the electromagnetic field. That can be done by decomposing the field into separate "plane waves." The total interaction can usually be obtained by simply summing the effects produced by the separate waves.

A single plane wave has an electric field $\overrightarrow{\mathcal{E}}$ and a magnetic field $\overrightarrow{\mathcal{B}}$ that can be written in the form, (13.10):

$$
\overrightarrow{\mathcal{E}}=\hat{k} \mathcal{E}_{\mathrm{f}} \cos (\omega(t-y / c)-\alpha) \quad \overrightarrow{\mathcal{B}}=\hat{\imath} \frac{1}{c} \mathcal{E}_{\mathrm{f}} \cos (\omega(t-y / c)-\alpha)
$$

For convenience the $y$-axis was taken in the direction of propagation of the wave. Also the $z$-axis was taken in the direction of the electric field. Since there is just a single frequency $\omega$, the wave is monochromatic; it is a single color. And because of the direction of the electric field, the wave is said to be polarized in the $z$-direction. Note that the electric and magnetic fields for plane waves are normal to the direction of propagation and to each other. The constant $c$ is the speed of light, $\mathcal{E}_{\mathrm{f}}$ the amplitude of the electric field, and $\alpha$ is some unimportant phase angle.

Fortunately, the expression for the wave can be greatly simplified. The electron reacts primarily to the electric field, provided that its kinetic energy is small compared to its rest mass energy. That is certainly true for the electron in a hydrogen atom and for the outer electrons of atoms in general. Therefore the magnetic field can be ignored. (The error made in doing so is described more precisely in $\{\mathrm{D} .39\}$.) Also, the wave length of the electromagnetic wave is usually much larger than the size of the atom. For example, the Lymantransition wave lengths are of the order of a thousand $\AA$, while the atom is about one $\AA$. So, as far as the light wave is concerned, the atom is just a tiny speck at the origin. That means that $y$ can be put to zero in the expression for the plane wave. Then the wave simplifies to just:

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=\hat{k} \mathcal{E}_{\mathrm{f}} \cos (\omega t-\alpha) \tag{7.40}
\end{equation*}
$$

This may not be applicable to highly energetic radiation like X-rays.
Now the question is how this field changes the Hamiltonian of the electron. Ignoring the time dependence of the electric field, that is easy. The Hamiltonian is

$$
\begin{equation*}
H=H_{\text {atom }}+e \mathcal{E}_{\mathrm{f}} \cos (\omega t-\alpha) z \tag{7.41}
\end{equation*}
$$

where $H_{\text {atom }}$ is the Hamiltonian of the hydrogen atom without the external electromagnetic field. The expression for $H_{\text {atom }}$ was given in chapter 4.3, but it is not of any interest here.

The interesting term is the second one, the perturbation caused by the electromagnetic field. In this term $z$ is the $z$-position of the electron. It is just like the $m g h$ potential energy of gravity, with the charge $e$ playing the part of the mass $m$, the electric field strength $\mathcal{E}_{\mathrm{f}} \cos (\omega t-\alpha)$ that of the gravity strength $g$, and $z$ that of the height $h$.

To be sure, the electric field is time dependent. The above perturbation potential really assumes that "the electron moves so fast that the field seems steady to it." Indeed, if an electron "speed" is ballparked from its kinetic energy, the electron does seem to travel through the atom relatively fast compared to the frequency of the electric field. Of course, it is much better to write the correct unsteady Hamiltonian and then show it works out pretty much the same as the quasi-steady one above. That is done in $\{\mathrm{D} .39\}$.

$0-$ By approximation the atom sees a uniform, quasi-steady electric field.

### 7.7.2 The two-state model

The big question is how the electromagnetic field affects transitions between a typical atomic state $\psi_{\mathrm{L}}$ of lower energy and one of higher energy $\psi_{\mathrm{H}}$.

The answer depends critically on various Hamiltonian coefficients. In particular, the expectation values of the energies of the two states are needed. They are

$$
E_{\mathrm{L}}=\left\langle\psi_{\mathrm{L}}\right| H\left|\psi_{\mathrm{L}}\right\rangle \quad E_{\mathrm{H}}=\left\langle\psi_{\mathrm{H}}\right| H\left|\psi_{\mathrm{H}}\right\rangle
$$

Here the Hamiltonian to use is (7.41) of the previous subsection; it includes the electric field. But it can be seen that the energies are unaffected by the electric field. They are the unperturbed atomic energies of the states. That follows from symmetry; if you write out the inner products above using (7.41), the square wave function is the same at any two positions $\vec{r}$ and $-\vec{r}$, but $z$ in the electric field term changes sign. So integration values pairwise cancel each other.

Note however that the two energies are now expectation values of energy; due to the electric field the atomic states develop uncertainty in energy. That is why they are no longer stationary states.

The other key Hamiltonian coefficient is

$$
H_{\mathrm{HL}}=\left\langle\psi_{\mathrm{H}}\right| H\left|\psi_{\mathrm{L}}\right\rangle
$$

Plugging in the Hamiltonian (7.41), it is seen that the atomic part $H_{\text {atom }}$ does not contribute. The states $\psi_{\mathrm{H}}$ and $\psi_{\mathrm{L}}$ are orthogonal, and the atomic Hamiltonian just multiplies $\psi_{\mathrm{L}}$ by $E_{\mathrm{L}}$. But the electric field gives

$$
H_{\mathrm{HL}}=\mathcal{E}_{\mathrm{f}}\left\langle\psi_{\mathrm{H}}\right| e z\left|\psi_{\mathrm{L}}\right\rangle \frac{e^{\mathrm{i}(\omega t-\alpha)}+e^{-\mathrm{i}(\omega t-\alpha)}}{2}
$$

Here the cosine in (7.41) was taken apart into two exponentials using the Euler formula (2.5).

The next question is what these coeffients mean for the transitions between two atomic states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$. First, since the atomic states are complete, the wave function can always be written as

$$
\Psi=c_{\mathrm{L}} \psi_{\mathrm{L}}+c_{\mathrm{H}} \psi_{\mathrm{H}}+\ldots
$$

where the dots stand for other atomic states. The coefficients $c_{\mathrm{L}}$ and $c_{\mathrm{H}}$ are the key, because their square magnitudes give the probabilities of the states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$. So they determine whether transitions occur between them.

Evolution equations for these coefficients follow from the Schrödinger equation. The way to find them was described in section 7.6 , with additional manipulations in derivation $\{\mathrm{D} .38\}$. The resulting evolution equations are:

$$
\begin{equation*}
\mathrm{i} \hbar \dot{\bar{c}}_{\mathrm{L}}=\bar{H}_{\mathrm{LH}} \bar{c}_{\mathrm{H}}+\ldots \quad \mathrm{i} \hbar \dot{\bar{c}}_{\mathrm{H}}=\bar{H}_{\mathrm{HL}} \bar{c}_{\mathrm{L}}+\ldots \tag{7.42}
\end{equation*}
$$

where the dots represent terms involving states other than $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$. These equations use the modified coefficients

$$
\begin{equation*}
\bar{c}_{\mathrm{L}}=c_{\mathrm{L}} e^{\mathrm{i} E_{\mathrm{L}} t / \hbar} \quad \bar{c}_{\mathrm{H}}=c_{\mathrm{H}} e^{\mathrm{i} E_{\mathrm{H}} t / \hbar} \tag{7.43}
\end{equation*}
$$

The modified coefficients have the same square magnitudes as the original ones and the same values at time zero. That makes them fully equivalent to the original ones. The modified Hamiltonian coefficient in the evolution equations is

$$
\begin{equation*}
\bar{H}_{\mathrm{HL}}=\bar{H}_{\mathrm{LH}}^{*}=\frac{1}{2} \mathcal{E}_{\mathrm{f}}\left\langle\psi_{\mathrm{H}}\right| e z\left|\psi_{\mathrm{L}}\right\rangle e^{\mathrm{i}\left(\omega_{0}-\omega\right) t+\alpha}+\frac{1}{2} \mathcal{E}_{\mathrm{f}}\left\langle\psi_{\mathrm{H}}\right| e z\left|\psi_{\mathrm{L}}\right\rangle e^{\mathrm{i}\left(\omega_{0}+\omega\right) t-\alpha} \tag{7.44}
\end{equation*}
$$

where $\omega_{0}$ is the frequency of a photon that has the exact energy $E_{\mathrm{H}}-E_{\mathrm{L}}$.
Note that this modified Hamiltonian coefficient is responsible for the interaction between the states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$. If this Hamiltonian coefficient is zero, the electromagnetic wave cannot cause transitions between the two states. At least not within the approximations made.

Whether this happens depends on whether the inner product $\left\langle\psi_{\mathrm{H}}\right| e z\left|\psi_{\mathrm{L}}\right\rangle$ is zero. This inner product is called the "atomic matrix element" because it depends only on the atomic states, not on the strength and frequency of the electric wave.

However, it does depend on the direction of the electric field. The assumed plane wave had its electric field in the $z$-direction. Different waves can have their electric fields in other directions. Therefore, waves can cause transitions as long as there is at least one nonzero atomic matrix element of the form $\left\langle\psi_{\mathrm{L}}\right| e r_{i}\left|\psi_{\mathrm{H}}\right\rangle$, with $r_{i}$ equal to $x, y$, or $z$. If there is such a nonzero matrix element, the transition is called allowed. Conversely, if all three matrix elements are zero, then transitions between the states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ are called forbidden.

Note however that so-called forbidden transitions often occur just fine. The derivation in the previous subsection made several approximations, including that the magnetic field can be ignored and that the electric field is independent of position. If these ignored effects are corrected for, many forbidden transitions turn out to be possible after all; they are just much slower.

The approximations made to arrive at the atomic matrix element $\left\langle\psi_{\mathrm{H}}\right| e z\left|\psi_{\mathrm{L}}\right\rangle$ are known as the "electric dipole approximation." The corresponding transitions are called "electric dipole transitions." If you want to know where the term comes from, why? Anyway, in that case note first that if the electron charge distribution is symmetric around the proton, the expectation value of $e z$ will be zero by symmetry. Negative $z$ values will cancel positive ones. But the electron charge distribution might get somewhat shifted to the positive $z$ side, say. The total atom is then still electrically neutral, but it behaves a bit like a combination of a negative charge at a positive value of $z$ and an equal and opposite positive charge at a negative value of $z$. Such a combination of two opposite charges is called a dipole in classical electromagnetics, chapter 13.3. So in quantum mechanics the operator $e z$ gives the dipole strength in the $z$-direction. And if the above atomic matrix element is nonzero, it can be seen that nontrivial combinations of $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ have a nonzero expectation dipole strength. So the name "electric dipole transitions" is justified, especially since "basic electric transitions" would be understandable by far too many nonexperts.

Allowed and forbidden transitions were discussed earlier in section 7.4. However, that was based on assumed properties of the emitted photon. The allowed atomic matrix elements above, and similar forbidden ones, make it possible to check the various most important results directly from the governing equations. That is done in derivation $\{\mathrm{D} .39\}$.

There is another requirement to get a decent transition probability. The exponentials in the modified Hamiltonian coefficient (7.44) must not oscillate too rapidly in time. Otherwise opposite values of the exponentials will average away against each other. So no significant transition probability can build up. (This is similar to the cancelation that gives rise to the adiabatic theorem, $\{\mathrm{D} .34\}$.) Now under real-life conditions, the second exponential in (7.44) will always oscillate rapidly. Normal electromagnetic frequencies are very high. Therefore the second term in (7.44) can normally be ignored.

And in order for the first exponential not too oscillate too rapidly requires a pretty good match between the frequencies $\omega$ and $\omega_{0}$. Recall that $\omega$ is the
frequency of the electromagnetic wave, while $\omega_{0}$ is the frequency of a photon whose energy is the difference between the atomic energies $E_{\mathrm{H}}$ and $E_{\mathrm{L}}$. If the electric field does not match the frequency of that photon, it will not do much. Using the Planck-Einstein relation, that means that

$$
\omega \approx \omega_{0} \equiv\left(E_{\mathrm{H}}-E_{\mathrm{L}}\right) / \hbar
$$

One consequence is that in transitions between two atomic states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$, other states usually do not need to be considered. Unless an other state matches either the energy $E_{\mathrm{H}}$ or $E_{\mathrm{L}}$, it will give rise to rapidly oscillating exponentials that can be ignored.

In addition, the interest is often in the so-called collision-dominated regime in which the atom evolves for only a short time before being disturbed by "collisions" with its surroundings. In that case, the short evolution time prevents nontrivial interactions between different transition processes to build up. Transition rates for the individual transition processes can be found separately and simply added together.

The obtained evolution equations (7.42) can explain why absorption and stimulated emission compete on an equal footing in the operation of lasers. The reason is that the equations have a remarkable symmetry: for every solution $\bar{c}_{\mathrm{L}}$, $\bar{c}_{\mathrm{H}}$ there is a second solution $\bar{c}_{\mathrm{L}, 2}=\bar{c}_{\mathrm{H}}^{*}, \bar{c}_{\mathrm{H}, 2}=-\bar{c}_{\mathrm{L}}^{*}$ that has the probabilities of the low and high energy states exactly reversed. It means that

> An electromagnetic field that takes an atom out of the low energy state $\psi_{\mathrm{L}}$ towards the high energy state $\psi_{\mathrm{H}}$ will equally take that atom out of the high energy state $\psi_{\mathrm{H}}$ towards the low energy state $\psi_{\mathrm{L}}$.

It is a consequence of the Hermitian nature of the Hamiltonian; it would not apply if $\bar{H}_{\mathrm{LH}}$ was not equal to $\bar{H}_{\mathrm{HL}}^{*}$.

## Key Points

$0-$ The governing evolution equations for the probabilities of two atomic states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ in an electromagnetic wave have been found.
$0-$ The equations have a symmetry property that makes electromagnetic waves equally effective for absorption and stimulated emission.
0- Normally the electromagnetic field has no significant effect on transitions between the states unless its frequency $\omega$ closely matches the frequency $\omega_{0}$ of a photon with energy $E_{\mathrm{H}}-E_{\mathrm{L}}$.
$0-$ The governing equations can explain why some transitions are allowed and others are forbidden. The key are so-called "atomic matrix elements."

### 7.8 General Interaction with Radiation

Under typical conditions, a collection of atoms is not just subjected to a single electromagnetic wave, as described in the previous section, but to "broadband" incoherent radiation of all frequencies moving in all directions. Also, the interactions of the atoms with their surroundings tend to be rare compared to the frequency of the radiation but frequent compared to the typical life time of the various excited atomic states. In other words, the evolution of the atomic states is collision-dominated. The question in this subsection is what can be said about the emission and absorption of radiation by the atoms under such conditions.

Since both the electromagnetic field and the collisions are random, a statistical rather than a determinate treatment is needed. In it, the probability that a randomly chosen atom can be found in a typical atomic state $\psi_{\mathrm{L}}$ of low energy will be called $P_{\mathrm{L}}$. Similarly, the probability that an atom can be found in an atomic state $\psi_{\mathrm{H}}$ of higher energy will be called $P_{\mathrm{H}}$. More simplistic, $P_{\mathrm{L}}$ can be called the fraction of atoms in the low energy state and $P_{\mathrm{H}}$ the fraction in the high energy state.

The energy of the electromagnetic radiation, per unit volume and per unit frequency range, will be indicated by $\rho(\omega)$. The particular frequency $\omega_{0}$ that is relevant to transitions between two atomic states $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$ is related to the energy difference between the states. In particular,

$$
\omega_{0}=\left(E_{\mathrm{H}}-E_{\mathrm{L}}\right) / \hbar
$$

is the nominal frequency of the photon released or absorbed in a transition between the two states.

In those terms, the fractions $P_{\mathrm{L}}$ and $P_{\mathrm{H}}$ of atoms in the two states evolve in time according to the evolution equations, $\{\mathrm{D} .41\}$,

$$
\begin{align*}
& \frac{\mathrm{d} P_{\mathrm{L}}}{\mathrm{~d} t}=-B_{\mathrm{L} \rightarrow \mathrm{H}} \rho\left(\omega_{0}\right) P_{\mathrm{L}}+B_{\mathrm{H} \rightarrow \mathrm{~L}} \rho\left(\omega_{0}\right) P_{\mathrm{H}}+A_{\mathrm{H} \rightarrow \mathrm{~L}} P_{\mathrm{H}}+\ldots  \tag{7.45}\\
& \frac{\mathrm{d} P_{\mathrm{H}}}{\mathrm{~d} t}=+B_{\mathrm{L} \rightarrow \mathrm{H}} \rho\left(\omega_{0}\right) P_{\mathrm{L}}-B_{\mathrm{H} \rightarrow \mathrm{~L}} \rho\left(\omega_{0}\right) P_{\mathrm{H}}-A_{\mathrm{H} \rightarrow \mathrm{~L}} P_{\mathrm{H}}+\ldots \tag{7.46}
\end{align*}
$$

In the first equation, the first term in the right hand side reflects atoms that are excited from the low energy state to the high energy state. That decreases the number of low energy atoms, explaining the minus sign. The effect is of course proportional to the fraction $P_{\mathrm{L}}$ of low energy atoms that is available to be excited. It is also proportional to the energy $\rho\left(\omega_{0}\right)$ of the electromagnetic waves that do the actual exciting.

Similarly, the second term in the right hand side of the first equation reflects the fraction of low energy atoms that is created through de-excitation of excited
atoms by the electromagnetic radiation. The final term reflects the low energy atoms created by spontaneous decay of excited atoms. The constant $A_{\mathrm{H} \rightarrow \mathrm{L}}$ is the spontaneous emission rate. (It is really the decay rate $\lambda$ as defined earlier in section 7.5.3, but in the present context the term spontaneous emission rate and symbol $A$ tend to be used.)

The second equation can be understood similarly as the first. If there are transitions with states other than $\psi_{\mathrm{L}}$ and $\psi_{\mathrm{H}}$, all their effects should be summed together; that is indicated by the dots in (7.45) and (7.46).

The constants in the equations are collectively referred to as the "Einstein $A$ and $B$ coefficients." Imagine that some big shot in engineering was too lazy to select appropriate symbols for the quantities used in a paper and just called them $A$ and $B$. Referees and standards committees would be on his/her back, big shot or not. However, in physics they still stick with the stupid symbols almost a century later. At least in this context.

Anyway, the $B$ coefficients are, $\{\mathrm{D} .41\}$,

$$
\begin{equation*}
B_{\mathrm{L} \rightarrow \mathrm{H}}=B_{\mathrm{H} \rightarrow \mathrm{~L}}=\frac{\pi}{\hbar^{2} \epsilon_{0}} \frac{\left.\left|\left\langle\psi_{\mathrm{L}}\right| e \vec{r}\right| \psi_{\mathrm{H}}\right\rangle\left.\right|^{2}}{3} \tag{7.47}
\end{equation*}
$$

Here $\epsilon_{0}=8.8541910^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is the permittivity of space. Note from the appearance of the Planck constant that the emission and absorption of radiation is truly a quantum effect. The second ratio is the average atomic matrix element discussed in the previous section. The fact that $B_{\mathrm{L} \rightarrow \mathrm{H}}$ equals $B_{\mathrm{H} \rightarrow \mathrm{L}}$ reflects that the electric field is equally effective for absorption as for stimulated emission. It is a consequence of the symmetry property of two-state systems mentioned in the previous section.

The spontaneous emission rate was found by Einstein using a dirty trick, \{D.42\}. It is

$$
\begin{equation*}
A_{\mathrm{H} \rightarrow \mathrm{~L}}=B_{\mathrm{H} \rightarrow \mathrm{~L}} \rho_{\text {equiv }}\left(\omega_{0}\right) \quad \rho_{\text {equiv }}(\omega)=\frac{\hbar \omega^{3}}{\pi^{2} c^{3}} \tag{7.48}
\end{equation*}
$$

One way of thinking of the mechanism of spontaneous emission is that it is an effect of the ground state electromagnetic field. Just like normal particle systems still have nonzero energy left in their ground state, so does the electromagnetic field. You could therefore think of this ground state electromagnetic field as the source of the atomic perturbations that cause the atomic decay. If that picture is right, then the term $\rho_{\text {equiv }}$ in the expression above should be the energy of the field in the ground state. In terms of the analysis of chapter 6.8, that would mean that in the ground state, there is exactly one photon left in each radiation mode. Just drop the factor (6.10) from (6.11).

It is a pretty reasonable description, but it is not quite true. In the ground state of the electromagnetic field there is half a photon in each mode, not one.

It is just like a harmonic oscillator, which has half an energy quantum $\hbar \omega$ left in its ground state, chapter 4.1. Also, a ground state energy should not make a difference for the evolution of a system. Instead, because of a twilight effect, the photon that the excited atom interacts with is the one that it will emit, addendum \{A.24\}.

As a special example of the given evolution equations, consider a closed box whose inside is at absolute zero temperature. Then there is no ambient blackbody radiation, $\rho=0$. Now assume that initially there is a thin gas of atoms in the box in an excited state $\psi_{\mathrm{H}}$. These atoms will decay to whatever are the available atomic states of lower energy. In particular, according to (7.46) the fraction $P_{\mathrm{H}}$ of excited atoms left will evolve as

$$
\frac{\mathrm{d} P_{\mathrm{H}}}{\mathrm{~d} t}=-\left[A_{\mathrm{H} \rightarrow \mathrm{~L}_{1}}+A_{\mathrm{H} \rightarrow \mathrm{~L}_{2}}+A_{\mathrm{H} \rightarrow \mathrm{~L}_{3}}+\ldots\right] P_{\mathrm{H}}
$$

where the sum is over all the lower energy states that exist. It describes the effect of all possible spontaneous emission processes that the excited state is subject to. (The above equation is a rewrite of (7.28) of section 7.5.3 in the present notations.)

The above expression assumed that the excited atoms are in a box that is at absolute zero temperature. Atoms in a box that is at room temperature are bathed in thermal blackbody radiation. In principle you would then have to use the full equations (7.45) and (7.46) to figure out what happens to the number of excited atoms. Stimulated emission will add to spontaneous emission and new excited atoms will be created by absorption. However, at room temperature blackbody radiation has negligible energy in the visible light range, chapter 6.8 (6.10). Transitions in this range will not really be affected.

### 7.9 Position and Linear Momentum

The subsequent sections will be looking at the time evolution of various quantum systems, as predicted by the Schrödinger equation. However, before that can
be done, first the eigenfunctions of position and linear momentum must be found. That is something that the book has been studiously avoiding so far. The problem is that the position and linear momentum eigenfunctions have awkward issues with normalizing them.

These normalization problems have consequences for the coefficients of the eigenfunctions. In the orthodox interpretation, the square magnitudes of the coefficients should give the probabilities of getting the corresponding values of position and linear momentum. But this statement will have to be modified a bit.

One good thing is that unlike the Hamiltonian, which is specific to a given system, the position operator

$$
\widehat{\vec{r}}=(\widehat{x}, \widehat{y}, \widehat{z})
$$

and the linear momentum operator

$$
\widehat{\vec{p}}=\left(\widehat{p}_{x}, \widehat{p}_{y}, \widehat{p}_{z}\right)=\frac{\hbar}{\mathrm{i}}\left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right)
$$

are the same for all systems. So, you only need to find their eigenfunctions once.

### 7.9.1 The position eigenfunction

The eigenfunction that corresponds to the particle being at a precise $x$-position $\underline{x}, y$-position $\underline{y}$, and $z$-position $\underline{z}$ will be denoted by $R_{\underline{x} \underline{y} \underline{z}}(x, y, z)$. The eigenvalue problem is:

$$
\begin{aligned}
& \widehat{x} R_{\underline{x} \underline{y} \underline{z}}(x, y, z)=\underline{x} R_{\underline{\underline{y} \underline{z}}}(x, y, z) \\
& \widehat{y} R_{\underline{x} \underline{y} \underline{z}}(x, y, z)=\underline{y} R_{\underline{x} \underline{z} \underline{z}}(x, y, z) \\
& \widehat{z} R_{\underline{x} \underline{y} \underline{z}}(x, y, z)=\underline{z} R_{\underline{x} \underline{y} \underline{z}}(x, y, z)
\end{aligned}
$$

(Note the need in this analysis to use $(\underline{x}, \underline{y}, \underline{z})$ for the measurable particle position, since ( $x, y, z$ ) are already used for the eigenfunction arguments.)

To solve this eigenvalue problem, try again separation of variables, where it is assumed that $R_{\underline{x} \underline{y} z}(x, y, z)$ is of the form $X(x) Y(y) Z(z)$. Substitution gives the partial problem for $X$ as

$$
x X(x)=\underline{x} X(x)
$$

This equation implies that at all points $x$ not equal to $\underline{x}, X(x)$ will have to be zero, otherwise there is no way that the two sides can be equal. So, function $X(x)$ can only be nonzero at the single point $\underline{x}$. At that one point, it can be anything, though.

To resolve the ambiguity, the function $X(x)$ is taken to be the "Dirac delta function,"

$$
X(x)=\delta(x-\underline{x})
$$

The delta function is, loosely speaking, sufficiently strongly infinite at the single point $x=\underline{x}$ that its integral over that single point is one. More precisely, the delta function is defined as the limiting case of the function shown in the left hand side of figure 7.10.

Figure 7.10: Approximate Dirac delta function $\delta_{\varepsilon}(x-\underline{x})$ is shown left. The true delta function $\delta(x-\underline{x})$ is the limit when $\varepsilon$ becomes zero, and is an infinitely high, infinitely thin spike, shown right. It is the eigenfunction corresponding to a position $\underline{x}$.

The fact that the integral is one leads to a very useful mathematical property of delta functions: they are able to pick out one specific value of any arbitrary given function $f(x)$. Just take an inner product of the delta function $\delta(x-\underline{x})$ with $f(x)$. It will produce the value of $f(x)$ at the point $\underline{x}$, in other words, $f(\underline{x})$ :

$$
\begin{equation*}
\langle\delta(x-\underline{x}) \mid f(x)\rangle=\int_{x=-\infty}^{\infty} \delta(x-\underline{x}) f(x) \mathrm{d} x=\int_{x=-\infty}^{\infty} \delta(x-\underline{x}) f(\underline{x}) \mathrm{d} x=f(\underline{x}) \tag{7.49}
\end{equation*}
$$

(Since the delta function is zero at all points except $\underline{x}$, it does not make a difference whether $f(x)$ or $f(\underline{x})$ is used in the integral.) This is sometimes called the "filtering property" of the delta function.

The problems for the position eigenfunctions $Y$ and $Z$ are the same as the one for $X$, and have a similar solution. The complete eigenfunction corresponding to a measured position $(\underline{x}, \underline{y}, \underline{z})$ is therefore:

$$
\begin{equation*}
R_{\underline{x} \underline{z} \underline{z}}(x, y, z)=\delta(x-\underline{x}) \delta(y-\underline{y}) \delta(z-\underline{z}) \equiv \delta^{3}(\vec{r}-\underline{\vec{r}}) \tag{7.50}
\end{equation*}
$$

Here $\delta^{3}(\vec{r}-\vec{r})$ is the three-dimensional delta function, a spike at position $\vec{r}$ whose volume integral equals one.

According to the orthodox interpretation, the probability of finding the particle at $(\underline{x}, \underline{y}, \underline{z})$ for a given wave function $\Psi$ should be the square magnitude of the coefficient $c_{\underline{x y z}}$ of the eigenfunction. This coefficient can be found as an inner product:

$$
c_{\underline{x y} \underline{y}}(t)=\langle\delta(x-\underline{x}) \delta(y-\underline{y}) \delta(z-\underline{z}) \mid \Psi\rangle
$$

It can be simplified to

$$
\begin{equation*}
c_{\underline{x} \underline{y} \underline{z}}(t)=\Psi(\underline{x}, \underline{y}, \underline{z} ; t) \tag{7.51}
\end{equation*}
$$

because of the property of the delta functions to pick out the corresponding function value.

However, the apparent conclusion that $|\Psi(\underline{x}, \underline{y}, \underline{z} ; t)|^{2}$ gives the probability of finding the particle at $(\underline{x}, \underline{y}, \underline{z})$ is wrong. The reason it fails is that eigenfunctions should be normalized; the integral of their square should be one. The integral of the square of a delta function is infinite, not one. That is OK, however; $\vec{r}$ is a continuously varying variable, and the chances of finding the particle at $(\underline{x}, \underline{y}, \underline{z})$ to an infinite number of digits accurate would be zero. So, the properly normalized eigenfunctions would have been useless anyway.

Instead, according to Born's statistical interpretation of chapter 3.1, the expression

$$
|\Psi(x, y, z ; t)|^{2} \mathrm{~d} x \mathrm{~d} y \mathrm{~d} z
$$

gives the probability of finding the particle in an infinitesimal volume $\mathrm{d} x \mathrm{~d} y \mathrm{~d} z$ around $(x, y, z)$. In other words, $|\Psi(x, y, z ; t)|^{2}$ gives the probability of finding the particle near location $(x, y, z)$ per unit volume. (The underlines below the position coordinates are no longer needed to avoid ambiguity and have been dropped.)

Besides the normalization issue, another idea that needs to be somewhat modified is a strict collapse of the wave function. Any position measurement that can be done will leave some uncertainty about the precise location of the particle: it will leave $\Psi(x, y, z ; t)$ nonzero over a small range of positions, rather than just one position. Moreover, unlike energy eigenstates, position eigenstates are not stationary: after a position measurement, $\Psi$ will again spread out as time increases.

## Key Points

$0-$ Position eigenfunctions are delta functions.
$0-$ They are not properly normalized.
$0-$ The coefficient of the position eigenfunction for a position $(x, y, z)$ is the good old wave function $\Psi(x, y, z ; t)$.
$0-$ Because of the fact that the delta functions are not normalized, the square magnitude of $\Psi(x, y, z ; t)$ does not give the probability that the particle is at position $(x, y, z)$.
$0=$ Instead the square magnitude of $\Psi(x, y, z ; t)$ gives the probability that the particle is near position $(x, y, z)$ per unit volume.
$0-$ Position eigenfunctions are not stationary, so localized particle wave functions will spread out over time.

### 7.9.2 The linear momentum eigenfunction

Turning now to linear momentum, the eigenfunction that corresponds to a precise linear momentum $\left(p_{x}, p_{y}, p_{z}\right)$ will be indicated as $P_{p_{x} p_{y} p_{z}}(x, y, z)$. If you again assume that this eigenfunction is of the form $X(x) Y(y) Z(z)$, the partial problem for $X$ is found to be:

$$
\frac{\hbar}{\mathrm{i}} \frac{\partial X(x)}{\partial x}=p_{x} X(x)
$$

The solution is a complex exponential:

$$
X(x)=A e^{\mathrm{i} p_{x} x / \hbar}
$$

where $A$ is a constant.
Just like the position eigenfunction earlier, the linear momentum eigenfunction has a normalization problem. In particular, since it does not become small at large $|x|$, the integral of its square is infinite, not one. The solution is to ignore the problem and to just take a nonzero value for $A$; the choice that works out best is to take:

$$
A=\frac{1}{\sqrt{2 \pi \hbar}}
$$

(However, other books, in particular nonquantum ones, are likely to make a different choice.)

The problems for the $y$ and $z$ linear momenta have similar solutions, so the full eigenfunction for linear momentum takes the form:

$$
\begin{equation*}
P_{p_{x} p_{y} p_{z}}(x, y, z)=\frac{1}{\sqrt{2 \pi \hbar}} e^{\mathrm{i}\left(p_{x} x+p_{y} y+p_{z} z\right) / \hbar} \tag{7.52}
\end{equation*}
$$

The coefficient $c_{p_{x} p_{y} p_{z}}(t)$ of the momentum eigenfunction is very important in quantum analysis. It is indicated by the special symbol $\Phi\left(p_{x}, p_{y}, p_{z} ; t\right)$ and called the "momentum space wave function." Like all coefficients, it can be found by taking an inner product of the eigenfunction with the wave function:

$$
\begin{equation*}
\Phi\left(p_{x}, p_{y}, p_{z} ; t\right)=\frac{1}{\sqrt{2 \pi \hbar}^{3}}\left\langle e^{\mathrm{i}\left(p_{x} x+p_{y} y+p_{z} z\right) / \hbar} \mid \Psi\right\rangle \tag{7.53}
\end{equation*}
$$

The momentum space wave function does not quite give the probability for the momentum to be ( $p_{x}, p_{y}, p_{z}$ ). Instead it turns out that

$$
\left|\Phi\left(p_{x}, p_{y}, p_{z} ; t\right)\right|^{2} \mathrm{~d} p_{x} \mathrm{~d} p_{y} \mathrm{~d} p_{z}
$$

gives the probability of finding the linear momentum within a small momentum range $\mathrm{d} p_{x} \mathrm{~d} p_{y} \mathrm{~d} p_{z}$ around $\left(p_{x}, p_{y}, p_{z}\right)$. In other words, $\left|\Phi\left(p_{x}, p_{y}, p_{z} ; t\right)\right|^{2}$ gives the probability of finding the particle with a momentum near $\left(p_{x}, p_{y}, p_{z}\right)$ per unit "momentum space volume." That is much like the square magnitude $|\Psi(x, y, z ; t)|^{2}$ of the normal wave function gives the probability of finding the particle near location ( $x, y, z$ ) per unit physical volume. The momentum space wave function $\Phi$ is in the momentum space $\left(p_{x}, p_{y}, p_{z}\right)$ what the normal wave function $\Psi$ is in the physical space $(x, y, z)$.

There is even an inverse relationship to recover $\Psi$ from $\Phi$, and it is easy to remember:

$$
\begin{equation*}
\Psi(x, y, z ; t)=\frac{1}{\sqrt{2 \pi \hbar}^{3}}\left\langle e^{-\mathrm{i}\left(p_{x} x+p_{y} y+p_{z} z\right) / \hbar} \mid \Phi\right\rangle_{\vec{p}} \tag{7.54}
\end{equation*}
$$

where the subscript on the inner product indicates that the integration is over momentum space rather than physical space.

If this inner product is written out, it reads:

$$
\begin{equation*}
\Psi(x, y, z ; t)=\frac{1}{\sqrt{2 \pi \hbar}^{3}} \iiint_{\text {all }} \Phi\left(p_{x}, p_{y}, p_{z} ; t\right) e^{\mathrm{i}\left(p_{x} x+p_{y} y+p_{z} z\right) / \hbar} \mathrm{d} p_{x} \mathrm{~d} p_{y} \mathrm{~d} p_{z} \tag{7.55}
\end{equation*}
$$

Mathematicians prove this formula under the name "Fourier Inversion Theorem", $\{$ A. 26$\}$. But it really is just the same sort of idea as writing $\Psi$ as a sum of eigenfunctions $\psi_{n}$ times their coefficients $c_{n}$, as in $\Psi=\sum_{n} c_{n} \psi_{n}$. In this case, the coefficients are given by $\Phi$ and the eigenfunctions by the exponential (7.52). The only real difference is that the sum has become an integral since $\vec{p}$ has continuous values, not discrete ones.

## Key Points

$0-$ The linear momentum eigenfunctions are complex exponentials of the form:

$$
\frac{1}{\sqrt{2 \pi \hbar}^{3}} e^{\mathrm{i}\left(p_{x} x+p_{y} y+p_{z} z\right) / \hbar}
$$

0 - They are not properly normalized.
$0-$ The coefficient of the linear momentum eigenfunction for a momentum $\left(p_{x}, p_{y}, p_{z}\right)$ is indicated by $\Phi\left(p_{x}, p_{y}, p_{z} ; t\right)$. It is called the momentum space wave function.
$0-$ Because of the fact that the momentum eigenfunctions are not normalized, the square magnitude of $\Phi\left(p_{x}, p_{y}, p_{z} ; t\right)$ does not give the probability that the particle has momentum ( $p_{x}, p_{y}, p_{z}$ ).

0 - Instead the square magnitude of $\Phi\left(p_{x}, p_{y}, p_{z} ; t\right)$ gives the probability that the particle has a momentum close to $\left(p_{x}, p_{y}, p_{z}\right)$ per unit momentum space volume.
$0-$ In writing the complete wave function in terms of the momentum eigenfunctions, you must integrate over the momentum instead of sum.
$0-$ The transformation between the physical space wave function $\Psi$ and the momentum space wave function $\Phi$ is called the Fourier transform. It is invertible.

### 7.10 Wave Packets

This section gives a full description of the motion of a particle according to quantum mechanics. It will be assumed that the particle is in free space, so that the potential energy is zero. In addition, to keep the analysis concise and the results easy to graph, it will be assumed that the motion is only in the $x$-direction. The results may easily be extended to three dimensions by using separation of variables.

One thing that the analysis will show is how limiting the uncertainty in both momentum and position produces the various features of classical Newtonian motion. It may be recalled that in Newtonian motion through free space, the linear momentum $p$ is constant. In addition, since $p / m$ is the velocity $v$, the classical particle will move at constant speed. So classical Newtonian motion would say:

$$
v=\frac{p}{m}=\text { constant } \quad x=v t+x_{0} \quad \text { for Newtonian motion in free space }
$$

(Note that $p$ is used to indicate $p_{x}$ in this and the following sections.)

### 7.10.1 Solution of the Schrödinger equation.

As discussed in section 7.1, the unsteady evolution of a quantum system may be determined by finding the eigenfunctions of the Hamiltonian and giving them coefficients that are proportional to $e^{-\mathrm{i} E t / \hbar}$. This will be worked out in this subsection.

For a free particle, there is only kinetic energy, so in one dimension the Hamiltonian eigenvalue problem is:

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \psi}{\partial x^{2}}=E \psi \tag{7.56}
\end{equation*}
$$

Solutions to this equation take the form of exponentials

$$
\psi_{E}=A e^{ \pm \mathrm{i} \sqrt{2 m E} x / \hbar}
$$

where $A$ is a constant.
Note that $E$ must be positive: if the square root would be imaginary, the solution would blow up exponentially at large positive or negative $x$. Since the square magnitude of $\psi$ at a point gives the probability of finding the particle near that position, blow up at infinity would imply that the particle must be at infinity with certainty.

The energy eigenfunction above is really the same as the eigenfunction of the $x$-momentum operator $\widehat{p}_{x}$ derived in the previous section:

$$
\begin{equation*}
\psi_{E}=\frac{1}{\sqrt{2 \pi \hbar}} e^{\mathrm{i} p x / \hbar} \quad \text { with } p= \pm \sqrt{2 m E} \tag{7.57}
\end{equation*}
$$

The reason that the momentum eigenfunctions are also energy eigenfunctions is that the energy is all kinetic energy, and the kinetic operator equals $\widehat{T}=\widehat{p}^{2} / 2 m$. So eigenfunctions with precise momentum $p$ have precise energy $p^{2} / 2 m$.

As shown by (7.55) in the previous section, combinations of momentum eigenfunctions take the form of an integral rather than a sum. In the one-dimensional case that integral is:

$$
\Psi(x, t)=\frac{1}{\sqrt{2 \pi \hbar}} \int_{-\infty}^{\infty} \Phi(p, t) e^{\mathrm{i} p x / \hbar} \mathrm{d} p
$$

where $\Phi(p, t)$ is called the momentum space wave function.
Whether a sum or an integral, the Schrödinger equation still requires that the coefficient of each energy eigenfunction varies in time proportional to $e^{-\mathrm{i} E t / \hbar}$. The coefficient here is the momentum space wave function $\Phi$, and the energy is $E=p^{2} / 2 m$, so the solution of the Schrödinger equation must be:

$$
\begin{equation*}
\Psi(x, t)=\frac{1}{\sqrt{2 \pi \hbar}} \int_{-\infty}^{\infty} \Phi_{0}(p) e^{\mathrm{i} p\left(x-\frac{p}{2 m} t\right) / \hbar} \mathrm{d} p \tag{7.58}
\end{equation*}
$$

Here $\Phi_{0}(p) \equiv \Phi(p, 0)$ is determined by whatever initial conditions are relevant to the situation that is to be described. The above integral is the final solution for a particle in free space.

## Key Points

$0-$ In free space, momentum eigenfunctions are also energy eigenfunctions.

0 - The one-dimensional wave function for a particle in free space is given by (7.58).
0 - The function $\Phi_{0}$ is still to be chosen to produce whatever physical situation is to be described.

### 7.10.2 Component wave solutions

Before trying to interpret the complete obtained solution (7.58) for the wave function of a particle in free space, it is instructive first to have a look at the component solutions, defined by

$$
\begin{equation*}
\psi_{\mathrm{w}} \equiv e^{\mathrm{i} p\left(x-\frac{p}{2 m} t\right) / \hbar} \tag{7.59}
\end{equation*}
$$

These solutions will be called component waves; both their real and imaginary parts are sinusoidal, as can be seen from the Euler formula (2.5).

$$
\psi_{\mathrm{w}}=\cos \left(p\left(x-\frac{p}{2 m} t\right) / \hbar\right)+\mathrm{i} \sin \left(p\left(x-\frac{p}{2 m} t\right) / \hbar\right)
$$

In figure 7.11, the real part of the wave (in other words, the cosine), is sketched as the red curve; also the magnitude of the wave (which is unity) is shown as the top black line, and minus the magnitude is drawn as the bottom black line. The black lines enclose the real part of the wave, and will be called

Figure 7.11: The real part (red) and envelope (black) of an example wave.
the "envelope." Since their vertical separation is twice the magnitude of the wave function, the vertical separation between the black lines at a point is a measure for the probability of finding the particle near that point.

The constant separation between the black lines shows that there is absolutely no localization of the particle to any particular region. The particle is equally likely to be found at every point in the infinite range. This also graphically demonstrates the normalization problem of the momentum eigenfunctions discussed in the previous section: the total probability of finding the particle just keeps getting bigger and bigger, the larger the range you look in. So there is no way that the total probability of finding the particle can be limited to one as it should be.

The reason for the complete lack of localization is the fact that the component wave solutions have an exact momentum $p$. With zero uncertainty in momentum, Heisenberg's uncertainty relationship says that there must be infinite uncertainty in position. There is.

There is another funny thing about the component waves: when plotted for different times, it is seen that the real part of the wave moves towards the right with a speed $p / 2 m=\frac{1}{2} v$, as illustrated in figure 7.12.

This is unexpected, because classically the particle moves with speed $v$, not $\frac{1}{2} v$. The problem is that the speed with which the wave moves, called the "phase speed," is not meaningful physically. In fact, without anything like a location

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/wavemv.gif
Figure 7.12: The wave moves with the phase speed.
for the particle, there is no way to define a physical velocity for a component wave.

## Key Points

0 - Component waves provide no localization of the particle at all.
0 - Their real part is a moving cosine. Similarly their imaginary part is a moving sine.
$0-$ The speed of motion of the cosine or sine is half the speed of a classical particle with that momentum.
$0-$ This speed is called the phase speed and is not relevant physically.

### 7.10.3 Wave packets

As Heisenberg's principle indicates, in order to get some localization of the position of a particle, some uncertainty must be allowed in momentum. That means that you must take the initial momentum space wave function $\Phi_{0}$ in (7.58) to be nonzero over at least some small interval of different momentum values $p$. Such a combination of component waves is called a "wave packet".

The wave function for a typical wave packet is sketched in figure 7.13. The red line is again the real part of the wave function, and the black lines are the envelope enclosing the wave; they equal plus and minus the magnitude of the wave function.

Figure 7.13: The real part (red) and magnitude or envelope (black) of a wave packet. (Schematic).

The vertical separation between the black lines is again a measure of the probability of finding the particle near that location. It is seen that the possible
locations of the particle are now restricted to a finite region, the region in which the vertical distance between the black lines is nonzero.

If the envelope changes location with time, and it does, then so does the region where the particle can be found. This then finally is the correct picture of motion in quantum mechanics: the region in which the particle can be found propagates through space.

The limiting case of the motion of a macroscopic Newtonian point mass can now be better understood. As noted in section 7.2.1, for such a particle the uncertainty in position is negligible. The wave packet in which the particle can be found, as sketched in figure 7.13 , is so small that it can be considered to be a point. To that approximation the particle then has a point position, which is the normal classical description.

The classical description also requires that the particle moves with velocity $u=p / m$, which is twice the speed $p / 2 m$ of the wave. So the envelope should move twice as fast as the wave. This is indicated in figure 7.14 by the length of the bars, which show the motion of a point on the envelope and of a point on the wave during a small time interval.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/packetmv.gif
Figure 7.14: The velocities of wave and envelope are not equal.
That the envelope does indeed move at speed $p / m$ can be seen if you define the representative position of the envelope to be the expectation value of position. That position must be somewhere in the middle of the wave packet. The expectation value of position moves according to Ehrenfest's theorem of section 7.2.1 with a speed $\langle p\rangle / m$, where $\langle p\rangle$ is the expectation value of momentum, which must be constant since there is no force. Since the uncertainty in momentum is small for a macroscopic particle, the expectation value of momentum $\langle p\rangle$ can be taken to be "the" momentum $p$.

## Key Points

$0-$ A wave packet is a combination of waves with about the same momentum.
$0-$ Combining waves into wave packets can provide localization of particles.
0- The envelope of the wave packet shows the region where the particle is likely to be found.
$0-$ This region propagates with the classical particle velocity.

### 7.10.4 Group velocity

As the previous subsection explained, particle motion in classical mechanics is equivalent to the motion of wave packets in quantum mechanics. Motion of a wave packet implies that the region in which the particle can be found changes position.

Motion of wave packets is not just important for understanding where particles in free space end up. It is also critical for the quantum mechanics of for example solids, in which electrons, photons, and phonons (quanta of crystal vibrations) move around in an environment that is cluttered with other particles. And it is also of great importance in classical applications, such as acoustics in solids and fluids, water waves, stability theory of flows, electromagnetodynamics, etcetera. This section explains how wave packets move in such more general systems. Only the one-dimensional case will be considered, but the generalization to three dimensions is straightforward.

The systems of interest have component wave solutions of the general form:

$$
\begin{equation*}
\text { component wave: } \quad \psi_{\mathrm{w}}=e^{\mathrm{i}(k x-\omega t)} \tag{7.60}
\end{equation*}
$$

The constant $k$ is called the "wave number," and $\omega$ the "angular frequency." The wave number and frequency must be real for the analysis in this section to apply. That means that the magnitude of the component waves must not change with space nor time. Such systems are called nondissipative: although a combination of waves may get dispersed over space, its square magnitude integral will be conserved. (This is true on account of Parseval's relation, \{A.26\}.)

For a particle in free space according to the previous subsection:

$$
k=\frac{p}{\hbar} \quad \omega=\frac{p^{2}}{2 m \hbar}
$$

Therefore, for a particle in free space the wave number $k$ is just a rescaled linear momentum, and the frequency $\omega$ is just a rescaled kinetic energy. This will be different for a particle in a nontrivial surroundings.

Regardless of what kind of system it is, the relationship between the frequency and the wave number is called the

$$
\begin{equation*}
\text { dispersion relation: } \quad \omega=\omega(k) \tag{7.61}
\end{equation*}
$$

It really defines the physics of the wave propagation.
Since the waves are of the form $e^{\mathrm{i} k\left(x-\frac{\omega}{k} t\right)}$, the wave is constant if $x=(\omega / k) t$ plus any constant. Such points move with the

$$
\begin{equation*}
\text { phase velocity: } \quad v_{\mathrm{p}} \equiv \frac{\omega}{k} \tag{7.62}
\end{equation*}
$$

In free space, the phase velocity is half the classical velocity.
However, as noted in the previous subsection, wave packets do not normally move with the phase velocity. The velocity that they do move with is called the "group velocity." For a particle in free space, you can infer that the group velocity is the same as the classical velocity from Ehrenfest's theorem, but that does not work for more general systems. The approach will therefore be to simply define the group velocity as

$$
\begin{equation*}
\text { group velocity: } \quad v_{\mathrm{g}} \equiv \frac{\mathrm{~d} \omega}{\mathrm{~d} k} \tag{7.63}
\end{equation*}
$$

and then to explore how the so-defined group velocity relates to the motion of wave packets.

Wave packets are combinations of component waves, and the most general combination of waves takes the form

$$
\begin{equation*}
\Psi(x, t)=\frac{1}{\sqrt{2 \pi}} \int_{-\infty}^{\infty} \bar{\Phi}_{0}(k) e^{\mathrm{i}(k x-\omega t)} \mathrm{d} k \tag{7.64}
\end{equation*}
$$

Here $\bar{\Phi}_{0}$ is the complex amplitude of the waves. The combination $\bar{\Phi}_{0} e^{-\mathrm{i} \omega t}$ is called the "Fourier transform" of $\Psi$. The factor $\sqrt{2 \pi}$ is just a normalization factor that might be chosen differently in another book. Wave packets correspond to combinations in which the complex amplitude $\bar{\Phi}_{0}(k)$ is only nonzero in a small range of wave numbers $k$. More general combinations of waves may of course always be split up into such wave packets.

To describe the motion of wave packets is not quite as straightforward as it may seem: the envelope of a wave packet extends over a finite region, and different points on it actually move at somewhat different speeds. So what do you take as the point that defines the motion if you want to be precise? There is a trick here: consider very long times. For large times, the propagation distance is so large that it dwarfs the ambiguity about what point to take as the position of the envelope.

Finding the wave function $\Psi$ for large time is a messy exercise banned to derivation $\{$ D. 44$\}$. But the conclusions are fairly straightforward. Assume that the range of waves in the packet is restricted to some small interval $k_{1}<k<k_{2}$. In particular, assume that the variation in group velocity is relatively small and monotonous. In that case, for large times the wave function will be negligibly small except in the region

$$
v_{\mathrm{g} 1} t<x<v_{\mathrm{g} 2} t
$$

(In case $v_{\mathrm{g} 1}>v_{\mathrm{g} 2}$, invert these inequalities.) Since the variation in group velocity is small for the packet, it therefore definitely does move with "the" group velocity.

It is not just possible to say where the wave function is nonzero at large times. It is also possible to write a complete approximate wave function for large times:

$$
\Psi(x, t) \sim \frac{e^{\mp \mathrm{i} \pi / 4}}{\sqrt{\left|v_{\mathrm{g} 0}^{\prime}\right| t}} \bar{\Phi}_{0}\left(k_{0}\right) e^{\mathrm{i}\left(k_{0} x-\omega_{0} t\right)} \quad v_{\mathrm{g} 0}=\frac{x}{t}
$$

Here $k_{0}$ is the wave number at which the group speed is exactly equal to $x / t, \omega_{0}$ is the corresponding frequency, $v_{\mathrm{g} 0}^{\prime}$ is the derivative of the group speed at that point, and $\mp$ stands for the sign of $-v_{\mathrm{g} 0}^{\prime}$.

While this precise expression may not be that important, it is interesting to note that $\Psi$ decreases in magnitude proportional to $1 / \sqrt{t}$. That can be understood from conservation of the probability to find the particle. The wave packet spreads out proportional to time because of the small but nonzero variation in group velocity. Therefore $\Psi$ must be proportional to $1 / \sqrt{t}$ if its square integral is to remain unchanged.

One other interesting feature may be deduced from the above expression for $\Psi$. If you examine the wave function on the scale of a few oscillations, it looks as if it was a single component wave of wave number $k_{0}$ and frequency $\omega_{0}$. Only if you look on a bigger scale do you see that it really is a wave packet. To understand why, just look at the differential

$$
\mathrm{d}\left(k_{0} x-\omega_{0} t\right)=k_{0} \mathrm{~d} x-\omega_{0} \mathrm{~d} t+x \mathrm{~d} k_{0}-t \mathrm{~d} \omega_{0}
$$

and observe that the final two terms cancel because $\mathrm{d} \omega_{0} / \mathrm{d} k_{0}$ is the group velocity, which equals $x / t$. Therefore changes in $k_{0}$ and $\omega_{0}$ do not show up on a small scale.

For the particle in free space, the result for the large time wave function can be written out further to give

$$
\Psi(x, t) \sim e^{-\mathrm{i} \pi / 4} \sqrt{\frac{m}{t}} \Phi_{0}\left(\frac{m x}{t}\right) e^{\mathrm{i} m x^{2} / 2 \hbar t}
$$

Since the group speed $p / m$ in this case is monotonously increasing, the wave packets have negligible overlap, and this is in fact the large time solution for any combination of waves, not just narrow wave packets.

In a typical true quantum mechanics case, $\Phi_{0}$ will extend over a range of wave numbers that is not small, and may include both positive and negative values of the momentum $p$. So, there is no longer a meaningful velocity for the wave function: the wave function spreads out in all directions at velocities ranging from negative to positive. For example, if the momentum space wave function $\Phi_{0}$ consists of two narrow nonzero regions, one at a positive value of $p$ and one at a negative value, then the wave function in normal space splits into two separate wave packets. One packet moves with constant speed towards the left, the other with constant speed towards the right. The same particle is now
going in two completely different directions at the same time. That would be unheard of in classical Newtonian mechanics.

## Key Points

$0-$ Component waves have the generic form $e^{\mathrm{i}(k x-\omega t)}$.
$0-$ The constant $k$ is the wave number.
$0-$ The constant $\omega$ is the angular frequency.
$0-$ The relation between $\omega$ and $k$ is called the dispersion relation.
$0-$ The phase velocity is $\omega / k$. It describes how fast the wave moves.
$0-$ The group velocity is $\mathrm{d} \omega / \mathrm{d} k$. It describes how fast wave packets move.
$0=$ Relatively simple expressions exist for the wave function of wave packets at large times.

### 7.10.5 Electron motion through crystals

One important application of group velocity is the motion of conduction electrons through crystalline solids. This subsection discusses it.

Conduction electrons in solids must move around the atoms that make up the solid. You cannot just forget about these atoms in discussing the motion of the conduction electrons. Even semi-classically speaking, the electrons in a solid move in a roller-coaster ride around the atoms. Any external force on the electrons is on top of the large forces that the crystal already exerts. So it is simply wrong to say that the external force gives mass times acceleration of the electrons. Only the total force would do that.

Typically, on a microscopic scale the solid is crystalline; in other words, the atoms are arranged in a periodic pattern. That means that the forces on the electrons have a periodic nature. As usual, any direct interactions between particles will be ignored as too complex to analyze. Therefore, it will be assumed that the potential energy seen by an electron is a given periodic function of position.

It will also again be assumed that the motion is one-dimensional. In that case the energy eigenfunctions are determined from a one-dimensional Hamiltonian eigenvalue problem of the form

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \frac{\partial^{2} \psi}{\partial x^{2}}+V(x) \psi=E \psi \tag{7.65}
\end{equation*}
$$

Here $V(x)$ is a periodic potential energy, with some given atomic-scale period $d$.

Three-dimensional energy eigenfunctions may be found as products of onedimensional ones; compare chapter 3.5.8. Unfortunately however, that only works here if the three-dimensional potential is some sum of one-dimensional ones, as in

$$
V(x, y, z)=V_{x}(x)+V_{y}(y)+V_{z}(z)
$$

That is really quite limiting. The general conclusions that will be reached in this subsection continue to apply for any periodic potential, not just a sum of one-dimensional ones.

The energy eigenfunction solutions to (7.65) take the form of "Bloch waves:"

$$
\begin{equation*}
\psi_{k}^{\mathrm{p}}(x)=\psi_{\mathrm{p}, k}^{\mathrm{p}}(x) e^{\mathrm{i} k x} \tag{7.66}
\end{equation*}
$$

where $\psi_{\mathrm{p}, k}^{\mathrm{p}}$ is a periodic function of period $d$ like the potential.
The reason that the energy eigenfunctions take the form of Bloch waves is not that difficult to understand. It is a consequence of the fact that commuting operators have common eigenfunctions, chapter 4.5.1. Consider the "translation operator" $\mathcal{T}_{d}$ that shifts wave functions over one atomic period $d$. Since the potential is exactly the same after a wave function is shifted over an atomic period, the Hamiltonian commutes with the translation operator. It makes no difference whether you apply the Hamiltonian before or after you shift a wave function over an atomic period. Therefore, the energy eigenfunctions can be taken to be also eigenfunctions of the translation operator. The translation eigenvalue must have magnitude one, since the magnitude of a wave function does not change when you merely shift it. Therefore the eigenvalue can always be written as $e^{i k d}$ for some real value $k$. And that means that if you write the eigenfunction in the Bloch form (7.66), then the exponential will produce the eigenvalue during a shift. So the part $\psi_{\mathrm{p}, k}^{\mathrm{p}}$ must be the same after the shift. Which means that it is periodic of period $d$. (Note that you can always write any wave function in Bloch form; the nontrivial part is that $\psi_{\mathrm{p}, k}^{\mathrm{p}}$ is periodic for actual Bloch waves.)

If the crystal is infinite in size, the wave number $k$ can take any value. (For a crystal in a finite-size periodic box as studied in chapter 6.22 , the values of $k$ are discrete. However, this subsection will assume an infinite crystal.)

To understand what the Bloch form means for the electron motion, first consider the case that the periodic factor $\psi_{\mathrm{p}, k}^{\mathrm{p}}$ is just a trivial constant. In that case the Bloch waves are eigenfunctions of linear momentum. The linear momentum $p$ is then $\hbar k$. That case applies if the crystal potential is just a trivial constant. In particular, it is true if the electron is in free space.

Even if there is a nontrivial crystal potential, the so-called "crystal momentum" is still defined as:

$$
\begin{equation*}
p_{\mathrm{cm}}=\hbar k \tag{7.67}
\end{equation*}
$$

(In three dimensions, substitute the vectors $\vec{p}$ and $\vec{k}$ ). But crystal momentum is not normal momentum. In particular, for an electron in a crystal you can no
longer get the propagation velocity by dividing the crystal momentum by the mass.

Instead you can get the propagation velocity by differentiating the energy with respect to the crystal momentum, $\{\mathrm{D} .45\}$ :

$$
\begin{equation*}
v=\frac{\mathrm{d} E^{\mathrm{p}}}{\mathrm{~d} p_{\mathrm{cm}}} \quad p_{\mathrm{cm}}=\hbar k \tag{7.68}
\end{equation*}
$$

(In three dimensions, replace the $p$-derivative by $1 / \hbar$ times the gradient with respect to $\vec{k}$.) In free space, $E^{\mathrm{p}}=\hbar \omega$ and $p_{\mathrm{cm}}=\hbar k$, so the above expression for the electron velocity is just the expression for the group velocity.

One conclusion that can be drawn is that electrons in an ideal crystal keep moving with the same speed for all times like they do in free space. They do not get scattered at all. The reason is that energy eigenfunctions are stationary. Each eigenfunction corresponds to a single value of $k$ and so to a corresponding single value of the propagation speed $v$ above. An electron wave packet will involve a small range of energy eigenfunctions, and a corresponding small range of velocities. But since the range of energy eigenfunctions does not change with time, neither does the range of velocities. Scattering, which implies a change in velocity, does not occur.

This perfectly organized motion of electrons through crystals is quite surprising. If you make up a classical picture of an electron moving through a crystal, you would expect that the electron would pretty much bounce off every atom it encountered. It would then perform a drunkard's walk from atom to atom. That would really slow down electrical conduction. But it does not happen. And indeed, experimentally electrons in metals may move past many thousands of atoms without getting scattered. In very pure copper at very low cryogenic temperatures electrons may even move past many millions of atoms before getting scattered.

Note that a total lack of scattering only applies to truly ideal crystals. Electrons can still get scattered by impurities or other crystal defects. More importantly, at normal temperatures the atoms in the crystal are not exactly in their right positions due to thermal motion. That too can scatter electrons. In quantum terms, the electrons then collide with the phonons of the crystal vibrations. The details are too complex to be treated here, but it explains why metals conduct much better still at cryogenic temperatures than at room temperature.

The next question is how does the propagation velocity of the electron change if an external force $F_{\text {ext }}$ is applied? It turns out that Newton's second law, in terms of momentum, still works if you substitute the crystal momentum $\hbar k$ for the normal momentum, $\{\mathrm{D} .45\}$ :

$$
\begin{equation*}
\frac{\mathrm{d} p_{\mathrm{cm}}}{\mathrm{~d} t}=F_{\text {ext }} \quad p_{\mathrm{cm}}=\hbar k \tag{7.69}
\end{equation*}
$$

However, since the velocity is not just the crystal momentum divided by the mass, you cannot convert the left hand side to the usual mass times acceleration. The acceleration is instead, using the chain rule of differentiation,

$$
\frac{\mathrm{d} v}{\mathrm{~d} t}=\frac{\mathrm{d}^{2} E^{\mathrm{p}}}{\mathrm{~d} p_{\mathrm{cm}}^{2}} \frac{\mathrm{~d} p_{\mathrm{cm}}}{\mathrm{~d} t}=\frac{\mathrm{d}^{2} E^{\mathrm{p}}}{\mathrm{~d} p_{\mathrm{cm}}^{2}} F_{\mathrm{ext}}
$$

For mass times acceleration to be the force, the factor multiplying the force in the final expression would have to be the reciprocal of the electron mass. It clearly is not; in general it is not even a constant.

But physicists still like to think of the effect of force as mass times acceleration of the electrons. So they cheat. They ignore the true mass of the electron. Instead they simply define a new "effective mass" for the electron so that the external force equals that effective mass times the acceleration:

$$
\begin{equation*}
m_{\mathrm{eff}} \equiv 1 / \frac{\mathrm{d}^{2} E^{\mathrm{p}}}{\mathrm{~d} p_{\mathrm{cm}}^{2}} \quad p_{\mathrm{cm}}=\hbar k \tag{7.70}
\end{equation*}
$$

Unfortunately, the effective mass is often a completely different number than the true mass of the electron. Indeed, it is quite possible for this "mass" to become negative for some range of wave numbers. Physically that means that if you put a force on the electron that pushes it one way, it will accelerate in the opposite direction! That can really happen. It is a consequence of the wave nature of quantum mechanics. Waves in crystals can be reflected just like electromagnetic waves can, and a force on the electron may move it towards stronger reflection.

For electrons near the bottom of the conduction band, the effective mass idea may be a bit more intuitive. At the bottom of the conduction band, the energy has a minimum. From calculus, if the energy $E^{\mathrm{p}}$ has a minimum at some wave number vector, then in a suitably oriented axis system it can be written as the Taylor series

$$
E^{\mathrm{p}}=E_{\min }^{\mathrm{p}}+\frac{1}{2} \frac{\partial^{2} E^{\mathrm{p}}}{\partial k_{x}^{2}} k_{x}^{2}+\frac{1}{2} \frac{\partial^{2} E^{\mathrm{p}}}{\partial k_{y}^{2}} k_{y}^{2}+\frac{1}{2} \frac{\partial^{2} E^{\mathrm{p}}}{\partial k_{z}^{2}} k_{z}^{2}+\ldots
$$

Here the wave number values are measured from the position of the minimum. This can be rewritten in terms of the crystal momenta and effective masses in each direction as

$$
\begin{equation*}
E^{\mathrm{p}}=E_{\min }^{\mathrm{p}}+\frac{1}{2} \frac{1}{m_{\mathrm{eff}, x}} p_{\mathrm{cm}, x}^{2}+\frac{1}{2} \frac{1}{m_{\mathrm{eff}, y}} p_{\mathrm{cm}, y}^{2}+\frac{1}{2} \frac{1}{m_{\mathrm{eff}, z}} p_{\mathrm{cm}, z}^{2}+\ldots \tag{7.71}
\end{equation*}
$$

In this case the effective masses are indeed positive, since second derivatives must be positive near a minimum. These electrons act much like classical particles. They move in the right direction if you put a force on them. Unfortunately,
the effective masses are not necessarily similar to the true electron mass, or even the same in each direction.

For the effective mass of the holes at the top of a valence band things get much messier still. For typical semiconductors, the energy no longer behaves as an analytic function, even though the energy in a specific direction continues to vary quadratically with the magnitude of the wave number. So the Taylor series is no longer valid. You then end up with such animals as "heavy holes," "light holes," and "split-off holes." Such effects will be ignored in this book.

### 7.11 Almost Classical Motion

This section examines the motion of a particle in the presence of a single external force. Just like in the previous section, it will be assumed that the initial position and momentum are narrowed down sufficiently that the particle is restricted to a relatively small, coherent, region. Solutions of this type are called "wave packets."

In addition, for the examples in this section the forces vary slowly enough that they are approximately constant over the spatial extent of the wave packet. Hence, according to Ehrenfest's theorem, section 7.2.1, the wave packet should move according to the classical Newtonian equations.

The examples in this section were obtained on a computer, and should be numerically exact. Details about how they were computed can be found in addendum $\{$ A. 27$\}$, if you want to understand them better, or create some yourself.

There is an easy general way to find approximate energy eigenfunctions and eigenvalues applicable under the conditions used in this section. It is called the WKB method. Addendum \{A. 28$\}$ has a description.

### 7.11.1 Motion through free space

First consider the trivial case that there are no forces; a particle in free space. This will provide the basis against which the motion with forces in the next
subsections can be compared to.
Classically, a particle in free space moves at a constant velocity. In quantum mechanics, the wave packet does too; figure 7.15 shows it at two different times.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/free.gif
Hi-res: http://www.eng.famu.fsu.edu/~dommelen/quansup/freehi.html
Figure 7.15: A particle in free space.

If you step back far enough that the wave packet in the figures begins to resemble just a dot, you have classical motion. The blue point indicates the position of maximum wave function magnitude, as a visual anchor. It provides a reasonable approximation to the expectation value of position whenever the wave packet contour is more or less symmetric. A closer examination shows that the wave packet is actually changing a bit in size in addition to translating.

### 7.11.2 Accelerated motion

Figure 7.16 shows the motion when the potential energy (shown in green) ramps down starting from the middle of the plotted range. Physically this corresponds to a constant accelerating force beyond that point. A classical point particle would move at constant speed until it encounters the ramp, after which it would start accelerating at a constant rate. The quantum mechanical solution shows a corresponding acceleration of the wave packet, but in addition the wave packet stretches a lot.

Hi-res: http://www.eng.famu.fsu.edu/~dommelen/quansup/acchi.html
Figure 7.16: An accelerating particle.

### 7.11.3 Decelerated motion

Figure 7.17 shows the motion when the potential energy (shown in green) ramps up starting from the center of the plotting range. Physically this corresponds to a constant decelerating force beyond that point. A classical point particle would move at constant speed until it encounters the ramp, after which it would start decelerating until it runs out of kinetic energy; then it would be turned back, returning to where it came from.

The quantum mechanical solution shows a corresponding reflection of the wave packet back to where it came from. The black dot on the potential energy line shows the "turning point" where the potential energy becomes equal to the nominal energy of the wave packet. That is the point where classically the particle runs out of kinetic energy and is turned back.

### 7.11.4 The harmonic oscillator

The harmonic oscillator describes a particle caught in a force field that prevents it from escaping in either direction. In all three previous examples the particle could at least escape towards the far left. The harmonic oscillator was the first real quantum system that was solved, in chapter 4.1, but only now, near the end of part I, can the classical picture of a particle oscillating back and forward actually be created.

There are some mathematical differences from the previous cases, because the energy levels of the harmonic oscillator are discrete, unlike those of the particles that are able to escape. But if the energy levels are far enough above the ground state, localized wave packets similar to the ones in free space may be formed, $\{\mathrm{A} .27\}$. The animation in figure 7.18 gives the motion of a wave packet whose nominal energy is hundred times the ground state energy.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/harmmv.gif
Hi-res: http://www.eng.famu.fsu.edu/~dommelen/quansup/harmhi.html
Figure 7.18: Unsteady solution for the harmonic oscillator. The third picture shows the maximum distance from the nominal position that the wave packet reaches.

The wave packet performs a periodic oscillation back and forth just like a classical point particle would. In addition, it oscillates at the correct classical frequency $\omega$. Finally, the point of maximum wave function, shown in blue, fairly closely obeys the classical limits of motion, shown as black dots.

Curiously, the wave function does not return to the same values after one period: it has changed sign after one period and it takes two periods for the wave function to return to the same values. It is because the sign of the wave function cannot be observed physically that classically the particle oscillates at frequency $\omega$, and not at $\frac{1}{2} \omega$ like the wave function does.

## Key Points

$0-$ When the forces change slowly enough on quantum scales, wave packets move just like classical particles do.
$0-$ Examined in detail, wave packets may also change shape over time.

### 7.12 Scattering

The motion of the wave packets in section 7.11 approximated that of classical Newtonian particles. However, if the potential starts varying nontrivially over distances short enough to be comparable to a quantum wave length, much more interesting behavior results, for which there is no classical equivalent. This section gives a couple of important examples.

### 7.12.1 Partial reflection

A classical particle entering a region of changing potential will keep going as long as its total energy exceeds the potential energy. Consider the potential shown in green in figure 7.19; it drops off to a lower level and then stays there. A classical particle would accelerate to a higher speed in the region of drop off and maintain that higher speed from there on.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/drop.gif
Hi-res: http://www.eng.famu.fsu.edu/~dommelen/quansup/drophi.html
Figure 7.19: A partial reflection.
However, the potential in this example varies so rapidly on quantum scales that the classical Newtonian picture is completely wrong. What actually happens is that the wave packet splits into two, as shown in the bottom figure. One part returns to where the packet came from, the other keeps on going.

One hypothetical example used in chapter 3.1 was that of sending a single particle both to Venus and to Mars. As this example shows, a scattering setup gives a very real way of sending a single particle in two different directions at the same time.

Partial reflections are the norm for potentials that vary nontrivially on quantum scales, but this example adds a second twist. Classically, a decelerating force is needed to turn a particle back, but here the force is everywhere accelerating only! As an actual physical example of this weird behavior, neutrons trying to enter nuclei experience attractive forces that come on so quickly that they may be repelled by them.

### 7.12.2 Tunneling

A classical particle will never be able to progress past a point at which the potential energy exceeds its total energy. It will be turned back. However, the quantum mechanical truth is, if the region in which the potential energy exceeds the particle's energy is narrow enough on a quantum scale, the particle can go right through it. This effect is called "tunneling."

As an example, figure 7.20 shows part of the wave packet of a particle passing right through a region where the peak potential exceeds the particle's expectation energy by a factor three.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/tunnel.gif
Hi-res: http://www.eng.famu.fsu.edu/~dommelen/quansup/tunnelhi.html

## Figure 7.20: An tunneling particle.

Of course, the energy values have some uncertainty, but it is small. The reason the particle can pass through is not because it has a chance of having three times its nominal energy. It absolutely does not; the simulation set the probability of having more than twice the nominal energy to zero exactly. The particle has a chance of passing through because its motion is governed by the Schrödinger equation, instead of the equations of classical physics.

And if that is not convincing enough, consider the case of a delta function barrier in figure 7.21 ; the limit of an infinitely high, infinitely narrow barrier. Being infinitely high, classically nothing can get past it. But since it is also infinitely narrow, a quantum particle will hardly notice a weak-enough delta function barrier. In figure 7.21, the strength of the delta function was chosen just big enough to split the wave function into equal reflected and transmitted parts. If you look for the particle afterwards, you have a 50/50 chance of finding it at either side of this "impenetrable" barrier.

Animation: http://www.eng.famu.fsu.edu/~dommelen/quansup/del.gif Hi-res: http://www.eng.famu.fsu.edu/~dommelen/quansup/delhi.html

Figure 7.21: Penetration of an infinitely high potential energy barrier.
Curiously enough, a delta function well, (with the potential going down instead of up), reflects the same amount as the barrier version.

Tunneling has consequences for the mathematics of bound energy states. Classically, you can confine a particle by sticking it in between, say two delta function potentials, or between two other potentials that have a maximum potential energy $V$ that exceeds the particle's energy $E$. But such a particle trap does not work in quantum mechanics, because given time, the particle would
tunnel through a local potential barrier. In quantum mechanics, a particle is bound only if its energy is less than the potential energy at infinite distance. Local potential barriers only work if they have infinite potential energy, and that over a larger range than a delta function.

Note however that in many cases, the probability of a particle tunneling out is so infinitesimally small that it can be ignored. For example, since the electron in a hydrogen atom has a binding energy of 13.6 eV , a 110 or 220 V ordinary household voltage should in principle be enough for the electron to tunnel out of a hydrogen atom. But don't wait for it; it is likely to take much more than the total life time of the universe. You would have to achieve such a voltage drop within an atom-scale distance to get some action.

One major practical application of tunneling is the scanning tunneling microscope. Tunneling can also explain alpha decay of nuclei, and it is a critical part of much advanced electronics, including current leakage problems in VLSI devices.

## Key Points

$0-$ If the potential varies nontrivially on quantum scales, wave packets do not move like classical particles.
$0-$ A wave packet may split into separate parts that move in different ways.
0-A wave packet may be reflected by an accelerating force.
0-A wave packet may tunnel through regions that a classical particle could not enter.

### 7.13 Reflection and Transmission Coefficients

Scattering and tunneling can be described in terms of so-called "reflection and transmission coefficients." This section explains the underlying ideas.

Figure 7.22: Schematic of a scattering potential and the asymptotic behavior of an example energy eigenfunction for a wave packet coming in from the far left.

Consider an arbitrary scattering potential like the one in figure 7.22. To the far left and right, it is assumed that the potential assumes a constant value. In
such regions the energy eigenfunctions take the form

$$
\psi_{E}=C_{\mathrm{f}} e^{\mathrm{i} p_{c} x / \hbar}+C_{\mathrm{b}} e^{-\mathrm{i} p_{c} x / \hbar}
$$

where $p_{\mathrm{c}}=\sqrt{2 m(E-V)}$ is the classical momentum and $C_{\mathrm{f}}$ and $C_{\mathrm{b}}$ are constants. When eigenfunctions of slightly different energies are combined together, the terms $C_{\mathrm{f}} \mathrm{e}^{\mathrm{i} p_{c} x / \hbar}$ produce wave packets that move forwards in $x$, graphically from left to right, and the terms $C_{\mathrm{b}} e^{-\mathrm{i} p_{\mathrm{c}} x / \hbar}$ produce packets that move backwards. So the subscripts indicate the direction of motion.

This section is concerned with a single wave packet that comes in from the far left and is scattered by the nontrivial potential in the center region. To describe this, the coefficient $C_{\mathrm{b}}$ must be zero in the far-right region. If it was nonzero, it would produce a second wave packet coming in from the far right.

In the far-left region, the coefficient $C_{\mathrm{b}}$ is normally not zero. In fact, the term $C_{\mathrm{b}}^{\mathrm{l}} e^{-\mathrm{i} p_{\mathrm{c}} x / \hbar}$ produces the part of the incoming wave packet that is reflected back towards the far left. The relative amount of the incoming wave packet that is reflected back is called the "reflection coefficient" $R$. It gives the probability that the particle can be found to the left of the scattering region after the interaction with the scattering potential. It can be computed from the coefficients of the energy eigenfunction in the left region as, $\{\mathrm{A} .32\}$,

$$
\begin{equation*}
R=\frac{\left|C_{\mathrm{b}}^{1}\right|^{2}}{\left|C_{\mathrm{f}}^{1}\right|^{2}} \tag{7.72}
\end{equation*}
$$

Similarly, the relative fraction of the wave packet that passes through the scattering region is called the "transmission coefficient" $T$. It gives the probability that the particle can be found at the other side of the scattering region afterwards. It is most simply computed as $T=1-R$ : whatever is not reflected must pass through. Alternatively, it can be computed as

$$
\begin{equation*}
T=\frac{p_{\mathrm{c}}^{\mathrm{r}}\left|C_{\mathrm{f}}^{\mathrm{r}}\right|^{2}}{p_{\mathrm{c}}^{\mathrm{l}}\left|C_{\mathrm{f}}^{1}\right|^{2}} \quad p_{\mathrm{c}}^{1}=\sqrt{2 m\left(E-V_{1}\right)} \quad p_{\mathrm{c}}^{\mathrm{r}}=\sqrt{2 m\left(E-V_{\mathrm{r}}\right)} \tag{7.73}
\end{equation*}
$$

where $p_{\mathrm{c}}^{1}$ respectively $p_{\mathrm{c}}^{\mathrm{r}}$ are the values of the classical momentum in the far left and right regions.

Note that a coherent wave packet requires a small amount of uncertainty in energy. Using the eigenfunction at the nominal value of energy in the above expressions for the reflection and transmission coefficients will involve a small error. It can be made to go to zero by reducing the uncertainty in energy, but then the size of the wave packet will expand correspondingly.

In the case of tunneling through a high and wide barrier, the WKB approximation may be used to derive a simplified expression for the transmission coefficient, $\{\mathrm{A} .29\}$. It is

$$
\begin{equation*}
T \approx e^{-2 \gamma_{12}} \quad \gamma_{12}=\frac{1}{\hbar} \int_{x_{1}}^{x_{2}}\left|p_{\mathrm{c}}\right| \mathrm{d} x \quad\left|p_{\mathrm{c}}\right|=\sqrt{2 m(V-E)} \tag{7.74}
\end{equation*}
$$

where $x_{1}$ and $x_{2}$ are the "turning points" in figure 7.22 , in between which the potential energy exceeds the total energy of the particle.

Therefore in the WKB approximation, it is just a matter of doing a simple integral to estimate what is the probability for a wave packet to pass through a barrier. One famous application of that result is for the alpha decay of atomic nuclei. In such decay a so-called alpha particle tunnels out of the nucleus.

For similar considerations in three-dimensional scattering, see addendum \{A. 30$\}$.

## Key Points

$0=$ A transmission coefficient gives the probability for a particle to pass through an obstacle. A reflection coefficient gives the probability for it to be reflected.
$0-$ A very simple expression for these coefficients can be obtained in the WKB approximation.

## Chapter 8

## The Meaning of Quantum Mechanics

Engineers tend to be fairly matter-of-fact about the physics they use. Many use entropy on a daily basis as a computational tool without worrying much about its vague, abstract mathematical definition. Such a practical approach is even more important for quantum mechanics.

Famous quantum mechanics pioneer Niels Bohr had this to say about it:
"For those who are not shocked when they first come across quantum theory cannot possibly have understood it." [Niels Bohr, quoted in W. Heisenberg (1971) Physics and Beyond. Harper and Row.]

Feynman was a Caltech quantum physicist who received a Nobel Prize for the creation of quantum electrodynamics with Schwinger and Tomonaga. He also pioneered nanotechnology with his famous talk "There's Plenty of Room at the Bottom." About quantum mechanics, he wrote:
"There was a time when the newspapers said that only twelve men understood the theory of relativity. I do not believe there ever was such a time. There might have been a time when only one man did, because he was the only guy who caught on, before he wrote his paper. But after people read the paper, a lot of people understood the theory of relativity in some way or other, certainly more than twelve. On the other hand, I think I can safely say that nobody understands quantum mechanics." [Richard P. Feynman (1965) The Character of Physical Law 129. BBC/Penguin.]

Still, saying that quantum mechanics is ununderstandable raises the obvious question: "If we cannot understand it, does it at least seem plausible?" That is the question to be addressed in this chapter. When you read this chapter, you will see that the answer is simple and clear. Quantum mechanics is the most implausible theory ever formulated. Nobody would ever formulate a theory like
quantum mechanics in jest, because none would believe it. Physics ended up with quantum mechanics not because it seemed the most logical explanation, but because countless observations made it unavoidable.

### 8.1 Schrödinger's Cat

Schrödinger, apparently not an animal lover, came up with an example illustrating what the conceptual difficulties of quantum mechanics really mean in everyday terms. This section describes the example.

A cat is placed in a closed box. Also in the box is a Geiger counter and a tiny amount of radioactive material that will cause the Geiger counter to go off in a typical time of an hour. The Geiger counter has been rigged so that if it goes off, it releases a poison that kills the cat.

Now the decay of the radioactive material is a quantum-mechanical process; the different times for it to trigger the Geiger counter each have their own probability. According to the orthodox interpretation, "measurement" is needed to fix a single trigger time. If the box is left closed to prevent measurement, then at any given time, there is only a probability of the Geiger counter having been triggered. The cat is then alive, and also dead, each with a nonzero probability.

Of course no reasonable person is going to believe that she is looking at a box with a cat in it that is both dead and alive. The problem is obviously with what is to be called a "measurement" or "observation." The countless trillions of air molecules are hardly going to miss "observing" that they no longer enter the cat's nose. The biological machinery in the cat is not going to miss "observing" that the blood is no longer circulating. More directly, the Geiger counter is not going to miss "observing" that a decay has occurred; it is releasing the poison, isn't it?

If you postulate that the Geiger counter is in this case doing the "measurement" that the orthodox interpretation so deviously leaves undefined, it agrees with our common sense. But of course, this Deus ex Machina only rephrases our common sense; it provides no explanation why the Geiger counter would cause quantum mechanics to apparently terminate its normal evolution, no proof or plausible reason that the Geiger counter is able to fundamentally change the normal evolution of the wave function, and not even a shred of hard evidence that it terminates the evolution, if the box is truly closed.

There is a strange conclusion to this story. The entire point Schrödinger was trying to make was that no sane person is going to believe that a cat can be both dead and kicking around alive at the same time. But when the equations of quantum mechanics are examined more closely, it is found that they require exactly that. The wave function evolves into describing a series of different realities. In our own reality, the cat dies at a specific, apparently random time, just as common sense tells us. Regardless whether the box is open or not.

But, as discussed further in section 8.6, the mathematics of quantum mechanics extends beyond our reality. Other realities develop, which we humans are utterly unable to observe, and in each of those other realities, the cat dies at a different time.

### 8.2 Instantaneous Interactions

Special relativity has shown that we humans cannot transmit information at more than the speed of light. However, according to the orthodox interpretation, nature does not limit itself to the same silly restrictions that it puts on us. This section discusses why not.

Consider again the $\mathrm{H}_{2}^{+}$-ion, with the single electron equally shared by the two protons. If you pull the protons apart, maintaining the symmetry, you get a wave function that looks like figure 8.1. You might send one proton off to your

Figure 8.1: Separating the hydrogen ion.
observer on Mars, the other to your observer on Venus. Where is the electron, on Mars or on Venus?

According to the orthodox interpretation, the answer is: neither. A position for the electron does not exist. The electron is not on Mars. It is not on Venus. Only when either observer makes a measurement to see whether the electron is there, nature throws its dice, and based on the result, might put the electron on Venus and zero the wave function on Mars. But regardless of the distance, it could just as well have put the electron on Mars, if the dice would have come up differently.

You might think that nature cheats, that when you take the protons apart, nature already decides where the electron is going to be. That the Venus proton secretly hides the electron "in its sleeve", ready to make it appear if an observation is made. John Bell devised a clever test to force nature to reveal whether it has something hidden in its sleeve during a similar sort of trick.

The test case Bell used was a generalization of an experiment proposed by Bohm. It involves spin measurements on an electron/positron pair, created by the decay of an $\pi$-meson. Their combined spins are in the singlet state because the meson has no net spin. In particular, if you measure the spins of the electron and positron in any given direction, there is a $50 / 50 \%$ chance for each that it
turns out to be positive or negative. However, if one is positive, the other must be negative. So there are only two different possibilities:

1. electron positive and positron negative,
2. electron negative and positron positive.

Now suppose Earth happens to be almost the same distance from Mars and Venus, and you shoot the positron out to Venus, and the electron to Mars, as shown at the left in the figure below:

Figure 8.2: The Bohm experiment before the Venus measurement (left), and immediately after it (right).

You have observers on both planets waiting for the particles. According to quantum mechanics, the traveling electron and positron are both in an indeterminate state.

The positron reaches Venus a fraction of a second earlier, and the observer there measures its spin in the direction up from the ecliptic plane. According to the orthodox interpretation, nature now makes a random selection between the two possibilities, and assume it selects the positive spin value for the positron, corresponding to a spin that is up from the ecliptic plane, as shown in figure 8.2. Immediately, then, the spin state of the electron on Mars must also have collapsed; the observer on Mars is guaranteed to now measure negative spin, or spin down, for the electron.

The funny thing is, if you believe the orthodox interpretation, the information about the measurement of the positron has to reach the electron instantaneously, much faster than light can travel. This apparent problem in the orthodox interpretation was discovered by Einstein, Podolski, and Rosen. They doubted it could be true, and argued that it indicated that something must be missing in quantum mechanics.

In fact, instead of superluminal effects, it seems much more reasonable to assume that earlier on earth, when the particles were sent on their way, nature attached a secret little "note" of some kind to the positron, saying the equivalent of "If your spin up is measured, give the positive value", and that it attached a little note to the electron "If your spin up is measured, give the negative value." The results of the measurements are still the same, and the little notes travel along with the particles, well below the speed of light, so all seems now fine. Of course, these would not be true notes, but some kind of additional information beyond the normal quantum mechanics. Such postulated additional information sources are called "hidden variables."

Bell saw that there was a fundamental flaw in this idea if you do a large number of such measurements and you allow the observers to select from more
than one measurement direction at random. He derived a neat little general formula, but the discussion here will just show the contradiction in a single case. In particular, the observers on Venus and Mars will be allowed to select randomly one of three measurement directions $\vec{a}, \vec{b}$, and $\vec{c}$ separated by 120 degrees:

Figure 8.3: Spin measurement directions.
Let's see what the little notes attached to the electrons might say. They might say, for example, "Give the + value if $\vec{a}$ is measured, give the - value if $\vec{b}$ is measured, give the + value if $\vec{c}$ is measured." The relative fractions of the various possible notes generated for the electrons will be called $f_{1}, f_{2}, \ldots$. There are 8 different possible notes:

|  | $f_{1}$ | $f_{2}$ | $f_{3}$ | $f_{4}$ | $f_{5}$ | $f_{6}$ | $f_{7}$ | $f_{8}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\vec{a}$ | + | + | + | + | - | - | - | - |
| $\vec{b}$ | + | + | - | - | + | + | - | - |
| $\vec{c}$ | + | - | + | - | + | - | + | - |

The sum of the fractions $f_{1}$ through $f_{8}$ must be one. In fact, because of symmetry, each note will probably on average be generated for $\frac{1}{8}$ of the electrons sent, but this will not be needed.

Of course, each note attached to the positron must always be just the opposite of the one attached to the electron, since the positron must measure + in a direction when the electron measures - in that direction and vice-versa.

Now consider those measurements in which the Venus observer measures direction $\vec{a}$ and the Mars observer measures direction $\vec{b}$. In particular, the question is in what fraction of such measurements the Venus observer measures the opposite sign from the Mars observer; call it $f_{a b, \text { opposite }}$. This is not that hard to figure out. First consider the case that Venus measures - and Mars +. If the Venus observer measures the - value for the positron, then the note attached to the electron must say "measure + for $\vec{a}$ "; further, if the Mars observer measures the + value for $\vec{b}$, that one should say "measure + " too. So, looking at the table, the relative fraction where Venus measures - and Mars measures + is where the electron's note has a + for both $\vec{a}$ and $\vec{b}: f_{1}+f_{2}$.

Similarly, the fraction of cases where Venus finds + and Mars - is $f_{7}+f_{8}$, and you get in total:

$$
f_{a b, \text { opposite }}=f_{1}+f_{2}+f_{7}+f_{8}=0.25
$$

The value 0.25 is what quantum mechanics predicts; the derivation will be skipped here, but it has been verified in the experiments done after Bell's work. Those experiments also made sure that nature did not get the chance to do subluminal communication. The same way you get

$$
f_{a c, \text { opposite }}=f_{1}+f_{3}+f_{6}+f_{8}=0.25
$$

and

$$
f_{b c, \text { opposite }}=f_{1}+f_{4}+f_{5}+f_{8}=0.25
$$

Now there is a problem, because the numbers add up to 0.75 , but the fractions add up to at least 1: the sum of $f_{1}$ through $f_{8}$ is one.

A seemingly perfectly logical and plausible explanation by great minds is tripped up by some numbers that just do not want to match up. They only leave the alternative nobody really wanted to believe.

Attaching notes does not work. Information on what the observer on Venus decided to measure, the one thing that could not be put in the notes, must have been communicated instantly to the electron on Mars regardless of the distance.

It can also safely be concluded that we humans will never be able to see inside the actual machinery of quantum mechanics. For, suppose the observer on Mars could see the wave function of the electron collapse. Then the observer on Venus could send her Morse signals faster than the speed of light by either measuring or not measuring the spin of the positron. Special relativity would then allow signals to be sent into the past, and that leads to logical contradictions such as the Venus observer preventing her mother from having her.

While the results of the spin measurements can be observed, they do not allow superluminal communication. While the observer on Venus affects the results of the measurements of the observer on Mars, they will look completely random to that observer. Only when the observer on Venus sends over the results of her measurements, at a speed less than the speed of light, and the two sets of results are compared, do meaningful patterns how up.

The Bell experiments are often used to argue that Nature must really make the collapse decision using a true random number generator, but that is of course crap. The experiments indicate that Nature instantaneously transmits the collapse decision on Venus to Mars, but say nothing about how that decision was reached.

Superluminal effects still cause paradoxes, of course. The left of figure 8.4 shows how a Bohm experiment appears to an observer on earth. The spins

Figure 8.4: Earth's view of events (left), and that of a moving observer (right).
remain undecided until the measurement by the Venus observer causes both the positron and the electron spins to collapse.

However, for a moving observer, things would look very different. Assuming that the observer and the particles are all moving at speeds comparable to the speed of light, the same situation may look like the right of figure 8.4, chapter 1.1.4. In this case, the observer on Mars causes the wave function to collapse at a time that the positron has only just started moving towards Venus!

So the orthodox interpretation is not quite accurate. It should really have said that the measurement on Venus causes a convergence of the wave function, not an absolute collapse. What the observer of Venus really achieves in the orthodox interpretation is that after her measurement, all observers agree that the positron wave function is collapsed. Before that time, some observers are perfectly correct in saying that the wave function is already collapsed, and that the Mars observer did it.

It should be noted that when the equations of quantum mechanics are correctly applied, the collapse and superluminal effects disappear. That is explained in section 8.6. But, due to the fact that there are limits to our observational capabilities, as far as our own human experiences are concerned, the paradoxes remain real.

To be perfectly honest, it should be noted that the example above is not quite the one of Bell. Bell really used the inequality:

$$
\left|2\left(f_{3}+f_{4}+f_{5}+f_{6}\right)-2\left(f_{2}+f_{4}+f_{5}+f_{7}\right)\right| \leqslant 2\left(f_{2}+f_{3}+f_{6}+f_{7}\right)
$$

So the discussion cheated. And Bell allowed general directions of measurement not just 120 degree ones. See [25, pp. 423-426]. The above discussion seems a lot less messy, even though not historically accurate.

### 8.3 Global Symmetrization

When computing, say a hydrogen molecule, it is all nice and well to say that the wave function must be antisymmetric with respect to exchange of the two electrons 1 and 2, so the spin state of the molecule must be the singlet one. But what about, say, electron 3 in figure 8.1, which can with $50 \%$ chance be found on Mars and otherwise on Venus? Should not the wave function also be antisymmetric, for example, with respect to exchange of this electron 3 in one of two places in space with electron 1 on the hydrogen molecule on Earth? And would this not locate electron 3 in space also in part on the hydrogen molecule, and electron 1 also partly in space?

The answer is: absolutely. Nature treats all electrons as one big connected bunch. The given solution for the hydrogen molecule is not correct; it should have included every electron in the universe, not just two of them. Every
electron in the universe is just as much present on this single hydrogen molecule as the assumed two.

From the difficulty in describing the 33 electrons of the arsenic atom, imagine having to describe all electrons in the universe at the same time! If the universe is truly flat, this number would not even be finite. Fortunately, it turns out that the observed quantities can be correctly predicted pretending there are only two electrons involved. Antisymmetrization with far-away electrons does not change the properties of the local solution.

If you are thinking that more advanced quantum theories will eventually do away with the preposterous notion that all electrons are present everywhere, do not be too confident. As mentioned in addendum \{A.15.1\}, the idea has become a fundamental tenet in quantum field theory.

### 8.4 A story by Wheeler

Consider a simple question. Why are all electrons so absolutely equal? Would it not be a lot less boring if they had a range of masses and charges? As in "I found a really big electron this morning, with an unbelievable charge!" It does not happen.

And it is in fact far, far, worse than that. In quantum mechanics electrons are absolutely identical. If you really write the correct (classical) wave function for an hydrogen atom following the rules of quantum mechanics, then in principle you must include every electron in the universe as being present, in part, on the atom. Electrons are so equal that one cannot be present on a hydrogen atom unless every electron in the universe is.

There is a simple explanation that the famous physicist Wheeler gave to his talented graduate student Richard Feynman. In Feynman's words:
"As a by-product of this same view, I received a telephone call one day at the graduate college at Princeton from Professor Wheeler, in which he said, 'Feynman, I know why all electrons have the same charge and the same mass' 'Why?' 'Because, they are all the same electron!' And, then he explained on the telephone, ..." [Richard P. Feynman (1965) Nobel prize lecture. $\llbracket 5 \rrbracket]$

What Professor Wheeler explained on the phone is sketched in the space-time diagram figure 8.5. The "world-line" of the only electron there is is constantly traveling back and forwards between the past and the future. At any given time, like today, this single electron can be observed at countless different locations. At the locations where the electron is traveling to the future it behaves like a normal electron. And Wheeler recognized that where the electron is traveling towards the past, it behaves like a positively charged electron, called a positron. The mystery of all those countless identical electrons was explained.

Figure 8.5: The space-time diagram of Wheeler's single electron.

What had Feynman to say about that!? Again in his words:
" 'But, Professor,' I said, 'there aren't as many positrons as electrons.' 'Well, maybe they are hidden in the protons or something,' he said. I did not take the idea that all the electrons were the same one from him as seriously as I took the observation that positrons could simply be represented as electrons going from the future to the past in a back section of their world lines. That, I stole!" [Richard P. Feynman (1965) Nobel prize lecture. 【5】]

And there are other problems, like that electrons can be created or destroyed in weak interactions.

But without doubt, if this was art instead of quantum mechanics, Wheeler's proposal would be considered one of the greatest works of all time. It is stunning in both its utter simplicity and its inconceivable scope.

There is a place for esthetics in quantum mechanics, as the Dirac equation illustrates. Therefore this section will take a very biased look at whether the idea is really so truly inconceivable as it might appear. To do so, only positrons and electrons will be considered, with their attendant photons. Shape-shifting electrons are a major additional complication. And recall classical mechanics. Some of the most esthetical results of classical mechanics are the laws of conservation of energy and momentum. Relativity and then quantum mechanics eventually found that classical mechanics is fundamentally completely wrong. But did conservation of energy and momentum disappear? Quite the contrary.

They took on an even deeper and more esthetically gratifying role in those theories.

With other particles shoved out of the way, the obvious question is the one of Feynman. Where are all the positrons? One idea is that they ended up in some other part of space. But that seems to be hard to reconcile with the fact that space seems quite similar in all directions. The positrons will still have to be around us. So why do we not see them? Recall that the model considered here has no protons for positrons to hide in.

Obviously, if the positrons have nowhere to hide, they must be in plain view. That seems theoretically possible if it is assumed that the positron quantum wave functions are delocalized on a gigantic scale. Note that astronomy is short of a large amount of mass in the universe one way or the other. Delocalized antimatter to the tune of the visible matter would be just a drop in the bucket.

A bit of mathematical trickery called the Cauchy-Schwartz inequality can be used to illustrate the idea. Consider a "universe" of volume $\mathcal{V}$. For simplicity, assume that there is just one electron and one positron in this universe. More does not seem to make a fundamental difference, at least not in a simplistic model. The electron has wave function $\psi_{1}$ and the positron $\psi_{2}$. The CauchySchwartz inequality says that:

$$
\left|\int_{\mathcal{V}} \psi_{1}^{*} \psi_{2} \mathrm{~d}^{2} \vec{r}\right|^{2} \leqslant \int_{\mathcal{V}}\left|\psi_{1}\right|^{2} \mathrm{~d}^{2} \vec{r} \int_{\mathcal{V}}\left|\psi_{2}\right|^{2} \mathrm{~d}^{2} \vec{r}=1
$$

Take the left hand side as representative for the interaction rate between electrons and positrons. Then if the wave functions of both electrons and positrons are completely delocalized, the interaction rate is 1 . However, if only the positrons are completely delocalized, it is much smaller. Suppose the electron is localized within a volume $\varepsilon \mathcal{V}$ with $\varepsilon$ a very small number. Then the interaction rate is reduced from 1 to $\varepsilon$. If both electrons and positrons are localized within volumes of size $\varepsilon \mathcal{V}$ it gets messier. If the electron and positron move completely randomly and quickly through the volume, the average interaction rate would still be $\varepsilon$. But electrons and positrons attract each other through their electric charges, and on a large scale also through gravity. That could increase the interaction rate greatly.

The obvious next question is then, how come that positrons are delocalized and electrons are not? The simple answer to that is: because electrons come to us from the compact Big Bang stages of the universe. The positrons come to us from the final stages of the evolution of the universe where it has expanded beyond limit.

Unfortunately, that answer, while simple, is not satisfactory. Motion in quantum mechanics is essentially time reversible. And that means that you should be able to explain the evolution of both electrons and positrons coming out of the initial Big Bang universe. Going forward in time.

A more reasonable idea is that the other options do not produce stable situations. Consider a localized positron in an early universe that by random chance happens to have more localized electrons than positrons. Because of attraction effects, such a positron is likely to find a localized electron to annihilate with. That is one less localized positron out of an already reduced population. A delocalized positron could interact similarly with a delocalized electron, but there are less of these. The reverse situation holds for electrons. So you could imagine a runaway process where the positron population evolves to delocalized states and the electrons to localized ones.

Another way to look at it is to consider how wave functions get localized in the first place. The wave function of a localized isolated particle wants to disperse out over time. Cosmic expansion would only add to that. In the orthodox view, particles get localized because they are "measured." The basics of this process, as described by another graduate student of Wheeler, Everett III, are in section 8.6. Unfortunately, the process remains poorly understood. But suppose, say, that matter localizes matter but delocalizes antimatter, and vice-versa. In that case a slight dominance of matter over antimatter could conceivably lead to a run-away situation where the matter gets localized and the antimatter delocalized.

Among all the exotic sources that have been proposed for the "dark matter" in the universe, delocalized antimatter does not seem to get mentioned. So probably someone has already solidly shown that it is impossible.

But that does not invalidate Wheeler's basic idea, of course. As Wheeler himself suggested, the positrons could in fact be hiding inside the protons through the weak-force mechanism. Then of course, you need to explain how the positrons came to be hiding inside the protons. Why not the electrons inside the antiprotons? That would be messier, but it does not mean it could not be true. In fact, it is one of the surprises of advanced particle physics that the entire lepton-quark family seems to be one inseparable multi-component particle, [27, p. 210]. It seems only fair to say that Wheeler's idea predicted this. For clearly, the electron could not maintain its unmutable identity if repeatedly changed into particles with a separate and independent identity. So Wheeler's idea may not be so crazy after all, looking at the facts. It provides a real explanation why identical particles are so perfectly identical. And it predicted something that would only be observed well into the future.

Still, the bottom line remains the beauty of the idea. As the mathematician Weyl noted, unfazed after Einstein shot down an idea of his:
"When there is a conflict between beauty and truth, I choose beauty."

### 8.5 Failure of the Schrödinger Equation?

Section $\{8.2\}$ mentioned sending half of the wave function of an electron to Venus, and half to Mars. A scattering setup as described in chapter 7.12 provides a practical means for actually doing this, (at least, for taking the wave function apart in two separate parts.) The obvious question is now: can the Schrödinger equation also describe the physically observed "collapse of the wave function", where the electron changes from being on both Venus and Mars with a 50/50 probability to, say, being on Mars with absolute certainty?

The answer obtained in this and the next subsection will be most curious: no, the Schrödinger equation flatly contradicts that the wave function collapses, but yes, it requires that measurement leads to the experimentally observed collapse. The analysis will take us to a mind-boggling but really unavoidable conclusion about the very nature of our universe.

This subsection will examine the problem the Schrödinger equation has with describing a collapse. First of all, the solutions of the linear Schrödinger equation do not allow a mathematically exact collapse like some nonlinear equations do. But that does not necessarily imply that solutions would not be able to collapse physically. It would be conceivable that the solution could evolve to a state where the electron is on Mars with such high probability that it can be taken to be certainty. In fact, a common notion is that, somehow, interaction with a macroscopic "measurement" apparatus could lead to such an end result.

Of course, the constituent particles that make up such a macroscopic measurement apparatus still need to satisfy the laws of physics. So let's make up a reasonable model for such a complete macroscopic system, and see what can then be said about the possibility for the wave function to evolve towards the electron being on Mars.

The model will ignore the existence of anything beyond the Venus, Earth, Mars system. It will be assumed that the three planets consist of a humongous, but finite, number of conserved classical particles $1,2,3,4,5, \ldots$, with a supercolossal wave function:

$$
\Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \vec{r}_{3}, S_{z 3}, \vec{r}_{4}, S_{z 4}, \vec{r}_{5}, S_{z 5}, \ldots\right)
$$

Particle 1 will be taken to be the scattered electron. It will be assumed that the wave function satisfies the Schrödinger equation:

$$
\begin{equation*}
\mathrm{i} \hbar \frac{\partial \Psi}{\partial t}=-\sum_{i} \sum_{j=1}^{3} \frac{\hbar^{2}}{2 m_{i}} \frac{\partial^{2} \Psi}{\partial r_{i, j}^{2}}+V\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \vec{r}_{3}, S_{z 3}, \vec{r}_{4}, S_{z 4}, \ldots\right) \Psi \tag{8.1}
\end{equation*}
$$

Trying to write the solution to this problem would of course be prohibitive, but the evolution of the probability of the electron to be on Venus can still be extracted from it with some fairly standard manipulations. First, taking the combination of the Schrödinger equation times $\Psi^{*}$ minus the complex conjugate
of the Schrödinger equation times $\Psi$ produces after some further manipulation an equation for the time derivative of the probability:

$$
\begin{equation*}
\mathrm{i} \hbar \frac{\partial \Psi^{*} \Psi}{\partial t}=-\sum_{i} \sum_{j=1}^{3} \frac{\hbar^{2}}{2 m_{i}} \frac{\partial}{\partial r_{i, j}}\left(\Psi^{*} \frac{\partial \Psi}{\partial r_{i, j}}-\Psi \frac{\partial \Psi^{*}}{\partial r_{i, j}}\right) \tag{8.2}
\end{equation*}
$$

The question is the probability for the electron to be on Venus, and you can get that by integrating the probability equation above over all possible positions and spins of the particles except for particle 1, for which you have to restrict the spatial integration to Venus and its immediate surroundings. If you do that, the left hand side becomes the rate of change of the probability for the electron to be on Venus, regardless of the position and spin of all the other particles.

Interestingly, assuming times at which the Venus part of the scattered electron wave is definitely at Venus, the right hand side integrates to zero: the wave function is supposed to disappear at large distances from this isolated system, and whenever particle 1 would be at the border of the surroundings of Venus.

It follows that the probability for the electron to be at Venus cannot change from $50 \%$. A true collapse of the wave function of the electron as postulated in the orthodox interpretation, where the probability to find the electron at Venus changes to $100 \%$ or $0 \%$ cannot occur.

Of course, the model was simple; you might therefore conjecture that a true collapse could occur if additional physics is included, such as nonconserved particles like photons, or other relativistic effects. But that would obviously be a moving target. The analysis made a good-faith effort to examine whether including macroscopic effects may cause the observed collapse of the wave function, and the answer was no. Having a scientifically open mind requires you to at least follow the model to its logical end; nature might be telling you something here.

Is it really true that the results disagree with the observed physics? You need to be careful. There is no reasonable doubt that if a measurement is performed about the presence of the electron on Venus, the wave function will be observed to collapse. But all you established above is that the wave function does not collapse; you did not establish whether or not it will be observed to collapse. To answer the question whether a collapse will be observed, you will need to include the observers in your reasoning.

The problem is with the innocuous looking phrase regardless of the position and spin of all the other particles in the arguments above. Even while the total probability for the electron to be at Venus must stay at $50 \%$ in this example system, it is still perfectly possible for the probability to become $100 \%$ for one state of the particles that make up the observer and her tools, and to be $0 \%$ for another state of the observer and her tools.

It is perfectly possible to have a state of the observer with brain particles, ink-on-paper particles, tape recorder particles, that all say that the electron is
on Venus, combined with $100 \%$ probability that the electron is on Venus, and a second state of the observer with brain particles, ink-on-paper particles, tape recorder particles, that all say the electron must be on Mars, combined with $0 \%$ probability for the electron to be on Venus. Such a scenario is called a "relative state interpretation;" the states of the observer and the measured object become entangled with each other.

The state of the electron does not change to a single state of presence or absence; instead two states of the macroscopic universe develop, one with the electron absent, the other with it present. As explained in the next subsection, the Schrödinger equation does not just allow this to occur, it requires this to occur. So, far from being in conflict with the observed collapse, the model above requires it. The model produces the right physics: observed collapse is a consequence of the Schrödinger equation, not of something else.

But all this ends up with the rather disturbing thought that there are now two states of the universe, and the two are different in what they think about the electron. This conclusion was unexpected; it comes as the unavoidable consequence of the mathematical equations that quantum mechanics abstracted for the way nature operates.

### 8.6 The Many-Worlds Interpretation

The Schrödinger equation has been enormously successful, but it describes the wave function as always smoothly evolving in time, in apparent contradiction to its postulated collapse in the orthodox interpretation. So, it would seem to be extremely interesting to examine the solution of the Schrödinger equation for measurement processes more closely, to see whether and how a collapse might occur.

Of course, if a true solution for a single arsenic atom already presents an unsurmountable problem, it may seem insane to try to analyze an entire macroscopic system such as a measurement apparatus. But in a brilliant Ph.D. thesis with Wheeler at Princeton, Hugh Everett, III did exactly that. He showed that the wave function does not collapse. However it seems to us humans that it does, so we are correct in applying the rules of the orthodox interpretation anyway. This subsection explains briefly how this works.

Let's return to the experiment of section 8.2 , where a positron is sent to Venus and an entangled electron to Mars, as in figure 8.6. The spin states are

Figure 8.6: Bohm's version of the Einstein, Podolski, Rosen Paradox.
uncertain when the two are sent from Earth, but when Venus measures the spin of the positron, it miraculously causes the spin state of the electron on Mars to collapse too. For example, if the Venus positron collapses to the spin-up state in the measurement, the Mars electron must collapse to the spin-down state. The problem, however, is that there is nothing in the Schrödinger equation to describe such a collapse, nor the superluminal communication between Venus and Mars it implies.

The reason that the collapse and superluminal communication are needed is that the two particles are entangled in the singlet spin state of chapter 5.5.6. This is a $50 \% / 50 \%$ probability state of (electron up and positron down) / (electron down and positron up).

It would be easy if the positron would just be spin up and the electron spin down, as in figure 8.7. You would still not want to write down the supercolossal

Figure 8.7: Nonentangled positron and electron spins; up and down.
wave function of everything, the particles along with the observers and their equipment for this case. But there is no doubt what it describes. It will simply describe that the observer on Venus measures spin up, and the one on Mars, spin down. There is no ambiguity.

The same way, there is no question about the opposite case, figure 8.8. It

Figure 8.8: Nonentangled positron and electron spins; down and up.
will produce a wave function of everything describing that the observer on Venus measures spin down, and the one on Mars, spin up.

Everett, III recognized that the solution for the entangled case is blindingly simple. Since the Schrödinger equation is linear, the wave function for the entangled case must simply be the sum of the two nonentangled ones above, as shown in figure 8.9. If the wave function in each nonentangled case describes a universe in which a particular state is solidly established for the spins, then the conclusion is undeniable: the wave function in the entangled case describes two universes, each of which solidly establishes states for the spins, but which end up with opposite results.

This explains the result of the orthodox interpretation that only eigenvalues are measurable. The linearity of the Schrödinger equation leaves no other option:

Figure 8.9: The wave functions of two universes combined
Assume that any measurement device at all is constructed that for a spin-up positron results in a universe that has absolutely no doubt that the spin is up, and for a spin-down positron results in a universe that has absolutely no doubt that the spin is down. In that case a combination of spin up and spin down states must unavoidably result in a combination of two universes, one in which there is absolutely no doubt that the spin is up, and one in which there is absolutely no doubt that it is down.

Note that this observation does not depend on the details of the Schrödinger equation, just on its linearity. For that reason it stays true even including relativity.

The two universes are completely unaware of each other. It is the very nature of linearity that if two solutions are combined, they do not affect each other at all: neither universe would change in the least whether the other universe is there or not. For each universe, the other universe "exists" only in the sense that the Schrödinger equation must have created it given the initial entangled state.

Nonlinearity would be needed to allow the solutions of the two universes to couple together to produce a single universe with a combination of the two eigenvalues, and there is none. A universe measuring a combination of eigenvalues is made impossible by linearity.

While the wave function has not collapsed, what has changed is the most meaningful way to describe it. The wave function still by its very nature assigns a value to every possible configuration of the universe, in other words, to every possible universe. That has never been a matter of much controversy. And after the measurement it is still perfectly correct to say that the Venus observer has marked down in her notebook that the positron was up and down, and has transmitted a message to earth that the positron was up and down, and earth has marked on in its computer disks and in the brains of the assistants that the positron was found to be up and down, etcetera.

But it is much more precise to say that after the measurement there are two universes, one in which the Venus observer has observed the positron to be up, has transmitted to earth that the positron was up, and in which earth has
marked down on its computer disks and in the brains of the assistants that the positron was up, etcetera; and a second universe in which the same happened, but with the positron everywhere down instead of up. This description is much more precise since it notes that up always goes with up, and down with down. As noted before, this more precise way of describing what happens is called the "relative state formulation."

Note that in each universe, it appears that the wave function has collapsed. Both universes agree on the fact that the decay of the $\pi$-meson creates an electron/positron pair in a singlet state, but after the measurement, the notebook, radio waves, computer disks, brains in one universe all say that the positron is up, and in the other, all down. Only the unobservable full wave function "knows" that the positron is still both up and down.

And there is no longer a spooky superluminal action: in the first universe, the electron was already down when sent from earth. In the other universe, it was sent out as up. Similarly, for the case of the last subsection, where half the wave function of an electron was sent to Venus, the Schrödinger equation does not fail. There is still half a chance of the electron to be on Venus; it just gets decomposed into one universe with one electron, and a second one with zero electron. In the first universe, earth sent the electron to Venus, in the second to Mars. The contradictions of quantum mechanics disappear when the complete solution of the Schrödinger equation is examined.

Next, let's examine why the results would seem to be covered by rules of chance, even though the Schrödinger equation is fully deterministic. To do so, assume earth keeps on sending entangled positron and electron pairs. When the third pair is on its way, the situation looks as shown in the third column of figure 8.10. The wave function now describes 8 universes. Note that in most universes the observer starts seeing an apparently random sequence of up and down spins. When repeated enough times, the sequences appear random in practically speaking every universe. Unable to see the other universes, the observer in each universe has no choice but to call her results random. Only the full wave function knows better.

Everett, III also derived that the statistics of the apparently random sequences are proportional to the absolute squares of the eigenfunction expansion coefficients, as the orthodox interpretation says.

How about the uncertainty relationship? For spins, the relevant uncertainty relationship states that it is impossible for the spin in the up/down directions and in the front/back directions to be certain at the same time. Measuring the spin in the front/back direction will make the up/down spin uncertain. But if the spin was always up, how can it change?

This is a bit more tricky. Let's have the Mars observer do a couple of additional experiments on one of her electrons, first one front/back, and then another again up/down, to see what happens. To be more precise, let's also ask her to write the result of each measurement on a blackboard, so that there is a

Figure 8.10: The Bohm experiment repeated.
good record of what was found. Figure 8.11 shows what happens.
When the electron is sent from Earth, two universes can be distinguished, one in which the electron is up, and another in which it is down. In the first one, the Mars observer measures the spin to be up and marks so on the blackboard. In the second, she measures and marks the spin to be down.

Next the observer in each of the two universes measures the spin front/ back. Now it can be shown that the spin-up state in the first universe is a linear combination of equal amounts of spin-front and spin-back. So the second measurement splits the wave function describing the first universe into two, one with spin-front and one with spin-back.

Similarly, the spin-down state in the second universe is equivalent to equal amounts of spin-front and spin-back, but in this case with opposite sign. Either way, the wave function of the second universe still splits into a universe with spin front and one with spin back.

Now the observer in each universe does her third measurement. The front electron consists of equal amounts of spin up and spin down electrons, and so does the back electron, just with different sign. So, as the last column in figure 8.11 shows, in the third measurement, as much as half the eight universes measure the vertical spin to be the opposite of the one they got in the first measurement!

The full wave function knows that if the first four of the final eight universes are summed together, the net spin is still down (the two down spins have equal

Figure 8.11: Repeated experiments on the same electron.
and opposite amplitude). But the observers have only their blackboard (and what is recorded in their brains, etcetera) to guide them. And that information seems to tell them unambiguously that the front-back measurement "destroyed" the vertical spin of the electron. (The four observers that measured the spin to be unchanged can repeat the experiment a few more times and are sure to eventually find that the vertical spin does change.)

The unavoidable conclusion is that the Schrödinger equation does not fail. It describes the observations exactly, in full agreement with the orthodox interpretation, without any collapse. The appearance of a collapse is actually just a limitation of our human observational capabilities.

Of course, in other cases than the spin example above, there are more than just two symmetric states, and it becomes much less self-evident what the proper partial solutions are. However, it does not seem hard to make some conjectures. For Schrödinger's cat, you might model the radioactive decay that gives rise to the Geiger counter going off as due to a nucleus with a neutron wave packet rattling around in it, trying to escape. As chapter 7.12 .1 showed, in quantum mechanics each rattle will fall apart into a transmitted and a reflected wave. The transmitted wave would describe the formation of a universe where the neutron escapes at that time to set off the Geiger counter which kills the cat, and the reflected wave a universe where the neutron is still contained.

For the standard quantum mechanics example of an excited atom emitting a photon, a model would be that the initial excited atom is perturbed by the ambient electromagnetic field. The perturbations will turn the atom into a linear combination of the excited state with a bit of a lower energy state thrown in, surrounded by a perturbed electromagnetic field. Presumably this situation
can be taken apart in a universe with the atom still in the excited state, and the energy in the electromagnetic field still the same, and another universe with the atom in the lower energy state with a photon escaping in addition to the energy in the original electromagnetic field. Of course, the process would repeat for the first universe, producing an eventual series of universes in almost all of which the atom has emitted a photon and thus transitioned to a lower energy state.

So this is where we end up. The equations of quantum mechanics describe the physics that we observe perfectly well. Yet they have forced us to the uncomfortable conclusion that, mathematically speaking, we are not at all unique. Beyond our universe, the mathematics of quantum mechanics requires an infinity of unobservable other universes that are nontrivially different from us.

Note that the existence of an infinity of universes is not the issue. They are already required by the very formulation of quantum mechanics. The wave function of say an arsenic atom already assigns a nonzero probability to every possible configuration of the positions of the electrons. Similarly, a wave function of the universe will assign a nonzero probability to every possible configuration of the universe, in other words, to every possible universe. The existence of an infinity of universes is therefore not something that should be ascribed to Everett, III \{N.15\}.

However, when quantum mechanics was first formulated, people quite obviously believed that, practically speaking, there would be just one universe, the one we observe. No serious physicist would deny that the monitor on which you may be reading this has uncertainty in its position, yet the uncertainty you are dealing with here is so astronomically small that it can be ignored. Similarly it might appear that all the other substantially different universes should have such small probabilities that they can be ignored. The actual contribution of Everett, III was to show that this idea is not tenable. Nontrivial universes must develop that are substantially different.

Formulated in 1957 and then largely ignored, Everett's work represents without doubt one of the human race's greatest accomplishments; a stunning discovery of what we are and what is our place in the universe.

### 8.7 The Arrow of Time

This section has some further musings on the many worlds interpretation. One question is why it matters. What is wrong with postulating a fairy-tale collapse mechanism that makes people feel unique? The alternate realities are fundamentally unobservable, so in normal terms they do truly not exist. For all practical purposes, the wave function really does collapse.

The main reason is of course because people are curious. We would also want to understand what nature is really all about, even if we may not like the
answer very much.
But there is also a more practical side. An understanding of nature can help guess what is likely to happen under circumstances that are not well known. And clearly, there is a difference in thinking. The Everett model is a universe following the established equations of physics in which observers only observe a very narrow and evolving part of a much larger reality. The Copenhagen model is a single universe run by gnomes that allow microscopic deviations from a unique reality following the equations of physics, but kindly eliminate anything bigger.

One major difference is what is considered to be real. In Everett's theory, for an observer reality is not the complete wave function but a small selection of it. That becomes a philosophical point when considering "vacuum energy." According to quantum field theory, even empty space still contains half a photon of electromagnetic energy at each frequency, \{A.23.4\}. That is much like a harmonic oscillator still has half a quantum of kinetic and potential energy left in its ground state. The electric and magnetic fields have quantum uncertainty. If you "measure" the electric or magnetic field in vacuum, you will get a nonzero value. The same applies to other fields of particles. Unfortunately, if you sum these energies over all frequencies, you get infinity. Even if the frequencies are assumed to be limited to scales about which there is solid knowledge, there is still an enormous amount of energy here. Its gravitational effect should be gigantic, it should dwarf anything else.

Somehow that does not happen. Now, in Everett's interpretation a particle only becomes real for a universe when a state is established in which there is no doubt that the particle exists. That obviously greatly limits the vacuum energy that affects that universe. The existence of other particles might be firmly established in other universes, but these will then affect those other universes. In the Copenhagen interpretation, however, there are no other universes, and therefore no good reason to exclude any vacuum energy from affecting the gravity of the only universe there is.

Then there is the arrow of time. It is observed that time has directionality. So why does time only go one way, from early to late? You might argue that "early" and "late" are just words. But they are not. They are given meaning by the second law of thermodynamics. This law says that a measurable definition of disorder in the observed universe, called entropy, always increases with time. The law applies to macroscopic systems. However, macroscopic systems consist of particles that satisfy microscopic mechanics. And the Schrödinger equation has no particular preference for the time $t$ above the backward time $-t$. So what happened to the processes that run according to $-t$, backwards to what we would consider forward in time? Why do we not observe such processes? And why are we composed of matter, not antimatter? And why does nature not look the same when viewed in the mirror? What is so different about a mirror image of the universe that we observe?

The conventional view postulates ad-hoc asymmetries that "just happened" to be that way. Why would that happen and why would it be in the same direction everywhere in an infinite space-time and an infinity of possible universes therein?

Then the conventional view adds evolution equations that magnify that asymmetry using small perturbation theory. That sounds reasonable until you examine those evolution equations more closely, chapter 11.10. The mechanism that provides the increasing asymmetry is, you guessed it, exactly that poorly defined collapse mechanism. Collapse is simply stated to apply for times greater than the "measurement" time. Obviously that produces asymmetry in time. But why could the collapse not apply for times less than the collapse time instead?

Now stand back from the details and take a look at the larger philosophical question. The well established equations of nature have no particular preference for either direction of time. True, the direction of time is correlated with matter versus antimatter, and with mirror symmetry. But that still does not make either direction of time any better than the other. According to the laws of physics that have been solidly established, there does not seem to be any big reason for nature to prefer one direction of time above the other.

According to Everett's theory, there is no reason to assume that it does. The many-worlds interpretation allows the wave function to describe both universes that are observed to evolve towards one direction of time and universes that are observed to evolve in the other direction.

That is not a trivial observation. The problem of the observed time asymmetry for a symmetric physics has now been removed. It has been replaced by the question why forward evolving systems appear to correlate with forward evolving systems, and backward evolving systems with backward evolving ones. While that is not a trivial question either, it is not implausible.

Perhaps, if we spend more time on listening to what nature is really telling us, rather than make up stories for what we want to believe, we would now understand those processes a lot more clearly.

## Chapter 9

## Numerical Procedures

Since analytical solutions in quantum mechanics are extremely limited, numerical solution is essential. This chapter outlines some of the most important ideas. The most glaring omission at this time is the DFT (Density Functional Theory.) A writer needs a sabbatical.

### 9.1 The Variational Method

Solving the equations of quantum mechanics is typically difficult, so approximations must usually be made. One very effective tool for finding approximate solutions is the variational principle. This section gives some of the basic ideas, including ways to apply it best.

### 9.1.1 Basic variational statement

Finding the state of a physical system in quantum mechanics means finding the wave function $\Psi$ that describes it. For example, at sufficiently low temperatures, physical systems will be described by the ground state wave function. The problem is that if there are more than a couple of particles in the system, the wave function is a very high-dimensional function. It is far too complex to be crunched out using brute force on any current computer.

However, the expectation value of energy is just a simple single number for any given wave function. It is defined as

$$
\langle E\rangle=\langle\Psi \mid H \Psi\rangle
$$

where $H$ is the Hamiltonian of the system. The key observation on which the variational method is based is that the ground state is the state among all allowable wave functions that has the lowest expectation value of energy:

$$
\langle E\rangle \text { is minimal for the ground state wave function. }
$$

That means that if you would find $\langle E\rangle$ for all possible system wave functions, you would be able to pick out the ground state simply as the state that has the lowest value.

Of course, finding the expectation value of the energy for all possible wave functions is still an impossible task. But you may be able to guess a generic type of wave function that you would expect to be able to approximate the ground state well, under suitable conditions. Normally, "suitable conditions" means that the approximation will be good only if various parameters appearing in the approximate wave function are well chosen.

That then leaves you with the much smaller task of finding good values for this limited set of parameters. Here the key idea is:

> | $\langle E\rangle$ is lowest for the best approximation to the ground state. |
| :--- | :--- |

Following that idea, what you do is adjust the parameters values so that you get the lowest possible value of the expectation energy for your type of approximate wave function. The true ground state wave function always has the lowest possible energy, so the lower you make your approximate energy, the closer that energy is to the exact value.

So this procedure gives you the best possible approximation to the true energy, and energy is usually the key quantity in quantum mechanics. In addition you know for sure that the true energy must be lower than your approximation, which is also often very useful information.

The variational method as described above has already been used earlier in this book to find an approximate ground state for the hydrogen molecular ion, chapter 4.6, and for the hydrogen molecule, chapter 5.2. It will also be used to find an approximate ground state for the helium atom, $\{$ A. 38.2$\}$. The method works quite well even for the crude approximate wave functions used in those examples.

To be sure, it is not at all obvious that getting the best energy will also produce the best wave function. After all, "best" is a somewhat tricky term for a complex object like a wave function. To take an example from another field, surely you would not argue that the best sprinter in the world must also be the best person in the world.

But in this case, your wave function will in fact be close to the exact wave function if you manage to get close enough to the exact energy. More precisely, assuming that the ground state is unique, the closer your energy gets to the exact energy, the closer your wave function gets to the exact wave function. One way of thinking about it is to note that your approximate wave function is always a combination of the desired exact ground state plus polluting amounts of higher energy states. By minimizing the energy, in some sense you minimize the amount of these polluting higher energy states. The mathematics of that idea is explored in more detail in addendum \{A.7\}.

And there are other benefits to specifically getting the energy as accurate as possible. One problem is often to figure out whether a system is bound. For example, can you add another electron to a hydrogen atom and have that electron at least weakly bound? The answer is not obvious. But if using a suitable approximate solution, you manage to show that the approximate energy of the bound system is less than that of having the additional electron at infinity, then you have proved that the bound state exist. Despite the fact that your solution has errors. The reason is that, by definition, the ground state must have lower energy than your approximate wave function. So the ground state is even more tightly bound together than your approximate wave function says.

Another reason to specifically getting the energy as accurate as possible is that energy values are directly related to how fast systems evolve in time when not in the ground state, chapter 7.

For the above reasons, it is also great that the errors in energy turn out to be unexpectedly small in a variational procedure, when compared to the errors in the guessed wave function, $\{\mathrm{A} .7\}$.

To get the second lowest energy state, you could search for the lowest energy among all wave functions orthogonal to the ground state. But since you would not know the exact ground state, you would need to use your approximate one instead. That would involve some error, and it is no longer sure that the true second-lowest energy level is no higher than what you compute, but anyway. The suprising accuracy in energy will still apply.

If you want to get truly accurate results in a variational method, in general you will need to increase the number of parameters. The molecular example solutions were based on the atomic ground states, and you could consider adding some excited states to the mix. In general, a procedure using appropriate guessed functions is called a Rayleigh-Ritz method. Alternatively, you could just chop space up into little pieces, or "elements," and use a simple polynomial within each piece. That is called a finite-element method. In either case, you end up with a finite, but relatively large number of unknowns; the parameters and coefficients of the functions, or the coefficients of the polynomials.

### 9.1.2 Differential form of the statement

You might by now wonder about the wisdom of trying to find the minimum energy by searching through the countless possible combinations of a lot of parameters. Brute-force search worked fine for the hydrogen molecule examples since they really only depended nontrivially on the distance between the nuclei. But if you add some more parameters for better accuracy, you quickly get into trouble. Semi-analytical approaches like Hartree-Fock even leave whole functions unspecified. In that case, simply put, every single function value is an unknown parameter, and a function has infinitely many of them. You would be searching in an infinite-dimensional space, and might search forever.

Usually it is a much better idea to write some equations for the minimum energy first. From calculus, you know that if you want to find the minimum of a function, the sophisticated way to do it is to note that the derivatives of the function must be zero at the minimum. Less rigorously, but a lot more intuitive, at the minimum of a function the changes in the function due to small changes in the variables that it depends on must be zero. Mathematicians may not like that, since the word "small" has no rigorous meaning. But unless you misuse your small quantities, you can always convert your results using them to rigorous mathematics after the fact.

In the simplest possible example of a function $f(x)$ of one variable $x$, a rigorous mathematician would say that at a minimum, the derivative $f^{\prime}(x)$ must be zero. But a physicists may not like that, for if you say derivative, you must say with respect to what variable; you must say what $x$ is as well as what $f$ is. There is often more than one possible choice for $x$, with none preferred under all circumstances. So a typical physicist would say that the change $\mathrm{d} f$ in $f$ due to a small change in whatever variable it depends on must be zero. It is the same thing, since for a small enough change $\mathrm{d} x$ in the variable, $\mathrm{d} f=f^{\prime} \mathrm{d} x$, so that if $f^{\prime}$ is zero, then so is $\mathrm{d} f$. (Mathematically more accurately, if $\mathrm{d} x$ becomes small enough, $\mathrm{d} f$ becomes zero compared to $\mathrm{d} x$.) If there is more than one independent variable that the function depends on, then the derivatives become partial derivatives, $\mathrm{d} f$ becomes $\partial f$, and specifying the precise derivatives would become much messier still.

In variational procedures, it is common to use $\delta f$ instead of $\mathrm{d} f$ or $\partial f$ for the small change in $f$. This book will do so too.

So in quantum mechanics, the fact that the expectation energy must be minimal in the ground state can be written as:
$\delta\langle E\rangle=0$ for all acceptable small changes in wave function
The changes must be acceptable; you cannot allow that the changed wave function is no longer normalized. Also, if there are boundary conditions, the changed wave function should still satisfy them. (There may be exceptions permitted to the latter under some conditions, but these will be ignored here.) So, in general you have "constrained minimization;" you cannot make your changes completely arbitrary.

### 9.1.3 Using Lagrangian multipliers

As an example of how the variational formulation of the previous subsection can be applied analytically, and how it can also describe eigenstates of higher energy, this subsection will work out a very basic example. The idea is to figure out what you get if you truly zero the changes in the expectation value of energy $\langle E\rangle=\langle\psi| H|\psi\rangle$ over all acceptable wave functions $\psi$. (Instead of just over all
possible versions of a numerical approximation, say.) It will illustrate how the "Lagrangian multiplier" method can deal with the constraints.

The differential statement is:

$$
\delta\langle\psi| H|\psi\rangle=0 \text { for all acceptable changes } \delta \psi \text { in } \psi
$$

But "acceptable" is not a mathematical concept. What does it mean? Well, if it is assumed that there are no boundary conditions, (like the harmonic oscillator, but unlike the particle in a pipe,) then acceptable just means that the wave function must remain normalized under the change. So the change in $\langle\psi \mid \psi\rangle$ must be zero, and you can write more specifically:

$$
\delta\langle\psi| H|\psi\rangle=0 \text { whenever } \delta\langle\psi \mid \psi\rangle=0
$$

But how do you crunch a statement like that down mathematically? Well, there is a very important mathematical trick to simplify this. Instead of rigorously trying to enforce that the changed wave function is still normalized, just allow any change in wave function. But add "penalty points" to the change in expectation energy if the change in wave function goes out of allowed bounds:

$$
\delta\langle\psi| H|\psi\rangle-\epsilon \delta\langle\psi \mid \psi\rangle=0
$$

Here $\epsilon$ is the penalty factor. Such penalty factors are called "Lagrangian multipliers" after a famous mathematician who probably watched a lot of soccer. For a change in wave function that does not go out of bounds, the second term is zero, so nothing changes. And if the change does go out of bounds, the second term will cancel any resulting erroneous gain or decrease in expectation energy, $\{D .48\}$, assuming that the penalty factor is carefully tuned. Note that the penalty factor $\epsilon$ must be real because the other two quantities in the equation above are changes in real functions.

You do not, however, have to explicitly tune the penalty factor yourself. All you need to know is that a proper one exists. In actual application, all you do in addition to ensuring that the penalized change in expectation energy is zero is ensure that at least the unchanged wave function is normalized. It is really a matter of counting equations versus unknowns. Compared to simply setting the change in expectation energy to zero with no constraints on the wave function, one additional unknown has been added, the penalty factor. And quite generally, if you add one more unknown to a system of equations, you need one more equation to still have a unique solution. As the one-more equation, use the normalization condition. With enough equations to solve, you will get the correct solution, which means that the implied value of the penalty factor should be OK too.

So what does this variational statement now produce? Writing out the differences explicitly, you must have

$$
(\langle\psi+\delta \psi| H|\psi+\delta \psi\rangle-\langle\psi| H|\psi\rangle)-\epsilon(\langle\psi+\delta \psi \mid \psi+\delta \psi\rangle-\langle\psi \mid \psi\rangle)=0
$$

Multiplying out, canceling equal terms and ignoring terms that are quadratically small in $\delta \psi$, you get

$$
\langle\delta \psi| H|\psi\rangle+\langle\psi| H|\delta \psi\rangle-\epsilon(\langle\delta \psi \mid \psi\rangle+\langle\psi \mid \delta \psi\rangle)=0
$$

Remarkably, you can throw away the second of each pair of inner products in the expression above. To see why, remember that you can allow any change $\delta \psi$ you want, including the $\delta \psi$ you are now looking at times -i. If you plug that into the above equation and divide the entire thing by i to get rid of the added factors i again, you get

$$
\langle\delta \psi| H|\psi\rangle-\langle\psi| H|\delta \psi\rangle-\epsilon(\langle\delta \psi \mid \psi\rangle-\langle\psi \mid \delta \psi\rangle)=0
$$

The two additional minus signs arise because an -i comes out of the left side of an inner product as i, but out of the right side as -i. Averaging this equation with the original above it has the effect of throwing away the second of each pair of inner products in the original equation.

You can now combine the remaining two terms into one inner product with $\delta \psi$ on the left:

$$
\langle\delta \psi \mid H \psi-\epsilon \psi\rangle=0
$$

If this is to be zero for any change $\delta \psi$, then the right hand side of the inner product must unavoidably be zero. For example, just take $\delta \psi$ equal to a small number $\varepsilon$ times the right hand side, you will get $\varepsilon$ times the square norm of the right hand side, and that can only be zero if the right hand side is. So $H \psi-\epsilon \psi$ $=0$, or

$$
H \psi=\epsilon \psi
$$

So you see that you have recovered the Hamiltonian eigenvalue problem from the requirement that the variation of the expectation energy is zero. Unavoidably then, $\epsilon$ will have to be an energy eigenvalue $E$. It often happens that Lagrangian multipliers have a physical meaning beyond being merely penalty factors. But note that there is no requirement for this to be the ground state. Any energy eigenstate would satisfy the equation; the variational principle works for them all.

Indeed, you may remember from calculus that the derivatives of a function may be zero at more than one point. For example, a function might also have a maximum, or local minima and maxima, or stationary points where the function is neither a maximum nor a minimum, but the derivatives are zero anyway. This sort of thing happens here too: the ground state is the state of lowest possible energy, but there will be other states for which $\delta\langle E\rangle$ is zero, and these will correspond to energy eigenstates of higher energy, $\{D .49\}$.

### 9.2 The Born-Oppenheimer Approximation

Exact solutions in quantum mechanics are hard to come by. In almost all cases, approximation is needed. The Born-Oppenheimer approximation in particular is a key part of real-life quantum analysis of atoms and molecules and the like. The basic idea is that the uncertainty in the nuclear positions is too small to worry about when you are trying to find the wave function for the electrons. That was already assumed in the earlier approximate solutions for the hydrogen molecule and molecular ion. This section discusses the approximation, and how it can be used, in more depth.

### 9.2.1 The Hamiltonian

The general problem to be discussed in this section is that of a number of electrons around a number of nuclei. You first need to know what is the true problem to be solved, and for that you need the Hamiltonian.

This discussion will be restricted to the strictly nonrelativistic case. Corrections for relativistic effects on energy, including those involving spin, can in principle be added later, though that is well beyond the scope of this book. The physical problem to be addressed is that there are a finite number $I$ of electrons around a finite number $J$ of nuclei in otherwise empty space. That describes basic systems of atoms and molecules, but modifications would have to be made for ambient electric and magnetic fields and electromagnetic waves, or for the infinite systems of electrons and nuclei used to describe solids.

The electrons will be numbered using an index $i$, and whenever there is a second electron involved, its index will be called $\underline{i}$. Similarly, the nuclei will be numbered with an index $j$, or $j$ where needed. The nuclear charge of nucleus number $j$, i.e. the number of protons in that nucleus, will be indicated by $Z_{j}$, and the mass of the nucleus by $m_{j}^{\mathrm{n}}$. Roughly speaking, the mass $m_{j}^{\mathrm{n}}$ will be the sum of the masses of the protons and neutrons in the nucleus; however, internal nuclear energies are big enough that there are noticeable relativistic deviations in total nuclear rest mass from what you would think. All the electrons have the same mass $m_{\mathrm{e}}$ since relativistic mass changes due to motion are ignored.

Under the stated assumptions, the Hamiltonian of the system consists of a number of contributions that will be looked at one by one. First there is the kinetic energy of the electrons, the sum of the kinetic energy operators of the individual electrons:

$$
\begin{equation*}
\widehat{T}^{\mathrm{E}}=-\sum_{i=1}^{I} \frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla_{i}^{2}=-\sum_{i=1}^{I} \frac{\hbar^{2}}{2 m_{\mathrm{e}}}\left(\frac{\partial^{2}}{\partial r_{1 i}{ }^{2}}+\frac{\partial^{2}}{\partial r_{2 i}{ }^{2}}+\frac{\partial^{2}}{\partial r_{3 i}{ }^{2}}\right) . \tag{9.4}
\end{equation*}
$$

where $\vec{r}_{i}=\left(r_{1 i}, r_{2 i}, r_{3 i}\right)$ is the position of electron number $i$. Note the use of $\left(r_{1}, r_{2}, r_{3}\right)$ as the notation for the components of position, rather than $(x, y, z)$.

For more elaborate mathematics, the index notation $\left(r_{1}, r_{2}, r_{3}\right)$ is often more convenient, since you can indicate any generic component by the single expression $r_{\alpha}$, (with the understanding that $\alpha=1,2$, or 3 ,) instead of writing them out all three separately.

Similarly, there is the kinetic energy of the nuclei,

$$
\begin{equation*}
\widehat{T}^{\mathrm{N}}=-\sum_{j=1}^{J} \frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}} \nabla_{j}^{\mathrm{n} 2}=-\sum_{j=1}^{J} \frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}}\left(\frac{\partial^{2}}{\partial r_{1 j}^{\mathrm{n}}}+\frac{\partial^{2}}{\partial r_{2 j}^{\mathrm{n}}{ }^{2}}+\frac{\partial^{2}}{\partial r_{3 j}^{\mathrm{n} 2}}\right) \tag{9.5}
\end{equation*}
$$

where $\vec{r}_{j}^{\mathrm{n}}=\left(r_{1 j}^{\mathrm{n}}, r_{2 j}^{\mathrm{n}}, r_{3 j}^{\mathrm{n}}\right)$ is the position of nucleus number $j$.
Next there is the potential energy due to the attraction of the $I$ electrons by the $J$ nuclei. That potential energy is, summing over all electrons and over all nuclei:

$$
\begin{equation*}
V^{\mathrm{NE}}=-\sum_{i=1}^{I} \sum_{j=1}^{J} \frac{Z_{j} e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i j}} \tag{9.6}
\end{equation*}
$$

where $r_{i j} \equiv\left|\vec{r}_{i}-\vec{r}_{j}^{\mathrm{n}}\right|$ is the distance between electron number $i$ and nucleus number $j$, and $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is the permittivity of space.

Next there is the potential energy due to the electron-electron repulsions:

$$
\begin{equation*}
V^{\mathrm{EE}}=\frac{1}{2} \sum_{i=1}^{I} \sum_{\substack{i=1 \\ \underline{i} \neq i}}^{I} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i \underline{i}}} \tag{9.7}
\end{equation*}
$$

where $r_{i \underline{i}} \equiv\left|\vec{r}_{i}-\vec{r}_{\underline{i}}\right|$ is the distance between electron number $i$ and electron number $\underline{i}$. Half of this repulsion energy will be attributed to electron $i$ and half to electron $\underline{i}$, accounting for the factor $\frac{1}{2}$.

Finally, there is the potential energy due to the nucleus-nucleus repulsions,

$$
\begin{equation*}
V^{\mathrm{NN}}=\frac{1}{2} \sum_{j=1}^{J} \sum_{\substack{j=1 \\ \underline{j} \neq j}}^{J} \frac{Z_{j} Z_{\underline{j}} e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{j \underline{j}}} \tag{9.8}
\end{equation*}
$$

where $r_{j \underline{j}} \equiv\left|\vec{r}_{j}^{\mathrm{n}}-\vec{r}_{\underline{j}}^{\mathrm{n}}\right|$ is the distance between nucleus number $j$ and nucleus number $\underline{j}$.

Solving the full quantum problem for this system of electrons and nuclei exactly would involve finding the eigenfunctions $\psi$ to the Hamiltonian eigenvalue problem

$$
\begin{equation*}
\left[\widehat{T}^{\mathrm{E}}+\widehat{T}^{\mathrm{N}}+V^{\mathrm{NE}}+V^{\mathrm{EE}}+V^{\mathrm{NN}}\right] \psi=E \psi \tag{9.9}
\end{equation*}
$$

Here $\psi$ is a function of the position and spin coordinates of all the electrons and all the nuclei, in other words:

$$
\begin{equation*}
\psi=\psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{I}, S_{z I}, \vec{r}_{1}^{\mathrm{n}}, S_{z 1}^{\mathrm{n}}, \vec{r}_{2}^{\mathrm{n}}, S_{z 2}^{\mathrm{n}}, \ldots, \vec{r}_{J}^{\mathrm{n}}, S_{z J}^{\mathrm{n}}\right) \tag{9.10}
\end{equation*}
$$

You might guess solving this problem is a tall order, and you would be perfectly right. It can only be done analytically for the very simplest case of one electron and one nucleus. That is the hydrogen atom solution, using an effective electron mass to include the nuclear motion. For any decent size system, an accurate numerical solution is a formidable task too.

### 9.2.2 Basic Born-Oppenheimer approximation

The general idea of the Born-Oppenheimer approximation is simple. First note that the nuclei are thousands of times heavier than the electrons. A proton is almost two thousand times heavier than an electron, and that does not even count any neutrons in the nuclei.

So, if you take a look at the kinetic energy operators of the two,

$$
\begin{aligned}
& \widehat{T}^{\mathrm{E}}=-\sum_{i=1}^{I} \frac{\hbar^{2}}{2 m_{\mathrm{e}}}\left(\frac{\partial^{2}}{\partial r_{1 i}{ }^{2}}+\frac{\partial^{2}}{\partial r_{2 i}^{2}}+\frac{\partial^{2}}{\partial r_{3 i}{ }^{2}}\right) \\
& \widehat{T}^{\mathrm{N}}=-\sum_{j=1}^{J} \frac{\hbar^{2}}{2 m_{j}^{\mathrm{n}}}\left(\frac{\partial^{2}}{\partial r_{1 j}^{\mathrm{n}}{ }^{2}}+\frac{\partial^{2}}{\partial r_{2 j}^{\mathrm{n}}{ }^{2}}+\frac{\partial^{2}}{\partial r_{3 j}^{\mathrm{n}}{ }^{2}}\right)
\end{aligned}
$$

then what would seem more reasonable than to ignore the kinetic energy $\widehat{T}^{\mathrm{N}}$ of the nuclei? It has those heavy masses in the bottom.

An alternative, and better, way of phrasing the assumption that $\widehat{T}^{\mathrm{N}}$ can be ignored is to say that you ignore the uncertainty in the positions of the nuclei. For example, visualize the hydrogen molecule, figure 5.2. The two protons, the nuclei, have pretty well defined positions in the molecule, while the electron wave function extends over the entire region like a big blob of possible measurable positions. So how important could the uncertainty in position of the nuclei really be?

Assuming that the nuclei do not suffer from quantum uncertainty in position is really equivalent to putting $\hbar$ to zero in their kinetic energy operator above, making the operator disappear, because $\hbar$ is nature's measure of uncertainty. And without a kinetic energy term for the nuclei, there is nothing left in the mathematics to force them to have uncertain positions. Indeed, you can now just guess numerical values for the positions of the nuclei, and solve the approximated eigenvalue problem $H \psi=E \psi$ for those assumed values.

That thought is the Born-Oppenheimer approximation in a nutshell. Just do the electrons, assuming suitable positions for the nuclei a priori. The solutions that you get doing so will be called $\psi^{\mathrm{E}}$ to distinguish them from the true solutions $\psi$ that do not use the Born-Oppenheimer approximation. Mathematically $\psi^{\mathrm{E}}$ will still be a function of the electron and nuclear positions:

$$
\begin{equation*}
\psi^{\mathrm{E}}=\psi^{\mathrm{E}}\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{I}, S_{z I} ; \vec{r}_{1}^{\mathrm{n}}, S_{z 1}^{\mathrm{n}}, \vec{r}_{2}^{\mathrm{n}}, S_{z 2}^{\mathrm{n}}, \ldots, \vec{r}_{J}^{\mathrm{n}}, S_{z J}^{\mathrm{n}}\right) \tag{9.11}
\end{equation*}
$$

But physically it will be a quite different thing: it describes the probability of finding the electrons, given the positions of the nuclei. That is why there is a semi-colon between the electron positions and the nuclear positions. The nuclear positions are here assumed positions, while the electron positions are potential positions, for which the square magnitude of the wave function $\psi^{\mathrm{E}}$ gives the probability. This is an electron wave function only.

In application, it is usually most convenient to write the Hamiltonian eigenvalue problem for the electron wave function as

$$
\left[\widehat{T}^{\mathrm{E}}+V^{\mathrm{NE}}+V^{\mathrm{EE}}+V^{\mathrm{NN}}\right] \psi^{\mathrm{E}}=\left(E^{\mathrm{E}}+V^{\mathrm{NN}}\right) \psi^{\mathrm{E}}
$$

which just means that the eigenvalue is called $E^{\mathrm{E}}+V^{\mathrm{NN}}$ instead of simply $E^{\mathrm{E}}$. The reason is that you can then get rid of $V^{\mathrm{NN}}$, and obtain the electron wave function eigenvalue problem in the more concise form

$$
\begin{equation*}
\left[\widehat{T}^{\mathrm{E}}+V^{\mathrm{NE}}+V^{\mathrm{EE}}\right] \psi^{\mathrm{E}}=E^{\mathrm{E}} \psi^{\mathrm{E}} \tag{9.12}
\end{equation*}
$$

After all, for given nuclear coordinates, $V^{\mathrm{NN}}$ is just a bothersome constant in the solution of the electron wave function that you may just as well get rid of.

Of course, after you compute your electron eigenfunctions, you want to get something out of the results. Maybe you are looking for the ground state of a molecule, like was done earlier for the hydrogen molecule and molecular ion. In that case, the simplest approach is to try out various nuclear positions and for each likely set of nuclear positions compute the electronic ground state energy $E_{\mathrm{gs}}^{\mathrm{E}}$, the lowest eigenvalue of the electronic problem (9.12) above.

For different assumed nuclear positions, you will get different values for the electronic ground state energy, and the nuclear positions corresponding to the actual ground state of the molecule will be the ones for which the total energy is least:

$$
\begin{equation*}
\text { nominal ground state condition: } E_{\mathrm{gs}}^{\mathrm{E}}+V^{\mathrm{NN}} \text { is minimal } \tag{9.13}
\end{equation*}
$$

This is what was used to solve the hydrogen molecule cases discussed in earlier chapters; a computer program was written to print out the energy $E_{\mathrm{gs}}^{\mathrm{E}}+$ $V^{\mathrm{NN}}$ for a lot of different spacings between the nuclei, allowing the spacing that had the lowest total energy to be found by skimming down the print-out. That identified the ground state. The biggest error in those cases was not in using the Born-Oppenheimer approximation or the nominal ground state condition above, but in the crude way in which the electron wave function for given nuclear positions was approximated.

For more accurate work, the nominal ground state condition (9.13) above does have big limitations, so the next subsection discusses a more advanced approach.

### 9.2.3 Going one better

Solving the wave function for electrons only, given positions of the nuclei is definitely a big simplification. But identifying the ground state as the position of the nuclei for which the electron energy plus nuclear repulsion energy is minimal is much less than ideal.

Such a procedure ignores the motion of the nuclei, so it is no use for figuring out any molecular dynamics beyond the ground state. And even for the ground state, it is really wrong to say that the nuclei are at the position of minimum energy, because the uncertainty principle does not allow precise positions for the nuclei.

Instead, the nuclei behave much like the particle in a harmonic oscillator. They are stuck in an electron blob that wants to push them to their nominal positions. But uncertainty does not allow that, and the wave function of the nuclei spreads out a bit around the nominal positions, adding both kinetic and potential energy to the molecule. One example effect of this "zero point energy" is to lower the required dissociation energy a bit from what you would expect otherwise.

It is not a big effect, maybe on the order of tenths of electron volts, compared to typical electron energies described in terms of multiple electron volts (and much more for the inner electrons in all but the lightest atoms.) But it is not as small as might be guessed based on the fact that the nuclei are at least thousands of times heavier than the electrons.

Moreover, though relatively small in energy, the motion of the nuclei may actually be the one that is physically the important one. One reason is that the electrons tend to get stuck in single energy states. That may be because the differences between electron energy levels tend to be so large compared to a typical unit $\frac{1}{2} k T$ of thermal energy, about one hundredth of an electron volt, or otherwise because they tend to get stuck in states for which the next higher energy levels are already filled with other electrons. The interesting physical effects then become due to the seemingly minor nuclear motion.

For example, the heat capacity of typical diatomic gases, like the hydrogen molecule or air under normal conditions, is not in any direct sense due to the electrons; it is kinetic energy of translation of the molecules plus a comparable energy due to angular momentum of the molecule; read, angular motion of the nuclei around their mutual center of gravity. The heat capacity of solids too is largely due to nuclear motion, as is the heat conduction of non metals.

For all those reasons, you would really, really, like to actually compute the motion of the nuclei, rather than just claim they are at fixed points. Does that mean that you need to go back and solve the combined wave function for the complete system of electrons plus nuclei anyway? Throw away the BornOppenheimer approximation results?

Fortunately, the answer is mostly no. It turns out that nature is quite coop-
erative here, for a change. After you have done the electronic structure computations for all relevant positions of the nuclei, you can proceed with computing the motion of nuclei as a separate problem. For example, if you are interested in the ground state nuclear motion, it is governed by the Hamiltonian eigenvalue problem

$$
\left[\widehat{T}^{\mathrm{N}}+V^{\mathrm{NN}}+E_{1}^{\mathrm{E}}\right] \psi_{1}^{\mathrm{N}}=E \psi_{1}^{\mathrm{N}}
$$

where $\psi_{1}^{\mathrm{N}}$ is a wave function involving the nuclear coordinates only, not any electronic ones. The trick is in the potential energy to use in such a computation; it is not just the potential energy of nucleus to nucleus repulsions, but you must include an additional energy $E_{1}^{\mathrm{E}}$.

So, what is this $E_{1}^{\mathrm{E}}$ ? Easy, it is the electronic ground state energy $E_{\mathrm{gs}}^{\mathrm{E}}$ that you computed for assumed positions of the nuclei. So it will depend on where the nuclei are, but it does not depend on where the electrons are. You can just computed $E_{1}^{\mathrm{E}}$ for a sufficient number of relevant nuclear positions, tabulate the results somehow, and interpolate them as needed. $E_{1}^{\mathrm{E}}$ is then a known function function of the nuclear positions and so is $V^{\mathrm{NN}}$. Proceed to solve for the wave function for the nuclei $\psi_{1}^{\mathrm{N}}$ as a problem not directly involving any electrons.

And it does not necessarily have to be just to compute the ground state. You might want to study thermal motion or whatever. As long as the electrons are not kicked strongly enough to raise them to the next energy level, you can assume that they are in their ground state, even if the nuclei are not. The usual way to explain this is to say something like that the electrons "move so fast compared to the slow nuclei that they have all the time in the world to adjust themselves to whatever the electronic ground state is for the current nuclear positions."

You might even decide to use classical molecular dynamics based on the potential $V^{\mathrm{NN}}+E_{1}^{\mathrm{E}}$ instead of quantum mechanics. It would be much faster and easier, and the results are often good enough.

So what if you are interested in what your molecule is doing when the electrons are at an elevated energy level, instead of in their ground state? Can you still do it? Sure. If the electrons are in an elevated energy level $E_{n}^{\mathrm{E}}$, (for simplicity, it will be assumed that the electron energy levels are numbered with a single index $n$,) just solve

$$
\begin{equation*}
\left[\widehat{T}^{\mathrm{N}}+V^{\mathrm{NN}}+E_{n}^{\mathrm{E}}\right] \psi_{n}^{\mathrm{N}}=E \psi_{n}^{\mathrm{N}} \tag{9.14}
\end{equation*}
$$

or equivalent.
Note that for a different value of $n$, this is truly a different motion problem for the nuclei, since the potential energy will be different. If you are a visual sort of person, you might vaguely visualize the potential energy for a given value of $n$ plotted as a surface in some high-dimensional space, and the state of the nuclei moving like a roller-coaster along that potential energy surface, speeding
up when the surface goes down, slowing down if it goes up. There is one such surface for each value of $n$. Anyway. The bottom line is that people refer to these different potential energies as "potential energy surfaces." They are also called "adiabatic surfaces" because "adiabatic" normally means processes sufficiently fast that heat transfer can be ignored. So, some quantum physicists figured that it would be a good idea to use the same term for quantum processes that are so slow that quasi-equilibrium conditions persist throughout, and that have nothing to do with heat transfer.

Of course, any approximation can fail. It is possible to get into trouble solving your problem for the nuclei as explained above. The difficulties arise if two electron energy levels, call them $E_{n}^{\mathrm{E}}$ and $E_{\underline{n}}^{\mathrm{E}}$, become almost equal, and in particular when they cross. In simple terms, the difficulty is that if energy levels are equal, the energy eigenfunctions are not unique, and the slightest thing can throw you from one eigenfunction to the completely different one.

You might now get alarmed, because for example the hydrogen molecular ion does have two different ground state solutions with the same energy. Its single electron can be in either the spin-up state or the spin down state, and it does not make any difference for the energy because the assumed Hamiltonian does not involve spin. In fact, all systems with an odd number of electrons will have a second solution with all spins reversed and the same energy \{D.50\}. There is no need to worry, though; these reversed-spin solutions go their own way and do not affect the validity of (9.14). It is spatial, rather than spin nonuniqueness that is a concern.

There is a derivation of the nuclear eigenvalue problem (9.14) in derivation $\{\mathrm{D} .51\}$, showing what the ignored terms are and why they can usually be ignored.

### 9.3 The Hartree-Fock Approximation

Many of the most important problems that you want to solve in quantum mechanics are all about atoms and/or molecules. These problems involve a number of electrons around a number of atomic nuclei. Unfortunately, a full quantum solution of such a system of any nontrivial size is very difficult. However, approximations can be made, and as section 9.2 explained, the real skill you need to master is solving the wave function for the electrons given the positions of the nuclei.

But even given the positions of the nuclei, a brute-force solution for any nontrivial number of electrons turns out to be prohibitively laborious. The Hartree-Fock approximation is one of the most important ways to tackle that problem, and has been so since the early days of quantum mechanics. This section explains some of the ideas.

### 9.3.1 Wave function approximation

The key to the basic Hartree-Fock method is the assumptions it makes about the form of the electron wave function. It will be assumed that there are a total of $I$ electrons in orbit around a number of nuclei. The wave function describing the set of electrons then has the general form:

$$
\Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}, \ldots, \vec{r}_{i}, S_{z i}, \ldots \vec{r}_{I}, S_{z I}\right)
$$

where $\vec{r}_{i}$ is the position of the electron numbered $i$, and $S_{z i}$ its spin (i.e. internal angular momentum) in a chosen $z$-direction. Recall that while the position of an electron can be anywhere in three-dimensional space, its spin component $S_{z}$ can have only two measurable values: $1 / 2 \hbar$ or $-1 / 2 \hbar$. Because of the factor $1 / 2$, an electron is a "particle of spin one-half". Such a particle is also called a "spin doublet" because of the two possible spin values.

The square magnitude of the wave function above gives the probability for the electrons $i=1,2, \ldots, I$ to be near the position $\vec{r}_{i}$, per unit volume, with spin component $S_{z i}$.

Of course, what the wave function is will also depend on where the nuclei are. However, in this section, the nuclei are supposed to be at given positions. Therefore to reduce the clutter, the dependence of the electron wave function on the nuclear positions will not be shown explicitly.

Hartree-Fock approximates the wave function above in terms of single-electron wave functions. Each single-electron wave function takes the form of a product of a spatial function $\psi^{\mathrm{s}}$ of the electron position $\vec{r}$, times a function of the electron spin component $S_{z}$. The spin function is either taken to be $\uparrow$ or $\downarrow ;$ by definition, function $\uparrow\left(S_{z}\right)$ equals 1 if the spin $S_{z}$ is $1 / 2 \hbar$, and 0 if it is $-1 / 2 \hbar$. Conversely, function $\downarrow\left(S_{z}\right)$ equals 0 if $S_{z}$ is $1 / 2 \hbar$ and 1 if it is $-1 / 2 \hbar$. Function $\uparrow$ is called "spin-up" and $\downarrow$ "spin-down."

A complete single-electron wave function is then of the form

$$
\psi^{s}(\vec{r}) \uparrow\left(S_{z}\right)
$$

where $\downarrow$ is either $\uparrow$ or $\downarrow$. Such a single-electron wave function is called an "orbital" or more accurately a "spin orbital." The reason is that people tend to think of the single-electron wave function as describing a single electron being in a particular orbit around the nuclei with a particular spin. Wrong, of course: the electrons do not have well-defined positions on these scales, so you cannot talk about "orbits" But people do tend to think of the "spatial orbitals" $\psi^{\mathrm{s}}(\vec{r})$ that way anyway.

For simplicity, it will be assumed that the spin orbitals are taken to be "normalized;" if you integrate the square magnitude of $\psi^{s}(\vec{r}) \uparrow\left(S_{z}\right)$ over all possible positions $\vec{r}$ of the electron and sum over the two possible values of its $\operatorname{spin} S_{z}$, you get 1. Physically that merely expresses that the electron must be at some
position and have some spin for certain (probability 1). The integral plus sum combination can be expressed using the concise bra[c]ket notation from chapter 2 ;

$$
\left\langle\psi^{\mathrm{s}} \uparrow \mid \psi^{\mathrm{s}} \downarrow\right\rangle=1
$$

Such a bracket, or "inner product," is equivalent to a dot product for functions.
If there is more than one electron, as will be assumed in this section, a single spin orbital $\psi^{\mathrm{s}} \uparrow$ is not enough to create a valid wave function for the complete system. In fact, the "Pauli exclusion principle" says that each of the $I$ electrons must go into a different spin orbital, chapter 5.7. So a series of orbitals is needed,

$$
\psi_{1}^{\mathrm{s}} \uparrow_{1}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \ldots, \psi_{n}^{\mathrm{s}} \uparrow_{n}, \ldots, \psi_{N}^{\mathrm{s}} \uparrow_{N}
$$

where the number of orbitals $N$ must be at least as big as the number of electrons I.

It will be assumed that any two different spin orbitals $\psi_{n}^{s} \uparrow_{n}$ and $\psi_{\underline{n}}^{s} \downarrow_{\underline{n}}$ are taken to be "orthogonal;" by definition this means that their bracket is zero:

$$
\left\langle\psi_{n}^{\mathrm{s}} \uparrow_{n} \mid \psi_{\underline{n}}^{\mathrm{s}} \imath_{\underline{n}}\right\rangle=0 \quad \text { if } \quad n \neq \underline{n}
$$

In short, it is assumed that the set of spin orbitals is orthonormal; mutually orthogonal and normalized.

Note that the bracket above can be written as a product of a spatial bracket and a spin one:

$$
\left\langle\psi_{n}^{\mathrm{s}} \uparrow_{n} \mid \psi_{\underline{n}}^{\mathrm{s}} \uparrow_{\underline{n}}\right\rangle \equiv\left\langle\psi_{n}^{\mathrm{s}} \mid \psi_{\underline{n}}^{\mathrm{s}}\right\rangle \times\left\langle\uparrow_{n} \mid \uparrow_{\underline{n}}\right\rangle
$$

So for different spin orbitals to be orthogonal, either the spatial states or the spin states must orthogonal; they do not both need to be orthogonal. (To verify the expression above, just write the first bracket out in terms of a spatial integral over $\vec{r}$ and a sum over the two values of $S_{z}$ and reorder terms.)

Note also that the spin states $\uparrow$ and $\downarrow$ are an orthonormal set:

$$
\langle\uparrow \mid \uparrow\rangle=\langle\downarrow \mid \downarrow\rangle=1 \quad\langle\uparrow \mid \downarrow\rangle=\langle\downarrow \mid \uparrow\rangle=0
$$

So if the spin states are opposite, the spatial states do not need to be orthogonal. In fact, the spatial states can then be the same.

The base Hartree-Fock method uses the absolute minimum number of orbitals $N=I$. In that case, the simplest you could do to create a system wave function is to put electron 1 in orbital 1 , electron 2 in orbital 2 , etcetera. That would give the system wave function

$$
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \downarrow_{1}\left(S_{z 1}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right) \downarrow_{2}\left(S_{z 2}\right) \psi_{3}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{3}\left(S_{z 3}\right) \ldots \psi_{I}^{\mathrm{s}}\left(\vec{r}_{I}\right) \downarrow_{I}\left(S_{z I}\right)
$$

A product of single-electron wave functions like this is called a "Hartree product."

But a single Hartree product like the one above is physically not acceptable as a wave function. The Pauli exclusion principle is only part of what is needed, chapter 5.7. The full requirement is that a system wave function must be "antisymmetric under electron exchange:" the wave function must simply change sign when any two electrons are swapped. But if, say, electrons 1 and 2 are swapped in the Hartree product above, it produces the new Hartree product

$$
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{1}\left(S_{z 2}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{1}\right) \downarrow_{2}\left(S_{z 2}\right) \psi_{3}^{\mathrm{s}}\left(\vec{r}_{3}\right) \downarrow_{3}\left(S_{z 3}\right) \ldots \psi_{I}^{\mathrm{s}}\left(\vec{r}_{I}\right) \downarrow_{I}\left(S_{z I}\right)
$$

That is a fundamentally different wave function, not just minus the first Hartree product; orbitals $\psi_{1}^{\mathrm{s}} \uparrow_{1}$ and $\psi_{2}^{\mathrm{s}} \uparrow_{2}$ are not allowed to be equivalent.

To get a wave function that does simply change sign when electrons 1 and 2 are swapped, you can take the first Hartree product minus the second one. That solves that problem. But it is not enough: the wave function must also simply change sign if electrons 1 and 3 are swapped. Or if 2 and 3 are swapped, etcetera.

So you must add more Hartree products with swapped electrons to the mix. A lot more in fact. There are $I$ ! ways to order $I$ electrons, and each ordering adds one Hartree product to the mix. (The Hartree product gets a plus sign or a minus sign in the mix depending on whether the number of swaps to get there from the first one is even or odd). So for, say, a single carbon atom with $I=6$ electrons, writing down the full Hartree-Fock wave function would mean writing down $6!=720$ Hartree products. Roughly a thousand of them, in short. Of course, writing all that out would be insane. Fortunately, there is a more concise way to write the complete wave function; it uses a so-called "Slater determinant,"

$$
\left|\begin{array}{cccccc}
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{1}\left(S_{z 1}\right) & \psi_{2}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{2}\left(S_{z 1}\right) & \ldots & \psi_{n}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{n}\left(S_{z 1}\right) & \ldots & \psi_{I}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{I}\left(S_{z 1}\right)  \tag{9.15}\\
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{1}\left(S_{z 2}\right) & \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{2}\left(S_{z 2}\right) & \ldots & \psi_{n}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{n}\left(S_{z 2}\right) & \ldots & \left.\psi_{I}^{\mathrm{s}} \vec{r}_{2}\right) \uparrow_{I}\left(S_{z 2}\right) \\
\vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{1}\left(S_{z i}\right) & \psi_{2}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{2}\left(S_{z i}\right) & \ldots & \psi_{n}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{n}\left(S_{z i}\right) & \ldots & \psi_{I}^{\mathrm{s}}\left(\vec{r}_{i}\right) \uparrow_{I}\left(S_{z i}\right) \\
\vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\
\psi_{1}^{\mathrm{s}\left(\vec{r}_{I}\right) \uparrow_{1}\left(S_{z I}\right)} & \psi_{2}^{\mathrm{s}}\left(\vec{r}_{I}\right) \uparrow_{2}\left(S_{z I}\right) & \ldots & \psi_{n}^{\mathrm{s}}\left(\vec{r}_{I}\right) \uparrow_{n}\left(S_{z I}\right) & \ldots & \psi_{I}^{\mathrm{s}}\left(\vec{r}_{I}\right) \uparrow_{I}\left(S_{z I}\right)
\end{array}\right|
$$

The determinant multiplies out to the $I$ ! individual Hartree products. (See chapter 5.7 and the notations section for more on determinants.) The factor $1 / / \sqrt{I}$ ! is there to ensure that the wave function remains normalized after summing the $I$ ! Hartree products together.

The most general system wave function $\Psi$ using only $N=I$ orbitals is any coefficient $a$ of magnitude 1 times the above Slater determinant. However, displaying the Slater determinant fully as above is still a lot to write and read. Therefore, from now on the Slater determinant will be abbreviated as in

$$
\begin{equation*}
\Psi=a\left|\operatorname{det} \psi_{1}^{\mathrm{s}} \uparrow_{1}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \ldots, \psi_{n}^{\mathrm{s}} \uparrow_{n}, \ldots, \psi_{I}^{\mathrm{s}} \uparrow_{I}\right\rangle \tag{9.16}
\end{equation*}
$$

where $|\operatorname{det} \ldots\rangle$ is the Slater determinant.
It is important to realize that using the minimum number of single-electron functions will unavoidably produce an error that is mathematically speaking not small $\{$ N.16\}. To get a vanishingly small error, you would need a large number of different Slater determinants, not just one. Still, the results you get with the basic Hartree-Fock approach may be good enough to satisfy your needs. Or you may be able to improve upon them enough with "post-Hartree-Fock methods."

But none of that would be likely if you just selected the single-electron functions $\psi_{1}^{\mathrm{s}} \uparrow_{1}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \ldots$ at random. The cleverness in the Hartree-Fock approach will be in writing down equations for these single-electron wave functions that produce the best approximation possible with a single Slater determinant.

Recall the approximate solutions that were written down for the electrons in atoms in chapter 5.9. These solutions were really single Slater determinants. To improve on these results, you might think of trying to find more accurate ways to average out the effects of the neighboring electrons than just putting them in the nucleus as that chapter essentially did. You could smear them out over some optimal area, say. But even if you did that, the Hartree-Fock solution will still be better, because it gives the best possible approximation obtainable with any single determinant.

That assumes of course that the spins are taken the same way. Consider that problem for a second. Typically, a nonrelativistic approach is used, in which spin effects on the energy are ignored. Then spin only affects the antisymmetrization requirements.

Things are straightforward if you try to solve, say, a helium atom. The correct ground state takes the form

$$
\Psi_{\mathrm{He}}\left(\vec{r}_{1}, \vec{r}_{2}\right) \times \frac{\uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
$$

The factor $\Psi_{\mathrm{He}}\left(\vec{r}_{1}, \vec{r}_{2}\right)$ is the spatial wave function that has the absolutely lowest energy, regardless of any antisymmetrization concerns. This wave function must be symmetric (unchanged) under electron exchange since the two electrons are identical and the ground state is unique. The antisymmetrization requirement is met because the spins combine together as shown in the second factor above; this factor changes sign when the electrons are exchanged. So the spatial state does not have to change sign.

The combined spin state shown in the second factor above is called the "singlet state," chapter 5.5.6. In the singlet state the two spins cancel each other completely: the net electron spin is zero. If you measure the net spin component in any direction, not just the chosen $z$-direction, you get zero.

Based on the exact helium ground state wave function above, you would take the Hartree-Fock approximation to be of the form

$$
\left|\operatorname{det} \psi_{1}^{\mathrm{s} \uparrow} \uparrow, \psi_{2}^{\mathrm{s}} \downarrow\right\rangle
$$

and then you would make things easier for yourself by postulating a priori that the spatial orbitals are the same, $\psi_{1}^{\mathrm{s}}=\psi_{2}^{\mathrm{s}}$. Lo and behold, when you multiply out the Slater determinant,

$$
\frac{1}{\sqrt{2}}\left|\begin{array}{ll}
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow\left(S_{z 1}\right) & \psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \downarrow\left(S_{z 1}\right) \\
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 2}\right) & \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 2}\right)
\end{array}\right|
$$

you get

$$
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \times \frac{\uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
$$

This automagically reproduces the correct singlet spin state! (The approximation comes in because the exact spatial ground state, $\Psi_{\mathrm{He}}\left(\vec{r}_{1}, \vec{r}_{2}\right)$ is not just the product of two single-electron functions as in Hartree-Fock.) And you only need to find one spatial orbital instead of two.

As discussed in chapter 5.9, a beryllium atom has two electrons with opposite spins in the " 1 s " shell like helium, and two more in the " 2 s " shell. An appropriate Hartree-Fock wave function would be

$$
\left|\operatorname{det} \psi_{1}^{\mathrm{s}} \uparrow, \psi_{1}^{\mathrm{s}} \downarrow, \psi_{3}^{\mathrm{s}} \uparrow, \psi_{3}^{\mathrm{s}} \downarrow\right\rangle
$$

in other words, two pairs of orbitals with the same spatial states and opposite spins. Similarly, Neon has an additional 6 paired electrons in a closed " 2 p " shell, and you could use 3 more pairs of orbitals with the same spatial states and opposite spins. The number of spatial orbitals that must be found in such solutions is only half the number of electrons. This procedure is called the "closed shell Restricted Hartree-Fock (RHF)" method. It restricts the form of the spatial states to be pair-wise equal.

But now look at lithium. Lithium has two paired 1s electrons like helium, and an unpaired 2s electron. For the third orbital in the Hartree-Fock determinant, you will now have to make a choice: whether to take it of the form $\psi_{3}^{\mathrm{s}} \uparrow$ or $\psi_{3}^{\mathrm{s}} \downarrow$. Lets assume you take $\psi_{3}^{\mathrm{s}} \uparrow$, so the wave function is

$$
\mid \operatorname{det} \psi_{1}^{\mathrm{s} \uparrow} \uparrow, \psi_{2}^{\mathrm{s}} \downarrow, \psi_{3}^{\mathrm{s} \uparrow\rangle}
$$

You have introduced a bias in the determinant: there is now a real difference between the spatial orbitals $\psi_{1}^{\mathrm{s}}$ and $\psi_{2}^{\mathrm{s}}: \psi_{1}^{\mathrm{s}} \uparrow$ has the same spin as the third spin orbital, but $\psi_{2}^{\varsigma} \downarrow$ the opposite.

If you find the best approximation to the energy among all possible spatial orbitals $\psi_{1}^{\mathrm{s}}, \psi_{2}^{\mathrm{s}}$, and $\psi_{3}^{\mathrm{s}}$, you will end up with orbitals $\psi_{1}^{\mathrm{s}}$ and $\psi_{2}^{\mathrm{s}}$ that are not the same. Allowing for them to be different is called the "Unrestricted HartreeFock (UHF)" method. In general, you no longer require that equivalent spatial orbitals are the same in their spin-up and spin down versions. For a bigger system, you will end up with one set of orthonormal spatial orbitals for the spin-up orbitals and a different set of orthonormal spatial orbitals for the spindown ones. These two sets of orthonormal spatial orbitals are not mutually
orthogonal; the only reason the complete spin orbitals are still orthonormal is because the two spins are orthogonal, $\langle\uparrow \mid \downarrow\rangle=0$.

If instead of using unrestricted Hartree-Fock, you insist on demanding that the spatial orbitals for spin up and down do form a single set of orthonormal functions, it is called "open shell Restricted Hartree-Fock (RHF)." In the case of lithium, you would then demand that $\psi_{2}^{\mathrm{s}}$ equals $\psi_{1}^{\mathrm{s}}$. Since the best (in terms of energy) solution has them different, your solution is then no longer the best possible. You pay a price, but you now only need to find two spatial orbitals rather than three. The spin orbital $\psi_{3}^{s} \uparrow$ without a matching opposite-spin orbital counts as an open shell. For nitrogen, you might want to use three open shells to represent the three different spatial states $2 \mathrm{p}_{x}, 2 \mathrm{p}_{y}$, and $2 \mathrm{p}_{z}$ with an unpaired electron in it.

If you use unrestricted Hartree-Fock instead, you will need to compute more spatial functions, and you pay another price, spin. Since all spin effects in the Hamiltonian are ignored, it commutes with the spin operators. So, the exact energy eigenfunctions are also, or can be taken to be also, spin eigenfunctions. Restricted Hartree-Fock has the capability of producing approximate energy eigenstates with well defined spin. Indeed, as you saw for helium, in restricted Hartree-Fock all the paired spin-up and spin-down states combine into zerospin singlet states. If any additional unpaired states are all spin up, say, you get an energy eigenstate with a net spin equal to the sum of the spins of the unpaired states. This allows you to deal with typical atoms, including lithium and nitrogen, very nicely.

But a true unrestricted Hartree-Fock solution does not have correct, definite, spin. For two electrons to produce states of definite combined spin, the coefficients of spin-up and spin-down must come in specific ratios. As a simple example, an unrestricted Slater determinant of $\psi_{1}^{\mathrm{s}} \uparrow$ and $\psi_{2}^{\mathrm{s}} \downarrow$ with unequal spatial orbitals multiplies out to

$$
\left|\operatorname{det} \psi_{1}^{\mathrm{s} \uparrow} \uparrow, \psi_{2}^{\mathrm{s}} \downarrow\right\rangle=\frac{\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\psi_{2}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
$$

or, writing the spin combinations in terms of singlets (which change sign under electron exchange) and triplets (which do not),

$$
\begin{aligned}
& \frac{\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right)+\psi_{2}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right)}{2} \times \frac{\uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}+ \\
& \frac{\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right)-\psi_{2}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right)}{2} \times \frac{\uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)+\downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
\end{aligned}
$$

So the spin will be some combination of the singlet state, the first term, and a triplet state, the second. And the precise combination will depend on the spatial locations of the electrons to boot. Now while the singlet state has net spin 0 , triplet states have net spin 1 . So the net spin is uncertain, either 0 or

1 , even though it should not be. (Spin 1 implies that the measured component of the spin in any direction must be one of the triplet of values $\hbar, 0$, or $-\hbar$. For the particular triplet state shown above, the component of spin in the $z$ direction happens to be zero. But the net spin is not; in a direction normal to the $z$-direction, the spin will be measured to be either $\hbar$ or $-\hbar$.) However, despite the spin problem, it may be noted that unrestricted wave functions are commonly used as first approximations of doublet (spin $1 / 2$ ) and triplet (spin 1) states anyway [46, p. 105].

To show that all this can make a real difference, take the example of the hydrogen molecule, chapter 5.2, when the two nuclei are far apart. The correct electronic ground state is

$$
\frac{\psi_{\mathrm{L}}\left(\vec{r}_{1}\right) \psi_{\mathrm{R}}\left(\vec{r}_{2}\right)+\psi_{\mathrm{R}}\left(\vec{r}_{1}\right) \psi_{\mathrm{L}}\left(\vec{r}_{2}\right)}{\sqrt{2}} \times \frac{\uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
$$

where $\psi_{\mathrm{L}}\left(\vec{r}_{1}\right) \psi_{\mathrm{R}}\left(\vec{r}_{2}\right)$ is the state in which electron 1 is around the left proton and electron 2 around the right one, and $\psi_{\mathrm{R}}\left(\vec{r}_{1}\right) \psi_{\mathrm{L}}\left(\vec{r}_{2}\right)$ is the same state but with the electrons reversed. Note that, like for the helium atom, the spatial state is symmetric under electron exchange. However, it is not just a product of two single-electron functions but a sum of two of such products. Note also that the correct spin state is the singlet one with zero net spin, just like for the helium atom. It takes care of the antisymmetrization requirement.

Now try to approximate this solution with a restricted closed shell HartreeFock wave function of the form

$$
\left|\operatorname{det} \psi_{1}^{\mathrm{s} \uparrow} \uparrow, \psi_{1}^{\mathrm{s}} \downarrow\right\rangle
$$

Multiplying out the determinant gives

$$
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \psi_{1}^{\mathrm{s}}\left(\vec{r}_{2}\right) \times \frac{\uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
$$

Note that you do get the correct singlet spin state. But $\psi_{1}^{\mathrm{s}}$ will be something like $\left(\psi_{\mathrm{L}}+\psi_{\mathrm{R}}\right) / \sqrt{2}$; the energy of either electron is lowest when it is near one of the nuclei. If you multiply out the resulting spatial wave function, the terms include $\psi_{\mathrm{L}} \psi_{\mathrm{L}}$ and $\psi_{\mathrm{R}} \psi_{\mathrm{R}}$, in addition to the correct $\psi_{\mathrm{L}} \psi_{\mathrm{R}}$ and $\psi_{\mathrm{R}} \psi_{\mathrm{L}}$. That produces a $50 / 50$ chance that the two electrons are found around the same nucleus. That is all wrong, since the electrons repel each other: if one electron is around the left nucleus, the other electron should be around the right nucleus. The computed energy, which should be that of two neutral hydrogen atoms far apart, will be much too high due to electron-electron repulsion.
(Fortunately, at the nuclear separation distance corresponding to the ground state of the complete molecule, the errors are much less, [46, p. 166]. Note that if you put the two nuclei completely on top of each other, you get a helium atom, for which Hartree-Fock gives a much more reasonable electron energy.

Only when you are "breaking the bond," dissociating the molecule, i.e. taking the nuclei far apart, do you get into major trouble.)

If instead you would use unrestricted Hartree-Fock, say

$$
\left|\operatorname{det} \psi_{1}^{\mathrm{s} \uparrow} \uparrow, \psi_{2}^{\mathrm{s}} \downarrow\right\rangle
$$

you should find $\psi_{1}^{\mathrm{s}}=\psi_{\mathrm{L}}$ and $\psi_{2}^{\mathrm{s}}=\psi_{\mathrm{R}}$ (or vice versa), which would produce a wave function

$$
\frac{\psi_{\mathrm{L}}\left(\vec{r}_{1}\right) \psi_{\mathrm{R}}\left(\vec{r}_{2}\right) \uparrow\left(S_{z 1}\right) \downarrow\left(S_{z 2}\right)-\psi_{\mathrm{R}}\left(\vec{r}_{1}\right) \psi_{\mathrm{L}}\left(\vec{r}_{2}\right) \downarrow\left(S_{z 1}\right) \uparrow\left(S_{z 2}\right)}{\sqrt{2}}
$$

In both terms, if the first electron is around the one nucleus, the second electron is around the other. So this produces the correct energy, that of two neutral hydrogen atoms. But the spin is now all wrong. It is not a singlet state, but the combination of a singlet and a triplet state already written down earlier. Little in life is ideal, is it?
(Actually there is a dirty trick to fix this. Note that which of the two orbitals you give spin-up and which spin-down is physically immaterial. So there is a trivially different solution

$$
\left|\operatorname{det} \psi_{1}^{\mathrm{s}} \downarrow, \psi_{2}^{\mathrm{s}} \uparrow\right\rangle
$$

If you take a 50/50 combination of the original Slater determinant and minus the one above, you get the correct singlet spin state. And the spatial state will now be the correct average of $\psi_{\mathrm{L}} \psi_{\mathrm{R}}$ and $\psi_{\mathrm{R}} \psi_{\mathrm{L}}$ to boot. This spatial state is more accurate than just two neutral atoms if the distance between the nuclei decreases, chapter 5.2. All this for free! This sort of dirty trick in Hartree-Fock is called a "spin adapted configuration." It is usually used to deal with a few open shells in an otherwise closed-shell restricted Hartree-Fock configuration.)

All of the above may be much more than you ever wanted to hear about the wave function. The purpose was mainly to indicate that things are not as simple as you might initially suppose. As the examples showed, some understanding of the system that you are trying to model definitely helps. Or experiment with different approaches.

Let's go on to the next step: how to get the equations for the spatial orbitals $\psi_{1}^{\mathrm{s}}, \psi_{2}^{\mathrm{s}}, \ldots$ that give the most accurate approximation of a multi-electron problem. The expectation value of energy will be needed for that, and to get that, first the Hamiltonian is needed. That will be the subject of the next subsection.

### 9.3.2 The Hamiltonian

The nonrelativistic Hamiltonian of the system of $I$ electrons consists of a number of contributions. First there is the kinetic energy of the electrons; the sum of the kinetic energy operators of the individual electrons:

$$
\begin{equation*}
\widehat{T}^{\mathrm{E}}=-\sum_{i=1}^{I} \frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla_{i}^{2}=-\sum_{i=1}^{I} \frac{\hbar^{2}}{2 m_{\mathrm{e}}}\left(\frac{\partial^{2}}{\partial x_{i}^{2}}+\frac{\partial^{2}}{\partial y_{i}^{2}}+\frac{\partial^{2}}{\partial z_{i}^{2}}\right) \tag{9.17}
\end{equation*}
$$

Next there is the potential energy due to the ambient electric field that the electrons move in. It will be assumed that this field is caused by $J$ nuclei, numbered using an index $j$, and having charge $Z_{j} e$ (i.e. there are $Z_{j}$ protons in nucleus number $j$ ). In that case, the total potential energy due to nucleuselectron attractions is, summing over all electrons and over all nuclei:

$$
\begin{equation*}
V^{\mathrm{NE}}=-\sum_{i=1}^{I}\left(\sum_{j=1}^{J} \frac{Z_{j} e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i j}^{\mathrm{n}}}\right) \tag{9.18}
\end{equation*}
$$

where $r_{i j}^{\mathrm{n}} \equiv\left|\vec{r}_{i}-\vec{r}_{j}^{\mathrm{n}}\right|$ is the distance between electron number $i$ and nucleus number $j$, and $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is the permittivity of space.

And now for the black plague of quantum mechanics, the electron to electron repulsions. The potential energy for those repulsions is

$$
\begin{equation*}
V^{\mathrm{EE}}=\sum_{i=1}^{I} \sum_{\underline{i>i}}^{I} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i \underline{i}}} \tag{9.19}
\end{equation*}
$$

where $r_{i \underline{i}} \equiv\left|\vec{r}_{i}-\vec{r}_{\underline{\underline{L}}}\right|$ is the distance between electron number $i$ and electron number $\underline{i}$. To avoid counting each repulsion energy twice, (the second time with reversed electron order), the second electron number is required to be larger than the first.

Without this repulsion between different electrons, you could solve for each electron separately, and all would be nice. But you do have it, and so you really need to solve for all electrons at once, usually an impossible task. You may recall that when chapter 5.9 examined the atoms heavier than hydrogen, those with more than one electron, the discussion cleverly threw out the electron to electron repulsion terms, by assuming that the effect of each neighboring electron is approximately like canceling out one proton in the nucleus. And you may also remember how this outrageous assumption led to all those wrong predictions that had to be corrected by various excuses. The Hartree-Fock approximation tries to do better than that.

It is helpful to split the Hamiltonian into the single electron terms and the troublesome interactions, as follows,

$$
\begin{equation*}
H=\sum_{i=1}^{I} h_{i}^{\mathrm{e}}+\sum_{i=1}^{I} \sum_{\underline{i}>i}^{I} v_{i \underline{i}}^{\mathrm{ee}} \tag{9.20}
\end{equation*}
$$

where $h_{i}^{e}$ is the single-electron Hamiltonian of electron $i$,

$$
\begin{equation*}
h_{i}^{\mathrm{e}}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla_{i}^{2}+\sum_{j=1}^{J} \frac{Z_{j} e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i j}^{\mathrm{n}}} \tag{9.21}
\end{equation*}
$$

and $v_{i i}^{\mathrm{ee}}$ is the electron $i$ to electron $\underline{i}$ repulsion potential energy,

$$
\begin{equation*}
v_{i \underline{i}}^{\mathrm{ee}}=\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{i \underline{i}}} \tag{9.22}
\end{equation*}
$$

Note that $h_{1}^{\mathrm{e}}, h_{2}^{\mathrm{e}}, \ldots, h_{I}^{\mathrm{e}}$ all take the same general form; the difference is just in which electron you are talking about. That is not surprising because the electrons all have the same properties. Similarly, the difference between $v_{12}^{\mathrm{e}}$, $v_{13}^{\mathrm{ee}}, \ldots, v_{(I-1) I}^{\mathrm{ee}}$ is just in which pair of electrons you talk about.

### 9.3.3 The expectation value of energy

As was discussed in more detail in section 9.1, to find the best possible HartreeFock approximation, the expectation value of energy will be needed. For example, the best approximation to the ground state is the one that has the smallest expectation value of energy.

The expectation value of energy $\langle E\rangle$ is defined as the inner product

$$
\langle\Psi| H|\Psi\rangle
$$

where $H$ is the Hamiltonian as given in the previous subsection. There is a problem with using this expression mindlessly, though. Take once again the example of the arsenic atom. There are 33 electrons in this atom, so you could try to choose 33 promising single-electron wave functions to describe it. You could then try to multiply out the Slater determinant for $\Psi$, but that produces 33!, or about $410^{36}$, Hartree products. If you put these 33 ! terms in both sides of the inner product, you get $(33!)^{2}$ or $7.510^{73}$ pairs of terms, each producing one inner product that must be integrated. Now since there are 3 coordinates for each of the positions of the 33 electrons, this means that each term requires integration over 99 scalar coordinates. Even using only 10 points in each direction, that would mean evaluating $10^{99}$ integration points for each of the $7.510^{73}$ pairs of terms. A computer that could do that is unimaginable. As of 2014, the fastest computer in the world can do no more than $10^{25}$ floating point computations if it stays at it for 10 years.

Fortunately, it turns out, $\{\mathrm{D} .52\}$, that almost all of those integrations are trivial since the single-electron functions are orthonormal. If you sit down and identify what is really left, you find that only a few three-dimensional and sixdimensional inner products survive the weeding-out process.

In particular, the single-electron Hamiltonians from the previous subsection produce only single-electron energy expectation values of the general form

$$
\begin{equation*}
E_{n}^{\mathrm{e}} \equiv\left\langle\psi_{n}^{\mathrm{s}}\right| h^{\mathrm{e}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \tag{9.23}
\end{equation*}
$$

If you had only one single electron, and it was in the spatial single-particle state $\psi_{n}^{\mathbf{s}}(\vec{r})$, the above inner product would be its energy.

The combined single-electron energy for all $I$ electrons is then

$$
\sum_{n=1}^{I} E_{n}^{e}
$$

It is just as if you had electron 1 in state $\psi_{1}^{\mathrm{s}}$, electron 2 in state $\psi_{2}^{\mathrm{s}}$, etcetera. Of course, that is not really true. Antisymmetrization requires that all electrons are partly in all states. Indeed, if you look a bit closer at the math, you see that each of the $I$ electrons contributes an equal fraction $1 / I$ to each of the $I$ terms above. But it does not make a real difference. Without electron-electron interactions, quantum mechanics would be so much easier!

But the repulsions are there. The Hamiltonians of the repulsions turn out to produce six-dimensional spatial inner products of two types. The inner products of the first type are called "Coulomb integrals:"

$$
\begin{equation*}
J_{n \underline{n}} \equiv\left\langle\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right\rangle \tag{9.24}
\end{equation*}
$$

To understand the Coulomb integrals better, the inner product above can be written out explicitly as an integral, while also expanding $v^{\mathrm{ee}}$ :

$$
\int_{\text {all } \vec{r}} \int_{\text {all }}\left|\psi_{n}^{\mathrm{s}}(\vec{r})\right|^{2} \left\lvert\, \psi_{\underline{n}}^{\mathrm{s}}\left(\underline{\vec{r}}| |^{2} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{|\vec{r}-\underline{\vec{r}}|} \mathrm{d}^{3} \vec{r} \mathrm{~d}^{3} \overrightarrow{\underline{r}}\right.\right.
$$

The integrand equals the probability of an electron in state $\psi_{n}^{s}$ to be found near a position $\vec{r}$, times the probability of an electron in state $\psi_{n}^{s}$ to be found near a position $\underline{\vec{r}}$, times the Coulomb repulsion energy if the two electrons are at those positions. In short, $J_{n \underline{n}}$ is the expectation value of the Coulomb repulsion potential between an electron in state $\psi_{n}^{\mathrm{s}}$ and one in state $\psi_{n}^{\mathrm{s}}$. Thinking again of electron 1 in state $\psi_{1}^{\mathrm{s}}$, electron 2 in state $\psi_{2}^{\mathrm{s}}$, etcetera, the total Coulomb repulsion energy would be

$$
\sum_{n=1}^{I} \sum_{\underline{n}>n}^{I} J_{n \underline{n}}
$$

which is indeed the correct combined sum of the Coulomb integrals.
Unfortunately, that is not the complete story for the repulsion energy. Recall that there are $I$ ! different ways in which you can distribute the $I$ electrons over the $I$ single particle states. And the antisymmetrization requirement requires that the system wave function is an equal combination of all these $I$ ! different possibilities. In terms of classical physics, it might still seem that this should make no difference: if any one of these $I$ ! possibilities is true, then the others must be untrue. But quantum mechanics allows states in which the electrons are distributed in one way to interact with states in which they are distributed in another way. That produces the so-called "exchange integrals:"

$$
\begin{equation*}
K_{n \underline{n}} \equiv\left\langle\psi_{n}^{\mathrm{s}} \psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}} \psi_{n}^{\mathrm{s}}\right\rangle \tag{9.25}
\end{equation*}
$$

Written out explicitly, that equals

$$
\int_{\mathrm{all} \vec{r}} \int_{\operatorname{all} \underline{\underline{r}}} \psi_{n}^{\mathrm{s}}(\vec{r})^{*} \psi_{\underline{n}}^{\mathrm{s}}(\underline{\vec{r}})^{*} \frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{|\vec{r}-\underline{\vec{r}}|} \psi_{\underline{n}}^{\mathrm{s}}(\vec{r}) \psi_{n}^{\mathrm{s}}(\underline{\vec{r}}) \mathrm{d}^{3} \vec{r} \mathrm{~d}^{3} \underline{\underline{r}}
$$

It is an interaction of the possibility that the first electron is in state $\psi_{n}^{\mathrm{s}}$ and the second in state $\psi_{n}^{\mathrm{s}}$ with the possibility that the second electron is in state $\psi_{n}^{\mathrm{s}}$ and the first in state $\psi_{\underline{n}}^{\mathrm{s}}$. This book likes to call terms like this "twilight terms," since in terms of classical physics they do not make sense.

It may be noted that a single Hartree product satisfying the Pauli exclusion principle would not produce exchange integrals; in such a wave function, there is no possibility for an electron to be in another state. But don't start thinking that the exchange integrals are there just because the wave function must be antisymmetric under electron exchange. They, and others, would show up in any reasonably general wave function. You can think of the exchange integrals instead as Coulomb integrals with the electrons in the right hand side of the inner product exchanged.

Adding it all up, the expectation energy of the complete system of $I$ electrons can be written as

$$
\begin{equation*}
\langle E\rangle=\sum_{n=1}^{I} E_{n}^{\mathrm{e}}+\frac{1}{2} \sum_{n=1}^{I} \sum_{\underline{n}=1}^{I} J_{n \underline{n}}-\frac{1}{2} \sum_{n=1}^{I} \sum_{\underline{n}=1}^{I}\left\langle\imath_{n} \mid \uparrow_{\underline{n}}\right\rangle^{2} K_{n \underline{n}} \tag{9.26}
\end{equation*}
$$

Note that the above expression sums over all values of $\underline{n}$, not just $\underline{n}>n$. That counts each pair of single-electron wave functions twice, so factors one-half have been added to compensate. It also adds terms in which $\underline{n}=n$, both electrons in the same state, which is not allowed by the Pauli principle. But since $J_{n n}=K_{n n}$, these additional terms cancel each other.

Note also the spin inner products multiplying the exchange terms. These are zero if the two states have opposite spin, so there are no exchange contributions between electrons in spin orbitals of opposite spins. And if the spin orbitals have the same spin, the spin inner product is 1 , so the square is somewhat superfluous.

There are also some a priori things you can say about the Coulomb and exchange integrals, $\{D .53\}$; they are real, and additionally

$$
\begin{equation*}
J_{n n}=K_{n n} \quad J_{n \underline{n}}=J_{\underline{n} n} \quad K_{n \underline{n}}=K_{\underline{n} n} \quad J_{n \underline{n}} \geqslant K_{n \underline{n}} \geqslant 0 \tag{9.27}
\end{equation*}
$$

Note in particular that since the $K_{n \underline{n}}$ terms are positive, they lower the net expectation energy of the system. So a wave function consisting of a single Hartree product, which produces no exchange terms, cannot be the state of lowest energy. Even without the antisymmetrization requirement, you would need Hartree products with the electrons exchanged, simply to lower the energy.

It is actually somewhat tricky to prove that the $K_{n \underline{n}}$ terms are positive and so lower the energy, $\{\mathrm{D} .53\}$. But there is a simple physical reason why you might guess that an antisymmetric wave function would lower the electron-electron repulsion energy compared to the individual Hartree products from which it is made up. In particular, the Coulomb repulsion between electrons becomes very large when they get close together. But for an anti-symmetric wave function, unlike for a single Hartree product, the relative probability of electrons of the same spin getting close together is vanishingly small. That prevents any strong Coulomb repulsion between electrons of the same spin.
(Recall that the relative probability for electrons to be at given positions and spins is given by the square magnitude of the wave function at those positions and spins. Now an antisymmetric wave function must be zero wherever any two electrons are at the same position with the same spin, making this impossible. After all, if you swap the two electrons, the antisymmetric wave function must change sign. But since neither electron changes position nor spin, the wave function cannot change either. Something can only change sign and stay the same if it is zero. See also $\{$ A. 34$\}$.)

The analysis given in this subsection can easily be extended to generalized orbitals that take the form

$$
\psi_{n}^{\mathrm{p}}\left(\vec{r}, S_{z}\right)=\psi_{n+}^{\mathrm{s}}(\vec{r}) \uparrow\left(S_{z}\right)+\psi_{n-}^{\mathrm{s}}(\vec{r}) \downarrow\left(S_{z}\right) .
$$

However, the normal unrestricted spin-up or spin-down orbitals, in which either $\psi_{n+}^{\mathrm{s}}$ or $\psi_{n-}^{\mathrm{s}}$ is zero, already satisfy the variational requirement $\delta\langle E\rangle=0$ even if generalized variations in the orbitals are allowed, $\{\mathrm{N} .17\}$.

In any case, the expectation value of energy has been found.

### 9.3.4 The canonical Hartree-Fock equations

The previous subsection found the expectation value of energy for any electron wave function described by a single Slater determinant. The final step is to find the orbitals that produce the best approximation of the true wave function using such a single determinant. For the ground state, the best single determinant would be the one with the lowest expectation value of energy. But surely you would not want to guess spatial orbitals at random until you find some with really, really, low energy.

What you would like to have is specific equations for the best spatial orbitals that you can then solve in a methodical way. And you can have them using the methods of section 9.1, \{D.54\}. In unrestricted Hartree-Fock, for every spatial
orbital $\psi_{n}^{\mathrm{s}}(\vec{r})$ there is an equation of the form:

$$
\begin{align*}
& h^{\mathrm{e}} \psi_{n}^{\mathrm{s}}(\vec{r})+\sum_{\underline{n}=1}^{I}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}(\vec{r}) \\
&-\sum_{\underline{n}=1}^{I}\left\langle\uparrow_{\underline{n}} \mid \uparrow_{n}\right\rangle^{2}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{\underline{n}}^{\mathrm{s}}(\vec{r})=\epsilon_{n} \psi_{n}^{\mathrm{s}}(\vec{r}) \tag{9.28}
\end{align*}
$$

These are called the "canonical Hartree-Fock equations." For equations valid for the restricted closed-shell and single-determinant open-shell approximations, see the derivation in \{D.54\}.

Recall that $h^{e}$ is the single-electron Hamiltonian consisting of the electron's kinetic energy and potential energy due to nuclear attractions, and that $v^{\text {ee }}$ is the potential energy of repulsion between the electron and another at a position $\stackrel{\rightharpoonup}{\vec{r}}:$

$$
h^{\mathrm{e}}=-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla^{2}-\sum_{j=1}^{J} \frac{Z_{j} e^{2}}{4 \pi \epsilon_{0}} \frac{1}{r_{j}} \quad r_{j} \equiv\left|\vec{r}-\vec{r}_{j}^{\mathrm{n}}\right| \quad v^{\mathrm{ee}}=\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{\underline{r}} \quad \underline{r} \equiv|\vec{r}-\overrightarrow{\vec{r}}|
$$

So, if there were no electron-electron repulsions, i.e. $v^{\text {ee }}=0$, the canonical equations above would be single-electron Hamiltonian eigenvalue problems of the form $h^{\mathrm{e}} \psi_{n}^{\mathrm{s}}=\epsilon_{n} \psi_{n}^{\mathrm{s}}$ where $\epsilon_{n}$ would be the energy of the single-electron orbital. This is really what happened in the approximate analysis of atoms in chapter 5.9: the electron to electron repulsions were ignored there in favor of nuclear strength reductions, and the result was single-electron hydrogen-atom orbitals.

In the presence of electron to electron repulsions, the equations for the orbitals can still symbolically be written as if they were single-electron eigenvalue problems,

$$
\mathcal{F} \psi_{n}^{\mathrm{s}}(\vec{r}) \uparrow_{n}\left(S_{z}\right)=\epsilon_{n} \psi_{n}^{\mathrm{s}}(\vec{r}) \uparrow_{n}\left(S_{z}\right)
$$

where $\mathcal{F}$ is called the "Fock operator," and is written out further as:

$$
\mathcal{F}=h^{\mathrm{e}}+v^{\mathrm{HF}}
$$

The first term in the Fock operator is the single-electron Hamiltonian. The mischief is in the innocuous-looking second term $v^{\mathrm{HF}}$. Supposedly, this is the potential energy related to the repulsion by the other electrons. What is it? Well, it will have to be the terms in the canonical equations (9.28) not described by the single-electron Hamiltonian $h^{e}$ :

$$
\begin{aligned}
v^{\mathrm{HF}} \psi^{\mathrm{s}}(\vec{r}) \uparrow\left(S_{z}\right)= & \sum_{\underline{n}=1}^{I}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}}\right\rangle \psi^{\mathrm{s}}(\vec{r}) \downarrow\left(S_{z}\right) \\
& \left.\quad-\sum_{\underline{n}=1}^{I}\left\langle\downarrow_{\underline{n}} \mid \uparrow\right\rangle\right\rangle\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi^{\mathrm{s}}(\vec{r})\right\rangle \psi_{\underline{n}}^{\mathrm{s}}(\vec{r}) \downarrow_{\underline{n}}\left(S_{z}\right)
\end{aligned}
$$

The definition of the Fock operator is unavoidably in terms of spin rather than just spatial orbitals: the spin of the state on which it operates must be known to evaluate the final term.

Note that the above expression did not give an expression for $v^{\mathrm{HF}}$ by itself, but only for $v^{\mathrm{HF}}$ applied to an arbitrary single-electron function $\psi^{\mathrm{s} \uparrow} \downarrow$. The reason is that $v^{\mathrm{HF}}$ is not a normal potential at all: the second term, the one due to the exchange integrals, does not multiply $\psi^{s} \uparrow$ by a potential function, it shoves it into an inner product! The Hartree-Fock "potential" $v^{\mathrm{HF}}$ is an operator, not a normal potential energy. Given a single-electron function including spin, it produces another single-electron function including spin.

Actually, even that is not quite true. The Hartree-Fock "potential" is only an operator after you have found the orbitals $\psi_{1}^{\mathrm{s}} \uparrow_{1}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \ldots, \psi_{\underline{n}}^{\mathrm{s}} \uparrow_{\underline{n}}, \ldots, \psi_{I}^{\mathrm{s}} \uparrow_{I}$ appearing in it. While you are still trying to find them, the Fock "operator" is not even an operator, it is just a "thing." However, given the orbitals, at least the Fock operator is a Hermitian one, one that can be taken to the other side if it appears in an inner product, and that has real eigenvalues and a complete set of eigenfunctions, $\{\mathrm{D} .55\}$.

So how do you solve the canonical Hartree-Fock equations for the orbitals $\psi_{n}^{\mathrm{s}}$ ? If the Hartree-Fock potential $v^{\mathrm{HF}}$ was a known operator, you would have only linear, single-electron eigenvalue problems to solve. That would be relatively easy, as far as those things come. But since the operator $v^{\mathrm{HF}}$ contains the unknown orbitals, you do not have a linear problem at all; it is a system of coupled cubic equations in infinitely many unknowns. The usual way to solve it is iteratively: you guess an approximate form of the orbitals and plug it into the Hartree-Fock potential. With this guessed potential, the orbitals may then be found from solving linear eigenvalue problems. If all goes well, the obtained orbitals, though not perfect, will at least be better than the ones that you guessed at random. So plug those improved orbitals into the HartreeFock potential and solve the eigenvalue problems again. Still better orbitals should result. Keep going until you get the correct solution to within acceptable accuracy.

You will know when you have got the correct solution since the Hartree-Fock potential will no longer change; the potential that you used to compute the final set of orbitals is really the potential that those final orbitals produce. In other words, the final Hartree-Fock potential that you compute is consistent with the final orbitals. Since the potential would be a field if it was not an operator, that explains why such an iterative method to compute the Hartree-Fock solution is called a "self-consistent field method." It is like calling an iterative scheme for the Laplace equation on a mesh a "self-consistent neighbors method," instead of "point relaxation." Surely the equivalent for Hartree-Fock, like"iterated potential" or "potential relaxation" would have been much clearer to a general audience?

### 9.3.5 Additional points

This brief section was not by any means a tutorial of the Hartree-Fock method. The purpose was only to explain the basic ideas in terms of the notations and coverage of this book. If you actually want to apply the method, you will need to take up a book written by experts who know what they are talking about. The book by Szabo and Ostlund [46] was the main reference for this section, and is recommended as a well written introduction. Below are some additional concepts you may want to be aware of.

### 9.3.5.1 Meaning of the orbital energies

In the single electron case, the "orbital energy" $\epsilon_{n}$ in the canonical Hartree-Fock equation

$$
\begin{aligned}
& h^{\mathrm{e}} \psi_{n}^{\mathrm{s}}(\vec{r})+\sum_{\underline{n}=1}^{I}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}(\vec{r}) \\
&-\sum_{\underline{n}=1}^{I}\left\langle\uparrow_{\underline{n}} \mid \uparrow_{n}\right\rangle^{2}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{\underline{n}}^{\mathrm{s}}(\vec{r})=\epsilon_{n} \psi_{n}^{\mathrm{s}}(\vec{r})
\end{aligned}
$$

represents the actual energy of the electron. It also represents the ionization energy, the energy required to take the electron away from the nuclei and leave it far away at rest. This subsubsection will show that in the multiple electron case, the "orbital energies" $\epsilon_{n}$ are not orbital energies in the sense of giving the contributions of the orbitals to the total expectation energy. However, they can still be taken to be approximate ionization energies. This result is known as "Koopman's theorem."

To verify the theorem, a suitable equation for $\epsilon_{n}$ is needed. It can be found by taking an inner product of the canonical equation above with $\psi_{n}^{\mathrm{s}}(\vec{r})$, i.e. by putting $\psi_{n}^{\mathrm{s}}(\vec{r})^{*}$ to the left of both sides and integrating over $\vec{r}$. That produces

$$
\begin{equation*}
\epsilon_{n}=E_{n}^{\mathrm{e}}+\sum_{\underline{n}=1}^{I} J_{n \underline{n}}-\sum_{\underline{n}=1}^{I}\left\langle\imath_{n} \mid \imath_{\underline{n}}\right\rangle^{2} K_{n \underline{n}} \tag{9.29}
\end{equation*}
$$

which consists of the single-electron energy $E_{n}^{\mathrm{e}}$, Coulomb integrals $J_{n \underline{n}}$ and exchange integrals $K_{n \underline{n}}$ as defined in subsection 9.3.3. It can already be seen that if all the $\epsilon_{n}$ are summed together, it does not produce the total expectation energy (9.26), because that one includes a factor $\frac{1}{2}$ in front of the Coulomb and exchange integrals. So, $\epsilon_{n}$ cannot be seen as the part of the system energy associated with orbital $\psi_{n}^{\mathrm{s}} \uparrow_{n}$ in any meaningful sense.

However, $\epsilon_{n}$ can still be viewed as an approximate ionization energy. Assume that the electron is removed from orbital $\psi_{n}^{\mathbf{s} \uparrow_{n}}$, leaving the electron at infinite distance at rest. No, scratch that; all electrons share orbital $\psi_{n}^{\mathrm{s}} \downarrow_{n}$, not just one.

Assume that one electron is removed from the system and that the remaining $I-1$ electrons stay out of the orbital $\psi_{n}^{\mathrm{s}} \imath_{n}$. Then, if it is assumed that the other orbitals do not change, the new system's Slater determinant is the same as the original system's, except that column $n$ and a row have been removed. The expectation energy of the new state then equals the original expectation energy, except that $E_{n}^{e}$ and the $n$-th column plus the $n$-th row of the Coulomb and exchange integral matrices have been removed. The energy removed is then exactly $\epsilon_{n}$ above. (While $\epsilon_{n}$ only involves the $n$-th row of the matrices, not the $n$-th column, it does not have the factor $\frac{1}{2}$ in front of them like the expectation energy does. And rows equal columns in the matrices, so half the row in $\epsilon_{n}$ counts as the half column in the expectation energy and the other half as the half row. This counts the element $\underline{n}=n$ twice, but that is zero anyway since $J_{n n}=K_{n n}$.)

So by the removal of the electron "from" (read: and) orbital $\psi_{n}^{\mathrm{s}} \uparrow_{n}$, an amount of energy $\epsilon_{n}$ has been removed from the expectation energy. Better put, a positive amount of energy $-\epsilon_{n}$ has been added to the expectation energy. So the ionization energy is $-\epsilon_{n}$ if the electron is removed from orbital $\psi_{n}^{\mathrm{s}} \uparrow_{n}$ according to this story.

Of course, the assumption that the other orbitals do not change after the removal of one electron and orbital is dubious. If you were a lithium electron in the expansive 2 s state, and someone removed one of the two inner 1 s electrons, would you not want to snuggle up a lot more closely to the now much less shielded three-proton nucleus? On the other hand, in the more likely case that someone removed the 2 s electron, it would probably not seem like that much of an event to the remaining two 1 s electrons near the nucleus, and the assumption that the orbitals do not change would appear more reasonable. And normally, when you say ionization energy, you are talking about removing the electron from the highest energy state.

But still, you should really recompute the remaining two orbitals from the canonical Hartree-Fock equations for a two-electron system to get the best, lowest, energy for the new $I-1$ electron ground state. The energy you get by not doing so and just sticking with the original orbitals will be too high. Which means that all else being the same, the ionization energy will be too high too.

However, there is another error of importance here, the error in the HartreeFock approximation itself. If the original and final system would have the same Hartree-Fock error, then it would not make a difference and $\epsilon_{n}$ would overestimate the ionization energy as described above. But Szabo and Ostlund [46, p. 128] note that Hartree-Fock tends to overestimate the energy for the original larger system more than for the final smaller one. The difference in HartreeFock error tends to compensate for the error you make by not recomputing the final orbitals, and in general the orbital energies provide reasonable first approximations to the experimental ionization energies.

The opposite of ionization energy is "electron affinity," the energy with which
the atom or molecule will bind an additional free electron [in its valence shell], \{N.19\}. It is not to be confused with electronegativity, which has to do with willingness to take on electrons in chemical bonds, rather than free electrons.

To compute the electron affinity of an atom or molecule with $I$ electrons using the Hartree-Fock method, you can either recompute the $I+1$ orbitals with the additional electron from scratch, or much easier, just use the Fock operator of the $I$ electrons to compute one more orbital $\psi_{I+1}^{\mathrm{s}} \downarrow_{I+1}$. In the later case however, the energy of the final system will again be higher than Hartree-Fock, and it being the larger system, the Hartree-Fock energy will be too high compared to the $I$-electron system already. So now the errors add up, instead of subtract as in the ionization case. If the final energy is too high, then the computed binding energy will be too low, so you would expect $\epsilon_{I+1}$ to underestimate the electron affinity relatively badly. That is especially so since affinities tend to be relatively small compared to ionization energies. Indeed Szabo and Ostlund [46, p. 128] note that while many neutral molecules will take up and bind a free electron, producing a stable negative ion, the orbital energies almost always predict negative binding energy, hence no stable ion.

### 9.3.5.2 Asymptotic behavior

The exchange terms in the Hartree-Fock potential are not really a potential, but an operator. It turns out that this makes a major difference in how the probability of finding an electron decays with distance from the system.

Consider again the Fock eigenvalue problem, but with the single-electron Hamiltonian identified in terms of kinetic energy and nuclear attraction,

$$
\begin{aligned}
-\frac{\hbar^{2}}{2 m_{\mathrm{e}}} \nabla^{2} \psi_{n}^{\mathrm{s}}(\vec{r})+v^{\mathrm{Ne}} \psi_{n}^{\mathrm{s}}(\vec{r})+ & \sum_{\underline{n}=1}^{I}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{\underline{n}}^{\mathrm{s}}\right\rangle \psi_{n}^{\mathrm{s}}(\vec{r}) \\
& -\sum_{\underline{n}=1}^{I}\left\langle\hat{\imath}_{\underline{n}} \mid \imath_{n}\right\rangle^{2}\left\langle\psi_{\underline{n}}^{\mathrm{s}}\right| v^{\mathrm{ee}}\left|\psi_{n}^{\mathrm{s}}\right\rangle \psi_{\underline{n}}^{\mathrm{s}}(\vec{r})=\epsilon_{n} \psi_{n}^{\mathrm{s}}(\vec{r})
\end{aligned}
$$

Now consider the question which of these terms dominate at large distance from the system and therefore determine the large-distance behavior of the solution.

The first term that can be thrown out is $v^{\mathrm{Ne}}$, the Coulomb potential due to the nuclei; this potential decays to zero approximately inversely proportional to the distance from the system. (At large distance from the system, the distances between the nuclei can be ignored, and the potential is then approximately the one of a single point charge with the combined nuclear strengths.) Since $\epsilon_{n}$ in the right hand side does not decay to zero, the nuclear term cannot survive compared to it.

Similarly the third term, the Coulomb part of the Hartree-Fock potential, cannot survive since it too is a Coulomb potential, just with a charge distribution given by the orbitals in the inner product.

However, the final term in the left hand side, the exchange part of the Hartree-Fock potential, is more tricky, because the various parts of this sum have other orbitals outside of the inner product. This term can still be ignored for the slowest-decaying spin-up and spin-down states, because for them none of the other orbitals is any larger, and the multiplying inner product still decays like a Coulomb potential (faster, actually). Under these conditions the kinetic energy will have to match the right hand side, implying

$$
\text { slowest decaying orbitals: } \psi_{n}^{\mathrm{s}}(\vec{r}) \sim \exp \left(-\sqrt{-2 m_{\mathrm{e}} \epsilon_{n}} r / \hbar+\ldots\right)
$$

From this expression, it can also be seen that the $\epsilon_{n}$ values must be negative, or else the slowest decaying orbitals would not have the exponential decay with distance of a bound state.

The other orbitals, however, cannot be less than the slowest decaying one of the same spin by more than algebraic factors: the slowest decaying orbital with the same spin appears in the exchange term sum and will have to be matched. So, with the exchange terms included, all orbitals normally decay slowly, raising the chances of finding electrons at significant distances. The decay can be written as

$$
\begin{equation*}
\psi_{n}^{\mathrm{s}}(\vec{r}) \sim \exp \left(-\sqrt{2 m_{\mathrm{e}}\left|\epsilon_{m}\right|_{\text {min, same spin, no ss }} r} / \hbar+\ldots\right) \tag{9.30}
\end{equation*}
$$

where $\epsilon_{m}$ is the $\epsilon$ value of smallest magnitude (absolute value) among all the orbitals with the same spin.

However, in the case that $\psi_{n}^{\mathrm{s}}(\vec{r})$ is spherically symmetric, (i.e. an s state), exclude other s-states as possibilities for $\epsilon_{m}$. The reason is a peculiarity of the Coulomb potential that makes the inner product appearing in the exchange term exponentially small at large distance for two orthogonal, spherically symmetric states. (For the incurably curious, it is a result of Maxwell's first equation applied to a spherically symmetric configuration like figure 13.1, but with multiple spherically distributed charges rather than one, and the net charge being zero.)

### 9.3.5.3 Hartree-Fock limit

The Hartree-Fock approximation greatly simplifies finding a many-dimensional wave function. But really, solving the "eigenvalue problems" (9.28) for the orbitals iteratively is not that easy either. Typically, what one does is to write the orbitals $\psi_{n}^{\mathrm{s}}$ as sums of chosen single-electron functions $f_{1}, f_{2}, \ldots$. You can then precompute various integrals in terms of those functions. Of course, the number of chosen single-electron functions will have to be a lot more than the number of orbitals $I$; if you are only using $I$ chosen functions, it really means that you are choosing the orbitals $\psi_{n}^{\mathrm{s}}$ rather than computing them.

But you do not want to choose too many functions either, because the required numerical effort will go up. So there will be an error involved; you will
not get as close to the true best orbitals as you can. One thing this means is that the actual error in the ground state energy will be even larger than true Hartree-Fock would give. For that reason, the Hartree-Fock value of the ground state energy is called the "Hartree-Fock limit:" it is how close you could come to the correct energy if you were able to solve the Hartree-Fock equations exactly.

In short, to compute the Hartree-Fock solution accurately, you want to select a large number of single-electron functions to represent the orbitals. But don't start using zillions of them. The problem is that even the exact Hartree-Fock solution still has a finite error; a wave function cannot in general be described accurately using only a single Slater determinant. So what would the point in computing the very inaccurate numbers to ten digits accuracy?

### 9.3.5.4 Correlation energy

As the previous subsubsection noted, the Hartree-Fock solution, even if computed exactly, will still have a finite error. You might think that this error would be called something like "Hartree-Fock error." Or maybe "representation error" or "single-determinant error," since it is due to an incomplete representation of the true wave function using a single Slater determinant.

However, the Hartree-Fock error in energy is called "correlation energy." The reason is because there is a energizing correlation between the more impenetrable and poorly defined your jargon, and the more respect you will get for doing all that incomprehensible stuff.

And of course the word "error" should never be used in the first place, God forbid. Or those hated non-experts might figure out that Hartree-Fock has an error in energy so big that it makes the base approximation pretty much useless for chemistry.

To understand what physicists are referring to with "correlation," reconsider the form of the Hartree-Fock wave function, as described in subsection 9.3.1. It consisted of a single Slater determinant. However, that Slater determinant in turn consisted of a lot of Hartree products, the first of which was

$$
\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \downarrow_{1}\left(S_{z 1}\right) \psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right) \downarrow_{2}\left(S_{z 2}\right) \psi_{3}^{\mathrm{s}}\left(\vec{r}_{3}\right) \downarrow_{3}\left(S_{z 3}\right) \ldots \psi_{I}^{\mathrm{s}}\left(\vec{r}_{I}\right) \downarrow_{I}\left(S_{z I}\right)
$$

The other Hartree products were different only in the order in which the electrons appear in the product. And since the electrons are all the same, the order does not make a difference: each of these Hartree products has the same expectation energy. Each also satisfies the Pauli exclusion principle but, by itself, not the antisymmetrization requirement.

Now, consider what the Born statistical interpretation says about the single Hartree product above. It says that the probability of electron 1 to be within a vicinity of volume $\mathrm{d}^{3} \vec{r}_{1}$ around a given position $\vec{r}_{1}$ with given $\operatorname{spin} S_{z 1}$, and electron 2 to be within a vicinity of volume $\mathrm{d}^{3} \vec{r}_{2}$ around a given position $\vec{r}_{2}$ with
given $\operatorname{spin} S_{z 2}$, etcetera, is given by

$$
\begin{aligned}
& \left|\psi_{1}^{\mathrm{s}}\left(\vec{r}_{1}\right) \uparrow_{1}\left(S_{z 1}\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{1} \\
& \quad \times\left|\psi_{2}^{\mathrm{s}}\left(\vec{r}_{2}\right) \uparrow_{2}\left(S_{z 2}\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{2} \\
& \quad \times\left|\psi_{3}^{\mathrm{s}}\left(\vec{r}_{3}\right) \uparrow_{3}\left(S_{z 3}\right)\right|^{2} \mathrm{~d}^{3} \vec{r}_{3}
\end{aligned}
$$

This takes the form of a probability for electron 1 to be in the given state that is independent of where the other electrons are, times a probability for electron 2 to be in the given state that is independent of where the other electrons are, etcetera. In short, in a single Hartree product the electrons do not care where the other electrons are. Their positions are "uncorrelated."

Uncorrelated positions would be OK if the electrons did not repel each other. In that case, each electron would indeed not care where the other electrons are. Then all Hartree products would have the same energy, which would also be the energy of the complete Slater determinant.

But electrons do repel each other. So, if electron 1 is at a given position $\vec{r}_{1}$, electron 2 can reduce its potential energy by preferring positions farther away from that position. It cannot overdo it, as that will increase its kinetic energy too much, but there is some room for improvement. So the exact wave function will have correlations between the positions of different electrons. Based on arguments like that, physicists then come up with the term correlation energy.

Not so fast, physicists! For one, a Slater determinant is not a single Hartree product but already includes some electron correlations. Also, "correlation energy" is not the same as "error in energy caused by incorrect correlations." And "error in energy caused by incorrect correlations" is not the same as "error in energy for an incorrect solution, including incorrect correlations." And the last is what the Hartree-Fock error really is. Note that while there is some rough qualitative relation between potential energy and electron position correlations, you cannot find the potential energy by pontificating about electrons trying to stay away from each other. And the correct energy state is found by delicately balancing subtle reductions in potential energy against subtle increases in kinetic energy. The kinetic energy does not even care about electron correlations. However, the kinetic energy is wrong too when applied on a single Slater determinant.

See note $\{$ N. 18$\}$ for more.

### 9.3.5.5 Configuration interaction

Since the base Hartree-Fock approximation has an error that is far too big for typical chemistry applications, the next question is what can be done about it. The basic answer is simple: use more that $I$ orbitals, i.e. single-particle wave
functions. As already noted in section 5.7, if you include enough orthonormal basis functions, using all their possible Slater determinants, you can approximate any function to arbitrary accuracy.

After the $I$, (or $I / 2$ in the restricted closed-shell case,) spatial orbitals have been found, the Hartree-Fock operator becomes just a Hermitian operator, and can be used to compute further orthonormal orbitals $\psi_{I+1}^{\mathrm{s}} \downarrow_{I+1}, \psi_{I+2}^{\mathrm{s}} \downarrow_{I+2}, \ldots$. You can add these to the mix, say to get a better approximation to the true ground state wave function of the system.

You might want to try to start small. If you include just one more orbital $\psi_{I+1}^{\mathrm{s}} \uparrow_{I+1}$, you can already form $I$ more Slater determinants: you can replace any of the $I$ orbitals in the original determinant by the new function $\psi_{I+1}^{\mathrm{s}} \uparrow_{I+1}$. So you can now approximate the true wave function by the more general expression

$$
\begin{aligned}
\Psi=a_{0} & \left(\left|\operatorname{det} \psi_{1}^{\mathrm{s} \uparrow} \uparrow_{1}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \psi_{3}^{\mathrm{s}} \uparrow_{3}, \ldots, \psi_{I}^{\mathrm{s}} \uparrow_{I}\right\rangle\right. \\
& +a_{1}\left|\operatorname{det} \psi_{I+1}^{\mathrm{s}} \uparrow_{I+1}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \psi_{3}^{\mathrm{s}} \uparrow_{3}, \ldots, \psi_{I}^{\mathrm{s}} \uparrow_{I}\right\rangle \\
& +a_{2}\left|\operatorname{det} \psi_{1}^{\mathrm{s}} \uparrow_{1}, \psi_{I+1}^{\mathrm{s}} \uparrow_{I+1}, \psi_{3}^{\mathrm{s}} \imath_{3}, \ldots, \psi_{I}^{\mathrm{s}} \uparrow_{I}\right\rangle \\
& +\ldots \\
& \left.+a_{I}\left|\operatorname{det} \psi_{1}^{\mathrm{s} \imath_{1}}, \psi_{2}^{\mathrm{s}} \uparrow_{2}, \psi_{3}^{\mathrm{s}} \uparrow_{3}, \ldots, \psi_{I+1}^{\mathrm{s}} \uparrow_{I+1}\right\rangle\right)
\end{aligned}
$$

where the coefficients $a_{1}, a_{2}, \ldots$ are to be chosen to approximate the ground state energy more closely and $a_{0}$ is a normalization constant.

The additional $I$ Slater determinants are called "excited determinants". For example, the first excited state

$$
\left|\operatorname{det} \psi_{I+1}^{\mathrm{s}} \uparrow_{I+1}, \psi_{2}^{\mathrm{s} \imath_{2}}, \psi_{3}^{\mathrm{s}} \uparrow_{3}, \ldots, \psi_{I}^{\mathrm{s}} \uparrow_{I}\right\rangle
$$

is like a state where you excited an electron out of the lowest state $\psi_{1}^{\mathrm{s}} \uparrow_{1}$ into an elevated energy state $\psi_{I+1}^{s} \imath_{I+1}$.
(However, note that if you really wanted to satisfy the variational requirement $\delta\langle E\rangle=0$ for such a state, you would have to recompute the orbitals from scratch, using $\psi_{I+1}^{\mathrm{s}} \mathfrak{\imath}_{I+1}$ in the Fock operator instead of $\psi_{1}^{\mathrm{s}} \uparrow_{1}$. That is not what you want to do here; you do not want to create totally new orbitals, just more of them.)

It may seem that this must be a winner: as much as $I$ more determinants to further minimize the energy. Unfortunately, now you pay the price for doing such a great job with the single determinant. Since, hopefully, the Slater determinant is the best single determinant that can be formed, any changes that are equivalent to simply changing the determinant's orbitals will do no good. And it turns out that the $I+1$-determinant wave function above is equivalent to the single-determinant wave function

$$
\Psi=a_{0}\left|\operatorname{det} \psi_{1}^{\mathrm{s}} \mathfrak{1}_{1}+a_{1} \psi_{I+1}^{\mathrm{s}} \mathfrak{\imath}_{I+1}, \psi_{2}^{\mathrm{s}} \mathfrak{\imath}_{2}+a_{2} \psi_{I+1}^{\mathrm{s}} \mathfrak{\imath}_{I+1}, \ldots, \psi_{I}^{\mathrm{s}} \mathfrak{\imath}_{I}+a_{I} \psi_{I+1}^{\mathrm{s}} \mathfrak{\imath}_{I+1}\right\rangle
$$

as you can check with some knowledge of the properties of determinants. Since you already have the best single determinant, all your efforts are going to be wasted if you try this.

You might try forming another set of $I$ excited determinants by replacing one of the orbitals in the original Hartree-Fock determinant by $\psi_{I+2}^{\mathrm{s}} \hat{\downarrow}_{I+2}$ instead of $\psi_{I+1}^{\mathrm{s}} \mathfrak{\imath}_{I+1}$, but the fact is that the infinitesimal variational condition $\delta\langle E\rangle=0$ is still going to be satisfied when the wave function is the original Hartree-Fock one. For small changes in wave function, the additional determinants can still be pushed inside the Hartree-Fock one. To ensure a decrease in energy, you want to include determinants that allow a nonzero decrease in energy even for small changes from the original determinant, and that requires "doubly" excited determinants, in which two different original states are replaced by excited ones like $\psi_{I+1}^{\mathrm{s}} \uparrow_{I+1}$ and $\psi_{I+2}^{\mathrm{s}} \downarrow_{I+2}$.

Note that you can form $I(I-1)$ such determinants; the number of determinants rapidly explodes when you include more and more orbitals. And a mathematically convergent process would require an asymptotically large set of orbitals, compare chapter 5.7. How big is your computer?

Most people would probably call improving the wave function representation using multiple Slater determinants something like "multiple-determinant representation," or "excited-determinant correction.". However, it is called "configuration interaction." The reason is that every hated non-expert will wonder whether the physicist is talking about the configuration of the nuclei or the electrons, and what it is interacting with.
(Actually, "configuration" refers to the practitioner "configuring" all those determinants, no kidding. The interaction is with the computer used to do so. Suppose you were creating the numerical mesh for some finite difference or finite element computation. If you called that "configuration interaction" instead of "mesh generation," because it required you to "configure" all those mesh points through interacting with your computer, some people might doubt your sanity. But in physics, the standards are not so high.)

## Chapter 10

## Solids

Quantum mechanics is essential to make sense out of the properties of solids. Some of the most important properties of solids were already discussed in chapter 6 . It is a good idea to review these sections before reading this chapter.

The discussion will remain restricted to solids that have a "crystal structure." In a crystal the atoms are packed together in a regular manner. Some important materials, like glass and plastic, are amorphous, they do not have such a regular crystal structure, and neither do liquids, so not all the ideas will apply to them.

### 10.1 Molecular Solids

The hydrogen molecule is the most basic example in quantum mechanics of how atoms can combine into molecules in order to share electrons. So, the question suggests itself whether, if hydrogen molecules are brought close together in a solid, will the atoms start sharing their electrons not just with one other atom, but with all surrounding atoms? The answer under normal conditions is no. Metals do that, but hydrogen under normal conditions does not. Hydrogen atoms are very happy when combined in pairs, and have no desire to reach out to further atoms and weaken the strong bond they have already created. Normally hydrogen is a gas, not a metal.

However, if you cool hydrogen way down to 20 K , it will eventually condense into a liquid, and if you cool it down even further to 14 K , it will then freeze into a solid. That solid still consists of hydrogen molecules, so it is called a molecular solid. (Note that solidified noble gases, say frozen neon, are called molecular solids too, even though they are made up of atoms rather than molecules.)

The forces that glue the hydrogen molecules together in the liquid and solid phases are called Van der Waals forces, and more specifically, they are called London forces. (Van der Waals forces are often understood to be all intermolecular forces, not just London forces.) London forces are also the only forces that can glue noble gas atoms together. These forces are weak.

It is exactly because these forces are so weak that hydrogen must be cooled down so much to condense it into liquid and finally freeze it. At the time of this writing, that is a significant issue in the "hydrogen economy." Unless you go to very unusual temperatures and pressures, hydrogen is a very thin gas, hence extremely bulky.

Helium is even worse; it must be cooled down to 4 K to condense it into a liquid, and under normal pressure it will not freeze into a solid at all. These two, helium and hydrogen are the worst elements of them all, and the reason is that their atoms are so small. Van der Waals forces increase with size.

To explain why the London forces occur is easy; there are in fact two explanations that can be given. There is a simple, logical, and convincing explanation that can easily be found on the web, and that is also completely wrong. And there is a weird quantum explanation that is also correct, $\{\mathrm{A} .33\}$.

If you are the audience that this book is primarily intended for, you may already know the London forces under the guise of the Lennard-Jones potential. London forces produce an attractive potential between atoms that is proportional to $1 / d^{6}$ where $d$ is a scaled distance between the molecules. So the Lennard-Jones potential is taken to be

$$
\begin{equation*}
V_{\mathrm{LJ}}=C\left(d^{-12}-d^{-6}\right) \tag{10.1}
\end{equation*}
$$

where $C$ is a constant. The second term represents the London forces.
The first term in the Lennard-Jones potential is there to model the fact that when the atoms get close enough, they rapidly start repelling instead of attracting each other. (See section 5.10 for more details.) The power 12 is computationally convenient, since it makes the first term just the square of the second one. However, theoretically it is not very justifiable. A theoretically more reasonable repulsion would be one of the form $\bar{C} e^{-d / c} / d^{n}$, with $\bar{C}, c$, and $n$ suitable constants, since that reflects the fact that the strength of the electron wave functions ramps up exponentially when you get closer to an atom. But practically, the Lennard-Jones potential works very well; the details of the first term make no big difference as long as the potential ramps up quickly.

It may be noted that at very large distances, the London force takes the Casimir-Polder form $1 / d^{7}$ rather than $1 / d^{6}$. Charged particles do not really interact directly as a Coulomb potential assumes, but through photons that move at the speed of light. At large separations, the time lag makes a difference, [26]. The separation at which this happens can be ballparked through dimensional arguments. The frequency of a typical photon corresponding to transitions between energy states is given by $\hbar \omega=E$ with $E$ the energy difference between the states. The frequency for light to bounce back and forwards between the molecules is given by $c / d$, with $c$ the speed of light. It follows that the frequency for light to bounce back and forward is no longer large compared to $\omega$ when $E d / \hbar c$ becomes order one. For hydrogen, $E$ is about 10 eV and $\hbar c$ is about 200
eV nm . That makes the typical separation at which the $1 / d^{6}$ relation breaks down about 20 nm , or $200 \AA ̊$.

Molecular solids may be held together by other Van der Waals forces besides London forces. Many molecules have an charge distribution that is inherently asymmetrical. If one side is more negative and the other more positive, the molecule is said to have a "dipole strength." The molecules can arrange themselves so that the negative sides of the molecules are close to the positive sides of neighboring molecules and vice versa, producing attraction. (Even if there is no net dipole strength, there will be some electrostatic interaction if the molecules are very close and are not spherically symmetric like noble gas atoms are.)

Chemguide 【1】notes: "Surprisingly dipole-dipole attractions are fairly minor compared to dispersion [London] forces, and their effect can only really be seen if you compare two molecules with the same number of electrons and the same size." One reason is that thermal motion tends to kill off the dipole attractions by messing up the alignment between molecules. But note that the dipole forces act on top of the London ones, so everything else being the same, the molecules with a dipole strength will be bound together more strongly

When more than one molecular species is around, species with inherent dipoles can induce dipoles in other molecules that normally do not have them.

Another way molecules can be kept together in a solid is by what are called "hydrogen bonds." In a sense, they too are dipole-dipole forces. In this case, the molecular dipole is created when the electrons are pulled away from hydrogen atoms. This leaves a partially uncovered nucleus, since an hydrogen atom does not have any other electrons to shield it. Since it allows neighboring molecules to get very close to a nucleus, hydrogen bonds can be strong. They remain a lot weaker than a typical chemical bond, though.

## Key Points

0- Even neutral molecules that do not want to create other bonds can be glued together by various "Van der Waals forces."

0 - These forces are weak, though hydrogen bonds are much less so.
0- The London type Van Der Waals forces affects all molecules, even noble gas atoms.
$0-$ London forces can be modeled using the Lennard-Jones potential.
$0-$ London forces are one of these weird quantum effects. Molecules with inherent dipole strength feature a more classically understandable version of such forces.

### 10.2 Ionic Solids

A typical example of a ionic solid is ordinary salt, NaCl . There is little quantitative quantum mechanics required to describe either the salt molecule or solid salt. Still, there are some important qualitative points, so it seems useful to include a discussion in this book. Both molecule and solid will be described in this subsection, since the ideas are very similar.

To form a NaCl salt molecule, a clorine atom takes the loosely bound lone 3s electron away from a natrium (sodium) atom and puts it in its single still vacant 3 p position. That leaves a negative chlorine ion with filled K , L , and M shells and a positive natrium ion with just filled K and L shells. Since the combined electron distribution of filled shells is spherically symmetric, you can reasonably think of the two ions as somewhat soft billiard balls. Since they have opposite charge, they stick together into a salt molecule as sketched in figure 10.1. The natrium ion is a bit less than two $\AA$ in diameter, the clorine one a bit less than four.

Figure 10.1: Billiard-ball model of the salt molecule.

The energetics of this process is rather interesting. Assume that you start out with a neutral natrium atom and a neutral chlorine atom that are far apart. To take the lone 2 s electron out of the natrium atom, and leave it at rest at a position far from either the natrium or the chlorine atom, takes an amount of energy called the "ionization energy" of natrium. Its value is 5.14 eV (electron volts).

To take that free electron at rest and put it into the vacant 3p position of the chlorine ion gives back an amount of energy called the "electron affinity" of clorine. Its value is 3.62 eV .
(Electron affinity, the willingness to take on free electrons, is not to be confused with "electronegativity," the willingness to take on electrons in chemical bonds. Unlike electronegativity, electron affinity varies wildly from element to element in the periodic table. There is some system in it, still, especially within single columns. It may also be noted that there seems to be some disagreement about the definition of electronegativity, in particular for atoms or molecules that cannot stably bind a free electron, $\{\mathrm{N} .19\}$.)

Anyway, since it takes 5.14 eV to take the electron out of natrium, and you get only 3.62 eV back by putting it into clorine, you may wonder how a salt molecule could ever be stable. But the described picture is very misleading.

It does not really take 5.14 eV to take the electron out of natrium; most of that energy is used to pull the liberated electron and positive ion far apart. In the NaCl molecule, they are not pulled far apart; the positive natrium ion and negative chlorine ion stick together as in figure 10.1.

In other words, to create the widely separated positive natrium ion and negative chlorine ion took $5.14-3.62 \mathrm{eV}$, but watch the energy that is recovered when the two ions are brought together to their correct $2.36 \AA$ separation distance in the molecule. It is approximately given by the Coulomb expression

$$
\frac{e^{2}}{4 \pi \epsilon_{0}} \frac{1}{d}
$$

where $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is the permittivity of space and $d$ is the 2.36 $\AA$ distance between the nuclei. Putting in the numbers, dropping an $e$ to get the result in eV , this energy is 6.1 eV . That gives the total binding energy as $-5.14+3.62+6.1$, or 4.58 eV . That is not quite right, but it is close; the true value is 4.26 eV .

There are a few reasons why it is slightly off, but one is that the Coulomb expression above is only correct if the ions were billiard balls that would move unimpeded towards each other until they hit. Actually, the atoms are somewhat softer than billiard balls; their mutual repulsion force ramps up quickly, but not instantaneously. That means that the repulsion force will do a small amount of negative work during the final part of the approach of the ions. Also, the uncertainty principle does not allow the localized ions to have exactly zero kinetic energy. But as you see, these are small effects. It may also be noted that the repulsion between the ions is mostly Pauli repulsion, as described in section 5.10.

Figure 10.2: Billiard-ball model of a salt crystal.
Now the electrostatic force that keeps the two ions together in the molecule is omni-directional. That means that if you bring a lot of salt molecules together,
the clorine ions will also attract the natrium ions of other molecules and vice versa. As a result, under normal conditions, salt molecules pack together into solid salt crystals, as shown in figure 10.2. The ions arrange themselves very neatly into a pattern that allows each ion to be surrounded by as many attracting ions of the opposite kind as possible. In fact, as figure 10.2 indicates, each ion is surrounded by six ions of the opposite kind: four in the same vertical plane, a fifth behind it, and a sixth in front of it. A more detailed description of the crystal structure will be given next, but first consider what it means for the energy.

Since when the molecules pack into a solid, each ion gets next to six ions of the opposite type, the simplest guess would be that the 6.1 eV Coulomb attraction of the ions in the molecule would increase by a factor 6 in the solid. But that is a bad approximation: in the solid, each ion is not just surrounded by six attracting ions of the opposite kind, but also by twelve repelling ions of the same kind that are only slightly further away, then again eight attracting ions still a bit further away, etcetera. The net effect is that the Coulomb attraction is only 1.75 times higher in the solid than the lone molecules would have. The factor 1.75 is called the "Madelung constant. So, all else being the same, by forming a salt crystal the salt molecules would raise their Coulomb attraction to $1.75 \times 6.1$ or 10.7 eV .

That is still not quite right, because in the solid, the ions are farther apart than in the molecule. Recall that in the solid, each attracting ion is surrounded by repelling ions of the opposite kind, reducing the attraction between pairs. In the solid, opposite ions are $2.82 \AA$ apart instead of 2.36 , so the Coulomb energy reduces to $10.7 \times 2.36 / 2.82$ or 8.93 eV . Still, the bottom line is that the molecules pick up about 2.8 eV more Coulomb energy by packing together into salt crystals, and that is quite a bit of energy. So it should not come as a surprise that salt must be heated as high as $801{ }^{\circ} \mathrm{C}$ to melt it, and as high as $1465^{\circ} \mathrm{C}$ to boil it.

Finally, consider the crystal structure that the molecules combine into. One way of thinking of it is as a three-dimensional chess board structure. In figure 10.2, think of the frontal plane as a chess board of black and white cubes, with a natrium nucleus in the center of each white cube and a clorine nucleus in the center of each black one. The next plane of atoms can similarly be considered to consists of black and white cubes, where the back cubes are behind the white cubes of the frontal plane and vice-versa. And the same way for further planes.

However, this is not how a material scientist would think about the structure. A material scientist likes to describe a crystal in terms copies of a simple unit, called the "basis," that are stacked together in a regular manner. One possible choice for the basis in salt is a single natrium ion plus a single clorine ion to the right of it, like the molecule of figure 10.1. In figure 10.3 the ions of the salt crystal have been moved far apart to make the actual structure visible, and the two atoms of the basis units have been joined by a blue line. Note that the

Figure 10.3: The salt crystal disassembled to show its structure.
entire structure consists of these basis units.
But also note that the molecules lose their identity in a ionic solid. You could just as well build up the crystal from vertical "molecules," say, instead of horizontal ones. In fact, there are six reasonable choices of basis, depending on which of its six surrounding chlorine ions you want to associate each natrium ion with. There are of course always countless unreasonable ones. .

The regular way in which the bases are stacked together to form the complete crystal structure is called the "lattice." You can think of the volume of the salt crystal as consisting of little cubes called "unit cells" indicated by the red frames in figure 10.3. There are clorine atoms at the corners of the cubes as well as at the center points of the faces of the cubes. That is the reason the salt lattice is called the "face centered cubic" (FCC) lattice. Also note that if you shift the unit cells half a cell to the left, it will be the natrium ions that are at the corners and face centers of the cubes. In general, every point of a basis is arranged in the crystal according to the same lattice.

You will agree that it sounds much more professional to say that you have studied the face-centered cubic arrangement of the basis in a NaCl crystal than to say that you have studied the three-dimensional chess board structure of salt.

### 10.3 Metals

Metals are unique in the sense that there is no true molecular equivalent to the way the atoms are bound together in metals. In a metal, the valence electrons are shared on crystal scales, rather than between pairs of atoms. This and subsequent sections will discuss what this really means in terms of quantum mechanics.

### 10.3.1 Lithium

The simplest metal is lithium. Before examining solid lithium, first consider once more the free lithium atom. Figure 10.4 gives a more realistic picture of the atom than the simplistic analysis of chapter 5.9 did . The atom is really made up of two tightly bound electrons in " $|1 \mathrm{~s}\rangle$ " states very close to the nucleus, plus a loosely bound third "valence" electron in an expansive " 2 s$\rangle$ " state. The core, consisting of the nucleus and the two closely bound 1 s electrons, resembles an helium atom that has picked up an additional proton in its nucleus. It will be referred to as the "atom core." As far as the 2 s electron is concerned, this entire atom core is not that much different from an hydrogen nucleus: it is compact and has a net charge equivalent to one proton.

Figure 10.4: The lithium atom, scaled more correctly than before.
One obvious question is then why under normal circumstances lithium is a solid metal and hydrogen is a thin gas. The quantitative difference is that a single-charge core has a favorite distance at which it would like to hold its electron, the Bohr radius. In the hydrogen atom, the electron is about at the Bohr radius, and hydrogen holds onto it tightly. It is willing to share electrons
with one other hydrogen atom, but after that, it is satisfied. It is not looking for any other hydrogen molecules to share electrons with; that would weaken the bond it already has. On the other hand, the 2 s electron in the lithium atom is only loosely attached and readily given up or shared among multiple atoms.

Figure 10.5: Body-centered-cubic (BCC) structure of lithium.
Now consider solid lithium. A perfect lithium crystal would look as sketched in figure 10.5. The atom cores arrange themselves in a regular, repeating, pattern called the " crystal structure." As indicated in the figure by the thick red lines, you can think of the total crystal volume as consisting of many identical little cubes called "(unit) cells.". There are atom cores at all eight corners of these cubes and there is an additional core in the center of the cubic cell. In solid mechanics, this arrangement of positions is referred to as the "body-centered cubic" (BCC) lattice. The crystal "basis" for lithium is a single lithium atom, (or atom core, really); if you put a single lithium atom at every point of the BCC lattice, you get the complete lithium crystal.

Around the atom cores, the 2 s electrons form a fairly homogeneous electron density distribution. In fact, the atom cores get close enough together that a typical 2 s electron is no closer to the atom core to which it supposedly "belongs" than to the surrounding atom cores. Under such conditions, the model of the 2 s electrons being associated with any particular atom core is no longer really meaningful. It is better to think of them as belonging to the solid as a whole, moving freely through it like an electron "gas."

Under normal conditions, bulk lithium is "poly-crystalline," meaning that it consists of many microscopically small crystals, or "grains," each with the above BCC structure. The "grain boundaries" where different crystals meet are crucial to understand the mechanical properties of the material, but not so much to understand its electrical or heat properties, and their effects will be ignored. Only perfect crystals will be discussed.

## Key Points

$0-$ Lithium can meaningfully be thought of as an atom core, with a net charge of one proton, and a 2 s valence electron around it.
$0-$ In the solid, the cores arrange themselves into a "body-centered cubic" (BCC) lattice.
$0-$ The $2 s$ electrons form an "electron gas" around the cores.
$0-$ Normally the solid, like other solids, does not have the same crystal lattice throughout, but consists of microscopic grains, each crystalline, (i.e. with its lattice oriented its own way).
$0-$ The grain structure is critical for mechanical properties like strength and plasticity. But that is another book.

### 10.3.2 One-dimensional crystals

Even the quantum mechanics of a perfect crystal like the lithium one described above is not very simple. So it is a good idea to start with an even simpler crystal. The easiest example would be a "crystal" consisting of only two atoms, but two lithium atoms do not make a lithium crystal, they make a lithium molecule.

Figure 10.6: Fully periodic wave function of a two-atom lithium "crystal."
Fortunately, there is a dirty trick to get a "crystal" with only two atoms: assume that nature keeps repeating itself as indicated in figure 10.6. Mathematically, this is called "using periodic boundary conditions." It assumes that
after moving towards the left over a distance called the period, you are back at the same point as you started, as if you are walking around in a circle and the period is the circumference.

Of course, this is an outrageous assumption. If nature repeats itself at all, and that is doubtful at the time of this writing, it would be on a cosmological scale, not on the scale of two atoms. But the fact remains that if you make the assumption that nature repeats, the two-atom model gives a much better description of the mathematics of a true crystal than a two-atom molecule would. And if you add more and more atoms, the point where nature repeats itself moves further and further away from the typical atom, making it less and less of an issue for the local quantum mechanics.

## Key Points

$0-$ Periodic boundary conditions are very artificial.
0- Still, for crystal lattices, periodic boundary conditions often work very well.
$0-$ And nobody is going to put any real grain boundaries into any basic model of solids anyway.

### 10.3.3 Wave functions of one-dimensional crystals

To describe the energy eigenstates of the electrons in one-dimensional crystals in simple terms, a further assumption must be made: that the detailed interactions between the electrons can be ignored, except for the exclusion principle. Trying to correctly describe the complex interactions between the large numbers of electrons found in a macroscopic solid is simply impossible. And it is not really such a bad assumption as it may appear. In a metal, electron wave functions overlap greatly, and when they do, electrons see other electrons in all directions, and effects tend to cancel out. The equivalent in classical gravity is where you go down far below the surface of the earth. You would expect that gravity would become much more important now that you are surrounded by big amounts of mass at all sides. But they tend to cancel each other out, and gravity is actually reduced. Little gravity is left at the center of the earth. It is not recommended as a vacation spot anyway due to excessive pressure and temperature.

In any case, it will be assumed that for any single electron, the net effect of the atom cores and smeared-out surrounding 2 s electrons produces a periodic potential that near every core resembles that of an isolated core. In particular, if the atoms are spaced far apart, the potential near each core is exactly the one of a free lithium atom core. For an electron in this two atom "crystal," the intuitive eigenfunctions would then be where it is around either the first or the second core in the 2 s state, (or rather, taking the periodicity into account, around every
first or every second core in each period.) Alternatively, since these two states are equivalent, quantum mechanics allows the electron to hedge its bets and to be about each of the two cores at the same time with some probability.

Figure 10.7: Flip-flop wave function of a two-atom lithium "crystal."
But as soon as the atoms are close enough to start noticeably affecting each other, only two true energy eigenfunctions remain, and they are ones in which the electron is around both cores with equal probability. There is one eigenfunction that is exactly the same around both of the atom cores. This eigenfunction is sketched in figure 10.6; it is periodic from core to core, rather than merely from pair of cores to pair of cores. The second eigenfunction is the same from core to core except for a change of sign, call it a flip-flop eigenfunction. It is shown in figure 10.7. Since the grey-scale electron probability distribution only shows the magnitude of the wave function, it looks periodic from atom to atom, but the actual wave function is only the same after moving along two atoms.

To avoid the grey fading away, the shown wave functions have not been normalized; the darkness level is as if the 2 s electrons of both the atoms are in that state.

As long as the atoms are far apart, the wave functions around each atom closely resemble the isolated-atom $|2 \mathrm{~s}\rangle$ state. But when the atoms get closer together, differences start to show up. Note for example that the flip-flop wave function is exactly zero half way in between two cores, while the fully periodic one is not. To indicate the deviations from the true free-atom $|2 \mathrm{~s}\rangle$ wave function, parenthetical superscripts will be used.

A one-dimensional crystal made up from four atoms is shown in figure 10.8. Now there are four energy eigenstates. The energy eigenstate that is the same from atom to atom is still there, as is the flip-flop one. But there is now also an energy eigenstate that changes by a factor i from atom to atom, and one that changes by a factor -i. They change more slowly from atom to atom than the flip-flop one: it takes two atom distances for them to change sign. Therefore it takes a distance of four atoms, rather than two, for them to return to the same values.

## Key Points

0- The electron energy eigenfunctions in a metal like lithium extend over the entire crystal.
$0-$ If the cores are relatively far apart, near each core the energy eigenfunction of an electron still resembles the 2 s state of the free lithium atom.
$0-$ However, the magnitude near each core is of course much less, since the electron is spread out over the entire crystal.
$0-$ Also, from core to core, the wave function changes by a factor of magnitude one.
$0-$ The extreme cases are the fully periodic wave function that changes by a factor one (stays the same) from core to core, versus the flip-flop mode that changes sign completely from one core to the next.
$0-$ The other eigenfunctions change by an amount in between these two extremes from core to core.

### 10.3.4 Analysis of the wave functions

There is a pattern to the wave functions of one-dimensional crystals as discussed in the previous subsection. First of all, while the spatial energy eigenfunctions of the crystal are different from those of the individual atoms, their number is the same. Four free lithium atoms would each have one $|2 \mathrm{~s}\rangle$ spatial state to put their one 2 s electron in. Put them in a crystal, and there are still four spatial states to put the four 2 s electrons in. But the four spatial states in the crystal
are no longer single atom states; each now extends over the entire crystal. The atoms share all the electrons. If there were eight atoms, the eight atoms would share the eight 2 s electrons in eight possible crystal-wide states. And so on.

To be very precise, a similar thing is true of the inner 1 s electrons. But since the $|1 \mathrm{~s}\rangle$ states remain well apart, the effects of sharing the electrons are trivial, and describing the 1 s electrons as belonging pair-wise to a single lithium nucleus is fine. In fact, you may recall that the antisymmetrization requirement of electrons requires every electron in the universe to be slightly present in every occupied state around every atom. Obviously, you would not want to consider that in the absence of a nontrivial need.

The reason that the energy eigenfunctions take the form shown in figure 10.8 is relatively simple. It follows from the fact that the Hamiltonian commutes with the "translation operator" that shifts the entire wave function over one atom spacing $\vec{d}$. After all, because the potential energy is exactly the same after such a translation, it does not make a difference whether you evaluate the energy before or after you shift the wave function over.

Now commuting operators have a common set of eigenfunctions, so the energy eigenfunctions can be taken to be also eigenfunctions of the translation operator. The eigenvalue must have magnitude one, since periodic wave functions cannot change in overall magnitude when translated. So the eigenvalue describing the effect of an atom-spacing translation on an energy eigenfunction can be written as $e^{\mathrm{i} 2 \pi \nu}$ with $\nu$ a real number. (The factor $2 \pi$ does nothing except rescale the value of $\nu$. Apparently, crystallographers do not even put it in. This book does so that you do not feel short-changed because other books have factors $2 \pi$ and yours does not.)

This can be verified for the example energy eigenfunctions shown in figure 10.8. For the fully periodic eigenfunction $\nu=0$, making the translation eigenvalue $e^{\mathrm{i} 2 \pi \nu}$ equal to one. So this eigenfunction is multiplied by one under a translation by one atom spacing $d$ : it is the same after such a translation. For the flip-flop mode, $\nu=\frac{1}{2}$; this mode changes by $e^{\mathrm{i} \pi}=-1$ under a translation over an atom spacing $d$. That means that it changes sign when translated over an atom spacing $d$. For the two intermediate eigenfunctions $\nu= \pm \frac{1}{4}$, so, using the Euler formula (2.5), they change by factors $e^{ \pm \mathrm{i} \pi / 2}= \pm \mathrm{i}$ for each translation over a distance $d$.

In general, for an $J$-atom periodic crystal, there will be $J$ values of $\nu$ in the range $-\frac{1}{2}<\nu \leqslant \frac{1}{2}$. In particular for an even number of atoms $J$ :

$$
\nu=\frac{j}{J} \quad \text { for } \quad j=-\frac{J}{2}+1,-\frac{J}{2}+2,-\frac{J}{2}+3, \ldots, \frac{J}{2}-1, \frac{J}{2}
$$

Note that for these values of $\nu$, if you move over $J$ atom spacings, $e^{\mathrm{i} 2 \pi \nu J}=1$ as it should; according to the imposed periodic boundary conditions, the wave functions must be the same after $J$ atoms. Also note that it suffices for $j$ to be restricted to the range $-J / 2<j \leqslant J / 2$, hence $-\frac{1}{2}<\nu \leqslant \frac{1}{2}$ : if $j$ is outside that
range, you can always add or subtract a whole multiple of $J$ to bring it back in that range. And changing $j$ by a whole multiple of $J$ does absolutely nothing to the eigenvalue $e^{\mathrm{i} 2 \pi \nu}$ since $e^{\mathrm{i} 2 \pi J / J}=e^{\mathrm{i} 2 \pi}=1$.

### 10.3.5 Floquet (Bloch) theory

Mathematically it is awkward to describe the energy eigenfunctions piecewise, as figure 10.8 does. To arrive at a better way, it is helpful first to replace the axial Cartesian coordinate $z$ by a new "crystal coordinate" $u$ defined by

$$
\begin{equation*}
z \hat{k}=u \vec{d} \tag{10.2}
\end{equation*}
$$

where $\vec{d}$ is the vector shown in figure 10.8 that has the length of one atom spacing $d$. Material scientists call this vector the "primitive translation vector" of the crystal lattice. Primitive vector for short.

The advantage of the crystal coordinate $u$ is that if it changes by one unit, it changes the $z$-position by exactly one atom spacing. As noted in the previous subsection, such a translation should multiply an energy eigenfunction by a factor $e^{\mathrm{i} 2 \pi \nu}$. A continuous function that does that is the exponential $e^{\mathrm{i} 2 \pi \nu u}$. And that means that if you factor out that exponential from the energy eigenfunction, what is left does not change under the translation; it will be periodic on atom scale. In other words, the energy eigenfunctions can be written in the form

$$
\psi^{\mathrm{p}}=e^{\mathrm{i} 2 \pi \nu u} \psi_{\mathrm{p}}^{\mathrm{p}}
$$

where $\psi_{\mathrm{p}}^{\mathrm{p}}$ is a function that is periodic on the atom scale $d$; it is the same in each successive interval $d$.

This result is part of what is called "Floquet theory:"
If the Hamiltonian is periodic of period $d$, the energy eigenfunctions are not in general periodic of period d, but they do take the form of exponentials times functions that are periodic of period d.
In physics, this result is known as "Bloch's theorem," and the Floquet-type wave function solutions are called "Bloch functions" or "Bloch waves," because Floquet was just a mathematician, and the physicists' hero is Bloch, the physicist who succeeded in doing it too, half a century later. $\{\mathrm{N} .20\}$.

The periodic part $\psi_{\mathrm{p}}^{\mathrm{p}}$ of the energy eigenfunctions is not the same as the $|2 \mathrm{~s}\rangle^{(.)}$states of figure 10.8 , because $e^{\mathrm{i} 2 \pi \nu u}$ varies continuously with the crystal position $z=u d$, unlike the factors shown in figure 10.8. However, since the magnitude of $e^{\mathrm{i} 2 \pi \nu u}$ is one, the magnitudes of $\psi_{\mathrm{p}}^{\mathrm{p}}$ and the $|2 \mathrm{~s}\rangle^{(.)}$states are the same, and therefore, so are their grey scale electron probability pictures.

It is often more convenient to have the energy eigenfunctions in terms of the Cartesian coordinate $z$ instead of the crystal coordinate $u$, writing them in the form

$$
\begin{equation*}
\psi_{k}^{\mathrm{p}}=e^{\mathrm{i} k z} \psi_{\mathrm{p}, k}^{\mathrm{p}} \text { with } \psi_{\mathrm{p}, k}^{\mathrm{p}} \text { periodic on the atom scale } d \tag{10.3}
\end{equation*}
$$

The constant $k$ in the exponential is called the wave number, and subscripts $k$ have been added to $\psi^{\mathrm{p}}$ and $\psi_{\mathrm{p}}^{\mathrm{p}}$ just to indicate that they will be different for different values of this wave number. Since the exponential must still equal $e^{\mathrm{i} 2 \pi \nu u}$, clearly the wave number $k$ is proportional to $\nu$. Indeed, substituting $z=$ $u d$ into $e^{\mathrm{i} k z}, k$ can be traced back to be

$$
\begin{equation*}
k=\nu D \quad D=\frac{2 \pi}{d} \quad-\frac{1}{2}<\nu \leqslant \frac{1}{2} \tag{10.4}
\end{equation*}
$$

### 10.3.6 Fourier analysis

As the previous subsection explained, the energy eigenfunctions in a crystal take the form of a Floquet exponential times a periodic function $\psi_{\mathrm{p}, k}^{\mathrm{p}}$. This periodic part is not normally an exponential. However, it is generally possible to write it as an infinite sum of exponentials:

$$
\begin{equation*}
\psi_{\mathrm{p}, k}^{\mathrm{p}}=\sum_{m=-\infty}^{\infty} c_{k m} e^{\mathrm{i} k_{m} z} \quad k_{m}=m D \text { for } m \text { an integer } \tag{10.5}
\end{equation*}
$$

where the $c_{k m}$ are constants whose values will depend on $x$ and $y$, as well as on $k$ and the integer $m$.

Writing the periodic function $\psi_{\mathrm{p}, k}^{\mathrm{p}}$ as such a sum of exponentials is called "Fourier analysis," after another French mathematician. That it is possible follows from the fact that these exponentials are the atom-scale-periodic eigenfunctions of the $z$-momentum operator $p_{z}=\hbar \partial / \mathrm{i} \partial z$, as is easily verified by straight substitution. Since the eigenfunctions of an Hermitian operator like $p_{z}$ are complete, any atom-scale-periodic function, including $\psi_{\mathrm{p}, k}^{\mathrm{p}}$, can be written as a sum of them. See also \{D.8\}.

### 10.3.7 The reciprocal lattice

As the previous two subsections discussed, the energy eigenfunctions in a onedimensional crystal take the form of a Floquet exponential $e^{\mathrm{i} k z}$ times a periodic function $\psi_{\mathrm{p}, k}^{\mathrm{p}}$. That periodic function can be written as a sum of Fourier exponentials $e^{i k_{m} z}$. It is a good idea to depict all those $k$-values graphically, to keep them apart. That is done in figure 10.9.

The Fourier $k$ values, $k_{m}=m D$ with $m$ an integer, form a lattice of points spaced a distance $D$ apart. This lattice is called the "reciprocal lattice." The spacing of the reciprocal lattice, $D=2 \pi / d$, is proportional to the reciprocal of the atom spacing $d$ in the physical lattice. Since on a macroscopic scale the atom spacing $d$ is very small, the spacing of the reciprocal lattice is very large.

The Floquet $k$ value, $k=\nu D$ with $-\frac{1}{2}<\nu \leqslant \frac{1}{2}$, is somewhere in the grey range in figure 10.9. This range is called the first "Brillouin zone.' It is an

Figure 10.9: Reciprocal lattice of a one-dimensional crystal.
interval, a unit cell if you want, of length $D$ around the origin. The first Brillouin zone is particularly important in the theory of solids. The fact that the Floquet $k$ value may be assumed to be in it is but one reason.

To be precise, the Floquet $k$ value could in principle be in an interval of length $D$ around any wave number $k_{m}$, not just the origin, but if it is, you can shift it to the first Brillouin zone by splitting off a factor $e^{i k_{m} z}$ from the Floquet exponential $e^{\mathrm{i} k z}$. The $e^{\mathrm{i} k_{m} z}$ can be absorbed in a redefinition of the Fourier series for the periodic part $\psi_{\mathrm{p}, k}^{\mathrm{p}}$ of the wave function, and what is left of the Floquet $k$ value is in the first zone. Often it is good to do so, but not always. For example, in the analysis of the free-electron gas done later, it is critical not to shift the $k$ value to the first zone because you want to keep the (there trivial) Fourier series intact.

The first Brillouin zone are the points that are closest to the origin on the $k$-axis, and similarly the second zone are the points that are second closest to the origin. The points in the interval of length $D / 2$ in between $k_{-1}$ and the first Brillouin zone make up half of the second Brillouin zone: they are closest to $k_{-1}$, but second closest to the origin. Similarly, the other half of the second Brillouin zone is given by the points in between $k_{1}$ and the first Brillouin zone. In one dimension, the boundaries of the Brillouin zone fragments are called the "Bragg points." They are either reciprocal lattice points or points half way in between those.

### 10.3.8 The energy levels

Valence band. Conduction band. Band gap. Crystal. Lattice. Basis. Unit cell. Primitive vector. Bloch wave. Fourier analysis. Reciprocal lattice. Brillouin zones. These are the jargon of solid mechanics; now they have all been defined. (Though certainly not fully discussed.) But jargon is not physics. The physically interesting question is what are the energy levels of the energy eigenfunctions.

For the two-atom crystal of figures 10.6 and 10.7, the answer is much like that for the hydrogen molecular ion of chapter 4.6 and hydrogen molecule of chapter 5.2. In particular, when the atom cores are far apart, the $|2 \mathrm{~s}\rangle^{(.)}$states are the same as the free lithium atom wave function $|2 \mathrm{~s}\rangle$. In either the fully periodic or the flip-flop mode, the electron is with $50 \%$ probability in that state around each of the two cores. That means that at large spacing $d$ between

actual separation between the atoms $\lrcorner$
Figure 10.10: Schematic of energy bands.
the cores, the energy is the 2 s free lithium atom energy, whether it is the fully periodic or flip-flop mode. That is shown in the left graph of figure 10.10.

When the distance $d$ between the atoms decreases so that the 2 s wave functions start to noticeably overlap, things change. As the same left graph in figure 10.10 shows, the energy of the flip-flop state increases, but that of the fully periodic state initially decreases. The reasons for the latter are similar to those that gave the symmetric hydrogen molecular ion and hydrogen molecule states lower energy. In particular, the electrons pick up more effective space to move in, decreasing their uncertainty-principle demanded kinetic energy. Also, when the electron clouds start to merge, the repulsion between electrons is reduced, allowing the electrons to lose potential energy by getting closer to the nuclei of the neighboring atoms. (Note however that the simple model used here would not faithfully reproduce that since the repulsion between the electrons is not correctly modeled.)

Next consider the case of a four-atom crystal, as shown in the second graph of figure 10.10. The fully periodic and flip flop states are unchanged, and so are their energies. But there are now two additional states. Unlike the fully periodic state, these new states vary from atom, but less rapidly than the flip flop mode. As you would then guess, their energy is somewhere in between that of the fully periodic and flip-flop states. Since the two new states have equal energy, it is shown as a double line in 10.10. The third graph in that figure shows the energy levels of an 8 atom crystal, and the final graph that of a 24 atom crystal. When the number of atoms increases, the energy levels become denser and denser. By the time you reach a one hundredth of an inch, onemillion atom one-dimensional crystal, you can safely assume that the energy levels within the band have a continuous, rather than discrete distribution.

Now recall that the Pauli exclusion principle allows up to two electrons in a single spatial energy state. Since there are an equal number of spatial states and electrons, that means that the electrons can pair up in the lowest half of the states. The upper states will then be unoccupied. Further, the actual separation distance between the atoms will be the one for which the total energy of the crystal is smallest. The energy spectrum at this actual separation distance is found inside the vanishingly narrow vertical frame in the rightmost graph of
figure 10.10. It shows that lithium forms a metal with a partially-filled band.
The partially filled band means that lithium conducts electricity well. As was already discussed earlier in chapter 6.20, an applied voltage does not affect the band structure at a given location. For an applied voltage to do that, it would have to drop an amount comparable to volts per atom. The current that would flow in a metal under such a voltage would vaporize the metal instantly. Current occurs because electrons get excited to states of slightly higher energy that produce motion in a preferential direction.

### 10.3.9 Merging and splitting bands

The explanation of electrical conduction in metals given in the previous subsection is incomplete. It incorrectly seems to show that beryllium, (and similarly other metals of valence two,) is an insulator. Two valence electrons per atom will completely fill up all 2s states. With all states filled, there would be no possibility to excite electrons to states of slightly higher energy with a preferential direction of motion. There would be no such states. All states would be red in figure 10.10, so nothing could change.

What is missing is consideration of the 2 p atom states. When the atoms are far enough apart not to affect each other, the 2 p energy levels are a bit higher than the 2 s ones and not involved. However, as figure 10.11 shows, when the atom spacing decreases to the actual one in a crystal, the widening bands merge together. With this influx of $300 \%$ more states, valence-two metals have plenty of free states to excite electrons to. Beryllium is actually a better conductor than lithium.

actual separation between the atoms $\triangle$
Figure 10.11: Schematic of merging bands.
Hydrogen is a more complicated story. Solid hydrogen consists of molecules and the attractions between different molecules are weak. The proper model of hydrogen is not a series of equally spaced atoms, but a series of pairs of atoms joined into molecules, and with wide gaps between the molecules. When the two
atoms in a single molecule are brought together, the energy varies with distance between the atoms much like the left graph in figure 10.10. The wave function that is the same for the two atoms in the current simple model corresponds to the normal covalent bond in which the electrons are symmetrically shared; the flipflop function that changes sign describes the "anti-bonding" state in which the two electrons are antisymmetrically shared. In the ground state, both electrons go into the state corresponding to the covalent bond, and the anti-bonding state stays empty. For multiple molecules, each of the two states turns into a band, but since the interactions between the molecules are weak, these two bands do not fan out much. So the energy spectrum of solid hydrogen remains much like the left graph in figure 10.10, with the bottom curve becoming a filled band and the top curve an empty one. An equivalent way to think of this is that the 1 s energy level of hydrogen does not fan out into a single band like the 2 s level of lithium, but into two half bands, since there are two spacings involved; the spacing between the atoms in a molecule and the spacing between molecules. In any case, because of the band gap energy required to reach the empty upper half 1 s band, hydrogen is an insulator.

### 10.3.10 Three-dimensional metals

The ideas of the previous subsections generalize towards three-dimensional crystals in a relatively straightforward way.

Figure 10.12: A primitive cell and primitive translation vectors of lithium.
As the lithium crystal of figure 10.12 illustrates, in a three-dimensional crystal there are three "primitive translation vectors." The three-dimensional Cartesian position $\vec{r}$ can be written as

$$
\begin{equation*}
\vec{r}=u_{1} \vec{d}_{1}+u_{2} \vec{d}_{2}+u_{3} \vec{d}_{3} \tag{10.6}
\end{equation*}
$$

where if any of the "crystal coordinates" $u_{1}, u_{2}$, or $u_{3}$ changes by exactly one unit, it produces a physically completely equivalent position.

Note that the vectors $\vec{d}_{1}$ and $\vec{d}_{2}$ are two bottom sides of the "cubic unit cell" defined earlier in figure 10.5. However, $\vec{d}_{3}$ is not the vertical side of the cube. The reason is that primitive translation vectors must be chosen to allow you to reach any point of the crystal from any equivalent point in whole steps. Now $\vec{d}_{1}$ and $\vec{d}_{2}$ allow you to step from any point in a horizontal plane to any equivalent point in the same plane. But if $\vec{d}_{3}$ was vertically upwards like the side of the cubic unit cell, stepping with $\vec{d}_{3}$ would miss every second horizontal plane. With $\vec{d}_{1}$ and $\vec{d}_{2}$ defined as in figure $10.12, \vec{d}_{3}$ must point to an equivalent point in an immediately adjacent horizontal plane, not a horizontal plane farther away.

Despite this requirement, there are still many ways of choosing the primitive translation vectors other than the one shown in figure 10.12. The usual way is to choose all three to extend towards adjacent cube centers. However, then it gets more difficult to see that no lattice point is missed when stepping around with them.

The parallelepiped shown in figure 10.12, with sides given by the primitive translation vectors, is called the "primitive cell." It is the smallest building block that can be stacked together to form the total crystal. The cubic unit cell from figure 10.5 is not a primitive cell since it has twice the volume. The cubic unit cell is instead called the "conventional cell."

Since the primitive vectors are not unique, the primitive cell they define is not either. These primitive cells are purely mathematical quantities; an arbitrary choice for the smallest single volume element from which the total crystal volume can be build up. The question suggests itself whether it would not be possible to define a primitive cell that has some physical meaning; whose definition is unique, rather than arbitrary. The answer is yes, and the unambiguously defined primitive cell is called the "Wigner-Seitz cell." The Wigner-Seitz cell around a lattice point is the vicinity of locations that are closer to that lattice point than to any other lattice point.

Figure 10.13: Wigner-Seitz cell of the BCC lattice.
Figure 10.13 shows the Wigner-Seitz cell of the BCC lattice. To the left, it is
shown as a wire frame, and to the right as an opaque volume element. To put it within context, the atom around which this Wigner-Seitz cell is centered was also put in the center of a conventional cubic unit cell. Note how the Wigner-Seitz primitive cell is much more spherical than the parallelepiped-shaped primitive cell shown in figure 10.12. The outside surface of the Wigner-Seitz cell consists of hexagonal planes on which the points are just on the verge of getting closer to a corner atom of the conventional unit cell than to the center atom, and of squares on which the points are just on the verge of getting closer to the center atom of an adjacent conventional unit cell. The squares are located within the faces of the conventional unit cell.

The reason that the entire crystal volume can be build up from Wigner-Seitz cells is simple: every point must be closest to some lattice point, so it must be in some Wigner-Seitz cell. When a point is equally close to two nearest lattice points, it is on the boundary where adjacent Wigner-Seitz cells meet.

Turning to the energy eigenfunctions, they can now be taken to be eigenfunctions of three translation operators; they will change by some factor $e^{\mathrm{i} 2 \pi \nu_{1}}$ when translated over $\vec{d}_{1}$, by $e^{\mathrm{i} 2 \pi \nu_{2}}$ when translated over $\vec{d}_{2}$, and by $e^{\mathrm{i} 2 \pi \nu_{3}}$ when translated over $\vec{d}_{3}$. All that just means that they must take the Floquet (Bloch) function form

$$
\psi^{\mathrm{p}}=e^{\mathrm{i} 2 \pi\left(\nu_{1} u_{1}+\nu_{2} u_{2}+\nu_{3} u_{3}\right)} \psi_{\mathrm{p}}^{\mathrm{p}}
$$

where $\psi_{\mathrm{p}}^{\mathrm{p}}$ is periodic on atom scales, exactly the same after one unit change in any of the crystal coordinates $u_{1}, u_{2}$ or $u_{3}$.

It is again often convenient to write the Floquet exponential in terms of normal Cartesian coordinates. To do so, note that the relation giving the physical position $\vec{r}$ in terms of the crystal coordinates $u_{1}, u_{2}$, and $u_{3}$,

$$
\vec{r}=u_{1} \vec{d}_{1}+u_{2} \vec{d}_{2}+u_{3} \vec{d}_{3}
$$

can be inverted to give the crystal coordinates in terms of the physical position, as follows:

$$
\begin{equation*}
u_{1}=\frac{1}{2 \pi} \vec{D}_{1} \cdot \vec{r} \quad u_{2}=\frac{1}{2 \pi} \vec{D}_{2} \cdot \vec{r} \quad u_{3}=\frac{1}{2 \pi} \vec{D}_{3} \cdot \vec{r} \tag{10.7}
\end{equation*}
$$

(Again, factors $2 \pi$ have been thrown in merely to fully satisfy even the most demanding quantum mechanics reader.) To find the vectors $\vec{D}_{1}, \vec{D}_{2}$, and $\vec{D}_{3}$, simply solve the expression for $\vec{r}$ in terms of $u_{1}, u_{2}$, and $u_{3}$ using linear algebra procedures. In particular, they turn out to be the rows of the inverse of matrix $\left(\vec{d}_{1}, \vec{d}_{2}, \vec{d}_{3}\right)$.

If you do not know linear algebra, it can be done geometrically: if you dot the expression for $\vec{r}$ above with $\vec{D}_{1} / 2 \pi$, you must get $u_{1}$; for that to be true, the first three conditions below are required:

$$
\begin{array}{lll}
\vec{d}_{1} \cdot \vec{D}_{1}=2 \pi, & \vec{d}_{2} \cdot \vec{D}_{1}=0, & \vec{d}_{3} \cdot \vec{D}_{1}=0, \\
\vec{d}_{1} \cdot \vec{D}_{2}=0, & \vec{d}_{2} \cdot \vec{D}_{2}=2 \pi, & \vec{d}_{3} \cdot \vec{D}_{2}=0  \tag{10.8}\\
\vec{d}_{1} \cdot \vec{D}_{3}=0, & \vec{d}_{2} \cdot \vec{D}_{3}=0, & \vec{d}_{3} \cdot \vec{D}_{3}=2 \pi
\end{array}
$$

The second set of three equations is obtained by dotting with $\vec{D}_{2} / 2 \pi$ to get $u_{2}$ and the third by dotting with $\vec{D}_{3} / 2 \pi$ to get $u_{3}$. From the last two equations in the first row, it follows that vector $\vec{D}_{1}$ must be orthogonal to both $\vec{d}_{2}$ and $\vec{d}_{3}$. That means that you can get $\vec{D}_{1}$ by first finding the vectorial cross product of vectors $\vec{d}_{2}$ and $\vec{d}_{3}$ and then adjusting the length so that $\vec{d}_{1} \cdot \vec{D}_{1}=2 \pi$. In similar ways, $\vec{D}_{2}$ and $\vec{D}_{3}$ may be found.

If the expressions for the crystal coordinates are substituted into the exponential part of the Bloch functions, the result is

$$
\begin{equation*}
\psi_{\vec{k}}^{\mathrm{p}}=e^{\mathrm{i} \vec{k} \cdot \overrightarrow{\vec{r}}} \psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}} \quad \vec{k}=\nu_{1} \vec{D}_{1}+\nu_{2} \vec{D}_{2}+\nu_{3} \vec{D}_{3} \tag{10.9}
\end{equation*}
$$

So, in three dimensions, a wave number $k$ becomes a "wave number vector" $\vec{k}$. Just like for the one-dimensional case, the periodic function $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$ too can be written in terms of exponentials. Converted from crystal to physical coordinates, it gives:

$$
\begin{gather*}
\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}=\sum_{m_{1}} \sum_{m_{2}} \sum_{m_{3}} c_{p, \vec{k} \vec{m}} e^{\mathrm{i} \vec{k}_{\vec{m}} \cdot \vec{r}} \\
\vec{k}_{\vec{m}}=m_{1} \vec{D}_{1}+m_{2} \vec{D}_{2}+m_{3} \vec{D}_{3} \text { for } m_{1}, m_{2}, \text { and } m_{3} \text { integers }  \tag{10.10}\\
\hline
\end{gather*}
$$

If these wave number vectors $\vec{k}_{\vec{m}}$ are plotted three-dimensionally, it again forms a lattice called the "reciprocal lattice," and its primitive vectors are $\vec{D}_{1}, \vec{D}_{2}$, and $\vec{D}_{3}$. Remarkably, the reciprocal lattice to lithium's BCC physical lattice turns out to be the FCC lattice of NaCl fame!

And now note the beautiful symmetry in the relations (10.8) between the primitive vectors $\vec{D}_{1}, \vec{D}_{2}$, and $\vec{D}_{3}$ of the reciprocal lattice and the primitive vectors $\vec{d}_{1}, \vec{d}_{2}$, and $\vec{d}_{3}$ of the physical lattice. Because these relations involve both sets of primitive vectors in exactly the same way, if a physical lattice with primitive vectors $\vec{d}_{1}, \vec{d}_{2}$, and $\vec{d}_{3}$ has a reciprocal lattice with primitive vectors $\vec{D}_{1}, \vec{D}_{2}$, and $\vec{D}_{3}$, then a physical lattice with primitive vectors $\vec{D}_{1}, \vec{D}_{2}$, and $\vec{D}_{3}$ has a reciprocal lattice with primitive vectors $\vec{d}_{1}, \vec{d}_{2}$, and $\vec{d}_{3}$. Which means that since NaCl's FCC lattice is the reciprocal to lithium's BCC lattice, lithium's BCC lattice is the reciprocal to NaCl's FCC lattice. You now see where the word "reciprocal" in reciprocal lattice comes from. Lithium and NaCl borrow each other's lattice to serve as their lattice of wave number vectors.

Finally, how about the definition of the "Brillouin zones" in three dimensions? In particular, how about the first Brillouin zone to which you often prefer to move the Floquet wave number vector $\vec{k}$ ? Well, it is the magnitude of the wave number vector that is important, so the first Brillouin zone is defined to be the Wigner-Seitz cell around the origin in the reciprocal lattice. Note that this means that in the first Brillouin zone, $\nu_{1}, \nu_{2}$, and $\nu_{3}$ are not simply
numbers in the range from $-\frac{1}{2}$ to $\frac{1}{2}$ as in one dimension; that would give a parallelepiped-shaped primitive cell instead.

Solid state physicists may tell you that the other Brillouin zones are also reciprocal lattice Wigner-Seitz cells, [29, p. 38], but if you look closer at what they are actually doing, the higher zones consist of fragments of reciprocal lattice Wigner-Seitz cells that can be assembled together to produce a Wigner-Seitz cell shape. Like for the one-dimensional crystal, the second zone are again the points that are second closest to the origin, etcetera.

The boundaries of the Brillouin zone fragments are now planes called "Bragg planes." Each is a perpendicular bisector of a lattice point and the origin. That is so because the locations where points stop being first/, second/, third/, ...closest to the origin and become first/, second/, third/, ... closest to some other reciprocal lattice point must be on the bisector between that lattice point and the origin. Sections 10.5 .1 and 10.6 will give Bragg planes and Brillouin zones for a simple cubic lattice.

The qualitative story for the valence electron energy levels is the same in three dimensions as in one. Sections 10.5 and 10.6 will look a bit closer at them quantitatively.

### 10.4 Covalent Materials

In covalent materials, the atoms are held together by covalent chemical bonds. Such bonds are strong. Note that the classification is somewhat vague; many crystals, like quartz (silicon dioxide), have partly ionic, partly covalent binding. Another ambiguity occurs for graphite, the stable form of carbon under normal condition. Graphite consists of layers of carbon atoms arranged in a hexagonal pattern. There are four covalent bonds binding each carbon to three neighboring atoms in the layer: three $\mathrm{sp}^{2}$ hybrid bonds in the plane and a fourth $\pi$-bond normal it. The $\pi$-electrons are delocalized and will conduct electricity. (When rolled into carbon nanotubes, this becomes a bit more complicated.) As far as the binding of the solid is concerned, however, the point is that different layers of graphite are only held together with weak Van der Waals forces, rather than covalent bonds. This makes graphite one of the softest solids known.

Under pressure, carbon atoms can form diamond rather than graphite, and diamond is one of the hardest substances known. The diamond structure is a very clean example of purely covalent bonding, and this section will have a look at its nature. Other group IV elements in the periodic table, in particular silicon, germanium, and grey tin also have the diamond structure. All these, of course, are very important for engineering applications.

One question that suggests itself in view of the earlier discussion of metals is why these materials are not metals. Consider carbon for example. Compared to beryllium, it has four rather than two electrons in the second, L, shell. But
the merged 2 s and 2 p bands can hold eight electrons, so that cannot be the explanation. In fact, tin comes in two forms under normal conditions: covalent grey tin is stable below $13{ }^{\circ} \mathrm{C}$; while above that temperature, metallic white tin is the stable form. It is often difficult to guess whether a particular element will form a metallic or covalent substance near the middle of the periodic table.

actual separation between the atoms
Figure 10.14: Schematic of crossing bands.
Figure 10.14 gives a schematic of the energy band structure for a diamondtype crystal when the spacing between the atoms is artificially changed. When the atoms are far apart, i.e. $d$ is large, the difference from beryllium is only that carbon has two electrons in 2p states versus beryllium none. But when the carbon atoms start coming closer, they have a group meeting and hit upon the bright idea to reduce their energy even more by converting their one 2 s and three 2 p spatial states into four hybrid $\mathrm{sp}^{3}$ states. This allows them to share pairs of electrons symmetrically in as much as four strong covalent bonds. And it does indeed work very well for lowering the energy of these states, filled to the gills with electrons. But it does not work well at all for the "anti-bonding" states that share the electrons antisymmetrically, (as discussed for the hydrogen molecule in chapter 5.2.4), and who do not have a single electron to support their case at the meeting. So a new energy gap now opens up.

At the actual atom spacing of diamond, this band gap has become as big as 5.5 eV , making it an electric insulator (unlike graphite, which is a semi-metal). For silicon however, the gap is a much smaller 1.1 eV , similar to the one for germanium of 0.7 eV ; grey tin is considerably smaller still; recent authoritative sources list it as zero. These smaller band gaps allow noticeable numbers of electrons to get into the empty conduction band by thermal excitation, so these materials are semiconductors at room temperature.

The crystal structure of these materials is rather interesting. It must allow each atom core to connect to 4 others to form the hybrid covalent bonds. That requires the rather spacious structure sketched in figure 10.15. For simplicity

Figure 10.15: Ball and stick schematic of the diamond crystal.
and clarity, the four hybrid bonds that attach each atom core to its four neighbors are shown as blue or dark grey sticks rather than as a distribution of grey tones.

Like for lithium, you can think of the spheres as representing the inner electrons. The grey gas represents the outer electrons, four per atom.

To understand the figure beyond that, first note that it turns out to be impossible to create the diamond crystal structure from a basis of a single atom. It is simply not possible to distribute clones of a single carbon atom around using a single set of three primitive vectors, and produce all the atoms in the diamond crystal. A basis of a pair of atoms is needed. The choice of which pair is quite arbitrary, but in figure 10.15 the clones of the chosen pair are linked by blue lines. Notice how the entire crystal is build up from such clones. (Physically, the choice of basis is artificial, and the blue sticks indicate hybrid bonds just like the grey ones.) One possible choice for a set of three primitive translation vectors is shown in the figure. The more usual choice is to take the one in the front plane to the atom located at 45 degrees instead.

Now notice that the lower members of these pairs are located at the corners and face centers of the cubic volume elements indicated by the fat red lines. Yes, diamond is another example of a face-centered cubic lattice. What is different from the NaCl case is the basis; two carbon atoms at some weird angle, instead of a natrium and a chlorine ion sensibly next to each other. Actually, if you look a bit closer, you will notice that in terms of the half-size cubes indicated by thin red frames, the structure is not that illogical. It is again that of a three-dimensional chess board, where the centers of the black cubes contain the upper carbon of a basis clone, while the centers of the white cubes are empty.

But of course, you would not want to tell people that. They might think you spend your time playing games, and terminate your support.

If you look at the massively cross-linked diamond structure, it may not come as that much of a surprise that diamond is the hardest substance to occur naturally. Under normal conditions, diamond will supposedly degenerate extremely slowly into graphite, but without doubt, diamonds are forever.

### 10.5 Free-Electron Gas

Chapter 6 discussed the model of noninteracting electrons in a periodic box. This simple model, due to Sommerfeld, is a first starting point for much analysis of solids. It was used to provide explanations of such effects as the incompressibility of solids and liquids, and of electrical conduction. This section will use the model to explain some of the analytical methods that are used to analyze electrons in crystals. A free-electron gas is a model for electrons in a crystal when the physical effect of the crystal structure on the electrons is ignored. The assumption is that the crystal structure is still there, but that it does not actually do anything to the electrons.

The single-particle energy eigenfunctions of a periodic box are given by

$$
\begin{equation*}
\psi_{\vec{k}}^{\mathrm{p}}(\vec{r})=\frac{1}{\sqrt{\mathcal{V}}} e^{\mathrm{i} \vec{k} \cdot \vec{r}}=\frac{1}{\sqrt{\mathcal{V}}} e^{\mathrm{i}\left(k_{x} x+k_{y} y+k_{z} z\right)} \tag{10.11}
\end{equation*}
$$

Here the wave numbers are related to the box dimensions as

$$
\begin{equation*}
k_{x}=n_{x} \frac{2 \pi}{\ell_{x}} \quad k_{y}=n_{y} \frac{2 \pi}{\ell_{y}} \quad k_{z}=n_{z} \frac{2 \pi}{\ell_{z}} \tag{10.12}
\end{equation*}
$$

where the quantum numbers $n_{x}, n_{y}$, and $n_{z}$ are integers. This section will use the wave number vector, rather than the quantum numbers, to indicate the individual eigenfunctions.

Note that each of these eigenfunctions can be regarded as a Bloch wave: the exponentials are the Floquet ones, and the periodic parts are trivial constants. The latter reflects the fact the periodic potential itself is trivially constant (zero) for a free-electron gas.

Of course, there is a spin-up version $\psi_{\vec{k}}^{\mathrm{p}} \downarrow$ and a spin-down version $\psi_{\vec{k}}^{\mathrm{p}} \uparrow$ of each eigenfunction above. However, spin will not be much of an issue in the analysis here.

The Floquet exponentials have not been shifted to any first Brillouin zone. In fact, since the electrons experience no forces, as far as they are concerned, there is no crystal structure, hence no Brillouin zones.

### 10.5.1 Lattice for the free electrons

As far as the mathematics of free electrons is concerned, the box in which they are confined may as well be empty. However,it is useful to put the results in
context of a surrounding crystal lattice anyway. That will allow some of the basic concepts of the solid mechanics of crystals to be defined within a simple setting.

It will therefore be assumed that there is a crystal lattice, but that its potential is zero. So the lattice does not affect the motion of the electrons. An appropriate choice for this lattice must now be made. The plan is to keep the same Floquet wave number vectors as for the free electrons in a rectangular periodic box. Those wave numbers form a rectangular grid in wave number space as shown in figure 6.17 of chapter 6.18. To preserve these wave numbers, it is best to figure out a suitable reciprocal lattice first.

To do so, compare the general expression for the Fourier $\vec{k}_{\vec{m}}$ values that make up the reciprocal lattice:

$$
\vec{k}_{\vec{m}}=m_{1} \vec{D}_{1}+m_{2} \vec{D}_{2}+m_{3} \vec{D}_{3}
$$

in which $m_{1}, m_{2}$, and $m_{3}$ are integers, with the Floquet $\vec{k}$ values,

$$
\vec{k}=\nu_{1} \vec{D}_{1}+\nu_{2} \vec{D}_{2}+\nu_{3} \vec{D}_{3}
$$

(compare section 10.3.10.) Now $\nu_{1}$ is of the form $\nu_{1}=j_{1} / J_{1}$ where $j_{1}$ is an integer just like $m_{1}$ is an integer, and $J_{1}$ is the number of lattice cells in the direction of the first primitive vector. For a macroscopic crystal, $J_{1}$ will be a very large number, so the conclusion must be that the Floquet wave numbers are spaced much more closely together than the Fourier ones. And so they are in the other two directions.
㞔

Figure 10.16: Assumed simple cubic reciprocal lattice, shown as black dots, in cross-section. The boundaries of the surrounding primitive cells are shown as thin red lines.

In particular, if it is assumed that there are an equal number of cells in each primitive direction, $J_{1}=J_{2}=J_{3}=J$, then the Fourier wave numbers are spaced farther apart than the Floquet ones by a factor $J$ in each direction. Such a reciprocal lattice is shown as fat black dots in figure 10.16.

Note that in this section, the wave number space will be shown only in the $k_{z}=0$ cross-section. A full three-dimensional space, like the one of figure 6.17, would get very messy when crystal structure effects are added.

A lattice like the one shown in figure 10.16 is called a "simple cubic lattice," and it is the easiest lattice that you can define. The primitive vectors are orthonormal, just a multiple of the Cartesian unit vectors $\hat{\imath}, \hat{\jmath}$, and $\hat{k}$. Each lattice point can be taken to be the center of a primitive cell that is a cube, and this cubic primitive cell just happens to be the Wigner-Seitz cell too.

It is of course not that strange that the simple cubic lattice would work here, because the assumed wave number vectors were derived for electrons in a rectangular periodic box.

How about the physical lattice? That is easy too. The simple cubic lattice is its own reciprocal. So the physical crystal too consists of cubic cells stacked together. (Atomic scale ones, of course, for a physical lattice.) In particular, the wave numbers as shown in figure 10.16 correspond to a crystal that is macroscopically a cube with equal sides $2 \ell$, and that on atomic scale consists of $J \times J \times J$ identical cubic cells of size $d=2 \ell / J$. Here $J$, the number of atom-scale cells in each direction, will be a very large number, so $d$ will be very small.

In $\vec{k}$-space, $J$ is the number of Floquet points in each direction within a unit cell. Figure 10.16 would correspond to a physical crystal that has only 40 atoms in each direction. A real crystal would have many thousands, and the Floquet points would be much more densely spaced than could be shown in a figure like figure 10.16 .

It should be pointed out that the simple cubic lattice, while definitely simple, is not that important physically unless you happen to be particularly interested in polonium or compounds like cesium chloride or beta brass. But the mathematics is really no different for other crystal structures, just messier, so the simple cubic lattice makes a good example. Furthermore, many other lattices feature cubic unit cells, even if these cells are a bit larger than the primitive cell. That means that the assumption of a potential that has cubic periodicity on an atomic scale is quite widely applicable.

### 10.5.2 Occupied states and Brillouin zones

The previous subsection chose the reciprocal lattice in wave number space to be the simple cubic one. The next question is how the occupied states show up in it. As usual, it will be assumed that the crystal is in the ground state, corresponding to zero absolute temperature.

As shown in figure 6.17, in the ground state the energy levels occupied by electrons form a sphere in wave number space. The surface of the sphere is the Fermi surface. The corresponding single-electron energy is the Fermi energy.

Figure 10.17 shows the occupied states in $k_{z}=0$ cross section if there are one, two, and three valence electrons per physical lattice cell. (In other words, if there are $J^{3}, 2 J^{3}$, and $3 J^{3}$ valence electrons.) For one valence electron per lattice cell, the spherical region of occupied states stays within the first Brillouin zone, i.e. the Wigner-Seitz cell around the origin, though just barely. There are $J^{3}$ spatial states in a Wigner-Seitz cell, the same number as the number of physical lattice cells, and each can hold two electrons, (one spin up and one spin down,) so half the states in the first Brillouin zone are filled. For two electrons per lattice cell, there are just as many occupied spatial states as there are states within the first Brillouin zone. But since in the ground state, the occupied free electron states form a spherical region, rather than a cubic one, the occupied states spill over into immediately adjacent Wigner-Seitz cells. For three valence electrons per lattice cell, the occupied states spill over into still more neighboring Wigner-Seitz cells. (It is hard to see, but the diameter of the occupied sphere is slightly larger than the diagonal of the Wigner-Seitz cell cross-section.)

However, these results may show up presented in a different way in literature. The reason is that a Bloch-wave representation is not unique. In terms of Bloch waves, the free-electron exponential solutions as used here can be represented in the form

$$
\psi_{\vec{k}}^{\mathrm{p}}=e^{\mathrm{i} \cdot \vec{k} \cdot \vec{r}} \psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}
$$

where the atom-scale periodic part $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$ of the solution is a trivial constant. In addition, the Floquet wave number $\vec{k}$ can be in any Wigner-Seitz cell, however far away from the origin. Such a description is called an "extended zone scheme".

This free-electron way of thinking about the solutions is often not the best way to understand the physics. Seen within a single physical lattice cell, a solution with a Floquet wave number in a Wigner-Seitz cell far from the origin looks like an extremely rapidly varying exponential. However, all of that atomscale physics is in the crystal-scale Floquet exponential; the lattice-cell scale part $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$ is a trivial constant. It may be better to shift the Floquet wave number to the Wigner-Seitz cell around the origin, the first Brillouin zone. That will turn the crystal-scale Floquet exponential into one that varies relatively slowly over the physical lattice cell; the rapid variation will now be absorbed into the lattice-cell part $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$. This idea is called the "reduced zone scheme." As long as the Floquet wave number vector is shifted to the first Brillouin zone by whole amounts of the primitive vectors of the reciprocal lattice, $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$ will remain an atom-scale-periodic function; it will just become nontrivial. This shifting of the Floquet wave numbers to the first Brillouin zone is illustrated in figures 10.18a

Figure 10.17: Occupied states for one, two, and three free electrons per physical lattice cell.
and $10.18 b$. The figures are for the case of three valence electrons per lattice cell, but with a slightly increased radius of the sphere to avoid visual ambiguity.

Figure 10.18: Redefinition of the occupied wave number vectors into Brillouin zones.

Now each Floquet wave number vector in the first Brillouin zone does no longer correspond to just one spatial energy eigenfunction like in the extended zone scheme. There will now be multiple spatial eigenfunctions, distinguished by different lattice-scale variations $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$. Compare that with the earlier approximation of one-dimensional crystals as widely separated atoms. That was in terms of different atomic wave functions like the 2 s and 2 p ones, not a single one, that were modulated by Floquet exponentials that varied relatively slowly over an atomic cell. In other words, the reduced zone scheme is the natural one for widely spaced atoms: the lattice scale parts $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$ correspond to the different atomic energy eigenfunctions. And since they take care of the nontrivial variations within each lattice cell, the Floquet exponentials become slowly varying ones.

But you might rightly feel that the critical Fermi surface is messed up pretty badly in the reduced zone scheme figure $10.18 b$. That does not seem to be such a hot idea, since the electrons near the Fermi surface are critical for the properties of metals. However, the picture can now be taken apart again to produce separate Brillouin zones. There is a construction credited to Harrison that is illustrated in figure $10.18 c$. For points that are covered by at least one fragment of the original sphere, (which means all points, here,) the first covering is moved into the first Brillouin zone. For points that are covered by at least two
fragments of the original sphere, the second covering is moved into the second Brillouin zone. And so on.

Figure 10.19: Second, third, and fourth Brillouin zones seen in the periodic zone scheme.

Remember that in say electrical conduction, the electrons change occupied states near the Fermi surfaces. To simplify talking about that, physicist like to extend the pictures of the Brillouin zones periodically, as illustrated in figure 10.19. This is called the "periodic zone scheme." In this scheme, the boundaries of the Wigner-Seitz cells, which are normally not Fermi surfaces, are no longer a distracting factor. It may be noted that a bit of a lattice potential will round off the sharp corners in figure 10.19, increasing the esthetics.

### 10.6 Nearly-Free Electrons

The free-electron energy spectrum does not have bands. Bands only form when some of the forces that the ambient solid exerts on the electrons are included. In this section, some of the mechanics of that process will be explored. The only force considered will be one given by a periodic lattice potential. The discussion will still ignore true electron-electron interactions, time variations of the lattice potential, lattice defects, etcetera.

In addition, to simplify the mathematics it will be assumed that the lattice potential is weak. That makes the approach here diametrically opposite to the one followed in the discussion of the one-dimensional crystals. There the
starting point was electrons tightly bound to widely spaced atoms; the atom energy levels then corresponded to infinitely concentrated bands that fanned out when the distance between the atoms was reduced. Here the starting idea is free electrons in closely packed crystals for which the bands are completely fanned out so that there are no band gaps left. But it will be seen that when a bit of nontrivial lattice potential is added, energy gaps will appear.

The analysis will again be based on the Floquet energy eigenfunctions for the electrons. As noted in the previous section, they correspond to periodic boundary conditions for periods $2 \ell_{x}, 2 \ell_{y}$, and $2 \ell_{z}$. In case that the energy eigenfunctions for confined electrons are desired, they can be obtained from the Bloch solutions to be derived in this section in the following way: Take a Bloch solution and flip it over around the $x=0$ plane, i.e. replace $x$ by $-x$. Subtract that from the original solution, and you have a solution that is zero at $x=0$. And because of periodicity and odd symmetry, it will also be zero at $x=\ell_{x}$. Repeat these steps in the $y$ and $z$ directions. It will produce energy eigenfunctions for electrons confined to a box $0<x<\ell_{x}, 0<y<\ell_{y}, 0<z$ $<\ell_{z}$. This method works as long as the lattice potential has enough symmetry that it does not change during the flip operations.
㡺

Figure 10.20: The red dot shows the wavenumber vector of a sample free electron wave function. It is to be corrected for the lattice potential.

The approach will be to start with the solutions for force-free electrons and see how they change if a small, but nonzero lattice potential is added to the motion. It will be a "nearly-free electron model." Consider a sample Floquet wave number as shown by the red dot in the wave number space figure 10.20. If there is no lattice potential, the corresponding energy eigenfunction is the
free-electron one,

$$
\psi_{\vec{k}, 0}^{\mathrm{p}}=\frac{1}{\sqrt{8 \ell_{x} \ell_{y} \ell_{z}}} e^{\mathrm{i}\left(k_{x} x+k_{y} y+k_{z} z\right)}
$$

where the subscript zero merely indicates that the lattice potential is zero. (This section will use the extended zone scheme because it is mathematically easiest.) If there is a lattice potential, the eigenfunction will change into a Bloch one of the form

$$
\psi_{\vec{k}}^{\mathrm{p}}=\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}} e^{\mathrm{i}\left(k_{x} x+k_{y} y+k_{z} z\right)}
$$

where $\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}}$ is periodic on an atomic scale. If the lattice potential is weak, as assumed here,

$$
\psi_{\mathrm{p}, \vec{k}}^{\mathrm{p}} \approx \frac{1}{\sqrt{8 \ell_{x} \ell_{y} \ell_{z}}}
$$

Also, the energy will be almost the free-electron one:

$$
E_{\vec{k}}^{\mathrm{e}} \approx E_{\vec{k}, 0}^{\mathrm{e}}=\frac{\hbar^{2}}{2 m_{\mathrm{e}}} k^{2}
$$

However, that is not good enough. The interest here is in the changes in the energy due to the lattice potential, even if they are weak. So the first thing will be to figure out these energy changes.

### 10.6.1 Energy changes due to a weak lattice potential

Finding the energy changes due to a small change in a Hamiltonian can be done by a mathematical technique called "perturbation theory." A full description and derivation are in $\{$ A. 38$\}$ and $\{$ D. 79$\}$. This subsection will simply state the needed results.

The effects of a small change in a Hamiltonian, here being the weak lattice potential, are given in terms of the so-called "Hamiltonian perturbation coefficients" defined as

$$
\begin{equation*}
H_{\vec{k} \overrightarrow{\vec{k}}} \equiv\left\langle\psi_{\vec{k}, 0}^{\mathrm{p}} \mid V \psi_{\overrightarrow{\underline{k}}, 0}^{\mathrm{p}}\right\rangle \tag{10.13}
\end{equation*}
$$

where $V$ is the lattice potential, and the $\psi_{\vec{k}, 0}^{\mathrm{p}}$ are the free-electron energy eigenfunctions.

In those terms, the energy of the eigenfunction $\psi_{\vec{k}}$ with Floquet wave number $\vec{k}$ is

$$
\begin{equation*}
E_{\vec{k}}^{\mathrm{e}} \approx E_{\vec{k}, 0}^{\mathrm{e}}+H_{\vec{k} \vec{k}}-\sum_{\underline{\vec{k}} \neq \vec{k}} \frac{\left|H_{\vec{k} \vec{k} \underline{k}}\right|^{2}}{E_{\overrightarrow{\underline{k}}, 0}^{\mathrm{e}}-E_{\vec{k}, 0}^{\mathrm{e}}}+\ldots \tag{10.14}
\end{equation*}
$$

Here $E_{\vec{k}, 0}^{\mathrm{e}}$ is the free-electron energy. The dots stand for contributions that can be ignored for sufficiently weak potentials.

The first correction to the free-electron energy is the Hamiltonian perturbation coefficient $H_{\vec{k} \vec{k}}$. However, by writing out the inner product, it is seen
that this perturbation coefficient is just the average lattice potential. Such a constant energy change is of no particular physical interest; it can be eliminated by redefining the zero level of the potential energy.

Figure 10.21: The grid of nonzero Hamiltonian perturbation coefficients and the problem sphere in wave number space.

That makes the sum in (10.14) the physically interesting change in energy. Now, unlike it seems from the given expression, it is not really necessary to sum over all free-electron energy eigenfunctions $\psi_{\vec{k}, 0}$. The only Hamiltonian perturbation coefficients that are nonzero occur for the $\overrightarrow{\underline{k}}$ values shown in figure 10.21 as blue stars. They are spaced apart by amounts $J \overline{\text { in }}$ each direction, where $J$ is the large number of physical lattice cells in that direction. These claims can be verified by writing the lattice potential as a Fourier series and then integrating the inner product. More elegantly, you can use the observation from addendum \{A.38.3\} that the only eigenfunctions that need to be considered are those with the same eigenvalues under displacement over the primitive vectors of the lattice. (Since the periodic lattice potential is the same after such displacements, these displacement operators commute with the Hamiltonian.)

The correct expression for the energy change has therefore now been identified. There is one caveat in the whole story, though. The above analysis is not justified if there are eigenfunctions $\psi_{\underline{\underline{k}}, 0}^{\mathrm{p}}$ on the grid of blue stars that have the same free-electron energy $E_{\vec{k}, 0}^{\mathrm{e}}$ as the eigenfunction $\psi_{\vec{k}, 0}^{\mathrm{p}}$. You can infer the problem from (10.14); you would be dividing by zero if that happened. You would have to fix the problem by using so-called "singular perturbation theory," which is much more elaborate.

Fortunately, since the grid is so widely spaced, the problem occurs only for relatively few energy eigenfunctions $\psi_{\vec{k}}^{\mathrm{p}}$. In particular, since the free-electron
energy $E_{\vec{k}, 0}^{\mathrm{e}}$ equals $\hbar^{2} k^{2} / 2 m_{\mathrm{e}}$, the square magnitude of $\underline{\vec{k}}$ would have to be the same as that of $\vec{k}$. In other words, $\underline{\vec{k}}$ would have to be on the same spherical surface around the origin as point $\vec{k}$. So, as long as the grid has no points other than $\vec{k}$ on the spherical surface, all is OK.

### 10.6.2 Discussion of the energy changes

The previous subsection determined how the energy changes from the freeelectron gas values due to a small lattice potential. It was found that an energy level $E_{\vec{k}, 0}^{\mathrm{e}}$ without lattice potential changes due to the lattice potential by an amount:

$$
\begin{equation*}
\Delta E_{\vec{k}}^{\mathrm{e}}=-\sum_{\vec{k} \neq \vec{k}} \frac{\left|H_{\vec{k} \underline{k}}\right|^{2}}{E_{\vec{k}, 0}^{\mathrm{e}}-E_{\vec{k}, 0}^{\mathrm{e}}} \tag{10.15}
\end{equation*}
$$

where the $H_{\vec{k} \vec{k}}$ were coefficients that depend on the details of the lattice potential; $\vec{k}$ was the wave number vector of the considered free-electron gas solution, shown as a red dot in the wavenumber space figure $10.21, \underline{\vec{k}}$ was an summation index over the blue grid points of that figure, and $E_{\underline{k}, 0}^{\mathrm{e}}$ and $E_{\vec{k}, 0}^{\mathrm{e}}$ were proportional to the square distances from the origin to points $\underline{\vec{k}}$, respectively $\vec{k}$. $E_{\vec{k}, 0}^{\mathrm{e}}$ is also the energy level of the eigenfunction without lattice potential.

The expression above for the energy change is not valid when $E_{\vec{k}, 0}^{\mathrm{e}}=E_{\vec{k}, 0}^{\mathrm{e}}$, in which case it would incorrectly give infinite change in energy. However, it is does apply when $E_{\vec{k}, 0}^{\mathrm{e}} \approx E_{\vec{k}, 0}^{\mathrm{e}}$, in which case it predicts unusually large changes in energy. The condition $E_{\underline{k}, 0}^{\mathrm{e}} \approx E_{\vec{k}, 0}^{\mathrm{e}}$ means that a blue star $\underline{\vec{k}}$ on the grid in figure 10.21 is almost the same distance from the origin as the red point $\vec{k}$ itself.

Figure 10.22: Tearing apart of the wave number space energies.

One case for which this happens is when the wave number vector $\vec{k}$ is right next to one of the boundaries of the Wigner-Seitz cell around the origin. Whenever a $\vec{k}$ is on the verge of leaving this cell, one of its lattice points is on the verge of getting in. As an example, figure 10.22 shows two neighboring states $\vec{k}$ straddling the right-hand vertical plane of the cell, as well as their lattice $\underline{\vec{k}}$ values that cause the unusually large energy changes.

For the left of the two states, $E_{\underline{k}, 0}^{\mathrm{e}}, \mathrm{is}$ just a bit larger than $E_{\vec{k} .0}^{\mathrm{e}}$, so the energy change (10.15) due to the lattice potential is large and negative. All energy decreases will be represented graphically by moving the points towards the origin, in order that the distance from the origin continues to indicate the energy of the state. That means that the left state will move strongly towards the origin. Consider now the other state just to the right; $E_{\underline{k}, 0}^{e}$, for that state is just a bit less than $E_{\vec{k}, 0}^{\mathrm{e}}$, so the energy change of this state will be large and positive; graphically, this point will move strongly away from the origin. The result is that the energy levels are torn apart along the surface of the WignerSeitz cell.

Figure 10.23: Effect of a lattice potential on the energy. The energy is represented by the square distance from the origin, and is relative to the energy at the origin.

That is illustrated for an arbitrarily chosen example lattice potential in figure 10.23. It is another reason why the Wigner-Seitz cell around the origin, i.e. the first Brillouin zone, is particularly important. For different lattices than the simple cubic one considered here, it is still the distance from the origin that is the deciding factor, so in general, it is the Wigner-Seitz cell, rather than some parallelepiped-shaped primitive cell along whose surfaces the energies get torn apart.

Figure 10.24: Bragg planes seen in wave number space cross section.

But notice in figure 10.23 that the energy levels get torn apart along many more surfaces than just the surface of the first Brillouin zone. In general, it can be seen that tears occur in wave number space along all the perpendicular bisector planes, or Bragg planes, between the points of the reciprocal lattice and the origin. Figure 10.24 shows their intersections with the cross section $k_{z}$ $=0$ as thin black lines. The $k_{x}$ and $k_{y}$ axes were left away to clarify that they do not hide any lines.

Recall that the Bragg planes are also the boundaries of the fragments that make up the various Brillouin zones. In fact the first Brillouin zone is the cube or Wigner-Seitz cell around the origin; (the square around the origin in the cross section figure 10.24). The second zone consists of six pyramid-shaped regions whose bases are the faces of the cube; (the four triangles sharing a side with the square in the cross section figure 10.24). They can be pushed into the first Brillouin zone using the fundamental translation vectors to combine into a Wigner-Seitz cell shape.

For a sufficiently strong lattice potential like the one in figure 10.23, the energy levels in the first Brillouin zone, the center patch, are everywhere lower than in the remaining areas. Electrons will then occupy these states first, and since there are $J \times J \times J$ spatial states in the zone, two valence electrons per physical lattice cell will just fill it, figure 10.25. That produces an insulator whose electrons are stuck in a filled valence band. The electrons must jump an finite energy gap to reach the outlying regions if they want to do anything nontrivial. Since no particular requirements were put onto the lattice potential, the forming of bands is self-evidently a very general process.

The wave number space in the right half of figure 10.25 also illustrates that a lattice potential can change the Floquet wave number vectors that get occupied.

Figure 10.25: Occupied states for the energies of figure 10.23 if there are two valence electrons per lattice cell. Left: energy. Right: wave numbers.

For the free-electron gas, the occupied states formed a spherical region in terms of the wave number vectors, as shown in the middle of figure 10.17, but here the occupied states have become a cube, the Wigner-Seitz cell around the origin. The Fermi surface seen in the extended zone scheme is now no longer a spherical surface, but consists of the six faces of this cell.

But do not take this example too literally: the small-perturbation analysis is invalid for the strong potential required for an insulator, and the real picture would look quite different. In particular, the "roll-over" of the states at the edge of the first Brillouin zone in the energy plot is a clear indication that the accuracy is poor. The error in the perturbation analysis is the largest for states immediately next to the Bragg planes. The example is given just to illustrate that the nearly-free electron model can indeed describe band gaps if taken far enough.

The nearly-free electron model is more reasonable for the smaller lattice forces experienced by valence electrons in metals. For example, at reduced strength, the same potential as before produces figure 10.26. Now the electrons have no trouble finding states of slightly higher energy, as it should be for a metal. Note, incidentally, that the Fermi surfaces in the right-hand graphs seem to meet the Bragg planes much more normally than the spherical freeelectron surface. That leads to smoothing out of the corners of the surface seen in the periodic zone scheme. For example, imagine the center zone of the one valence electron wave number space periodically continued.

### 10.7 Additional Points

This section mentions a couple of additional very basic issues in the quantum mechanics of solids.

Figure 10.26: Smaller lattice potential. From top to bottom shows one, two and three valence electrons per lattice cell. Left: energy. Right: wave numbers.

### 10.7.1 About ferromagnetism

Magnetism in all its myriad forms and complexity is far beyond the scope of this book. But there is one very important fundamental quantum mechanics issue associated with ferromagnetism that has not yet been introduced.

Ferromagnetism is the plain variety of magnetism, like in refrigerator magnets. Ferromagnetic solids like iron are of great engineering interest. They can significantly increase a magnetic field and can stay permanently magnetized even in the absence of a field. The fundamental quantum mechanics issue has to do with why they produce magnetic fields in the first place.

The source of the ferromagnetic field is the electrons. Electrons have spin, and just like a classical charged particle that is spinning around in a circle produces a magnetic field, so do electrons act as little magnets. A free iron atom has 26 electrons, each with spin $1 / 2$. But two of these electrons are in the 1 s states, the K shell, where they combine into a singlet state with zero net spin which produces no magnetic field. Nor do the two 2 s electrons and the six 2 p electrons in the L shell, and the two 3 s electrons and six 3 p electrons in the M shell and the two 4s electrons in the N shell produce net spin. All of that lack of net spin is a result of the Pauli exclusion principle, which says that if electrons want to go two at a time into the lowest available energy states, they must do it as singlet spin states. And these filled subshells produce no net orbital angular momentum either, having just as many positive as negative orbital momentum states filled in whatever way you look at it

However, iron has a final six electrons in 3d states, and the 3d states can accommodate ten electrons, five for each spin direction. So only two out of the six electrons need to enter the same spatial state as a zero spin singlet. The other four electrons can each go into their private spatial state. And the electrons do want to do so, since by going into different spatial states, they can stay farther away from each other, minimizing their mutual Coulomb repulsion energy.

According to the simplistic model of noninteracting electrons that was used to describe atoms in chapter 5.9, these last four electrons can then have equal or opposite spin, whatever they like. But that is wrong. The four electrons interact through their Coulomb repulsion, and it turns out that they achieve the smallest energy when their spatial wave function is antisymmetric under particle exchange.
(This is just the opposite of the conclusion for the hydrogen molecule, where the symmetric spatial wave function had the lowest energy. The difference is that for the hydrogen molecule, the dominant effect is the reduction of the kinetic energy that the symmetric state achieves, while for the single-atom states, the dominant effect is the reduction in electron to electron Coulomb repulsion that the antisymmetric wave function achieves. In the antisymmetric spatial wave function, the electrons stay further apart on average.)

If the spatial wave function of the four electrons takes care of the antisymmetrization requirement, then their spin state cannot change under particle exchange; they all must have the same spin. This is known as "Hund's first rule:" electron interaction makes the net spin as big as the exclusion principle allows. The four unpaired 3d electrons in iron minimize their Coulomb energy at the price of having to align all four of their spins. Which means their spin magnetic moments add up rather than cancel each other. $\{$ A.34\}.

Hund's second rule says that the electrons will next maximize their orbital angular momentum as much as is still possible. And according to Hund's third rule, this orbital angular momentum will add to the spin angular momentum since the ten 3d states are more than half full. It turns out that iron's 3d electrons have the same amount of orbital angular momentum as spin, however, orbital angular momentum is only about half as effective at creating a magnetic dipole.

In addition, the magnetic properties of orbital angular momentum are readily messed up when atoms are brought together in a solid, and more so for transition metals like iron than for the lanthanoid series, whose unfilled 4 f states are buried much deeper inside the atoms. In most of the common ferromagnets, the orbital contribution is negligible small, though in some rare earths there is an appreciable orbital contribution.

Guessing just the right amounts of net spin angular momentum, net orbital angular momentum, and net combined angular momentum for an atom can be tricky. So, in an effort make quantum mechanics as readily accessible as possible, physicists provide the data in an intuitive hieroglyph. For example

$$
{ }^{5} D_{4}
$$

gives the angular momentum of the iron atom. The 5 indicates that the spin angular momentum is 2 . To arrive at 5 , the physicists multiply by 2 , since spin can be half integer and it is believed that many people doing quantum mechanics have difficulty with fractions. Next 1 is added to keep people from cheating and mentally dividing by $2-$ you must subtract 1 first. (Another quick way of getting the actual spin: write down all possible values for the spin in increasing order, and then count until the fifth value. Start counting from 1, of course, because counting from 0 is so computer science.) The $D$ intimates that the orbital angular momentum is 2 . To arrive at $D$, physicists write down the intuitive sequence of letters $S, P, D, F, G, H, I, K, \ldots$ and then count, starting from zero, to the orbital angular momentum. Unlike for spin, here it is not the count, but the object being counted that is listed in the hieroglyph; unfortunately the object being counted is letters, not angular momentum. Physicists assume that after having practiced counting spin states and letters, your memory is refreshed about fractions, and the combined angular momentum is simply listed by value, 4 for iron. Listing spin and combined angular momentum in two different formats achieves that the class won't notice the error if the physics
professor misstates the spin or combined angular momentum for an atom with zero orbital momentum.

On to the solid. The atoms act as little magnets because of their four aligned electron spins and net orbital angular momentum, but why would different atoms want to align their magnetic poles in the same direction in a solid? If they don't, there is not going to be any macroscopically significant magnetic field. The logical reason for the electron spins of different atoms to align would seem to be that it minimizes the magnetic energy. However, if the numbers are examined, any such aligning force is far too small to survive random heat motion at normal temperatures.

The primary reason is without doubt again the same weird quantum mechanics as for the single atom. Nature does not care about magnetic alignment or not; it is squirming to minimize its Coulomb energy under the massive constraints of the antisymmetrization requirement. By aligning electron spins globally, it achieves that electrons can stay farther apart spatially. $\{\mathrm{N} .22\}$.

It is a fairly small effect; among the pure elements, it really only works under normal operating temperatures for cobalt and its immediate neighbors in the periodic table, iron and nickel. And alignment is normally not achieved throughout a bulk solid, but only in microscopic zones, with different zones having different alignment. But any electrical engineer will tell you it is a very important effect anyway. For one since the zones can be manipulated with a magnetic field.

And it clarifies that nature does not necessarily select singlet states of opposite spin to minimize the energy, despite what the hydrogen molecule and helium atom might suggest. Much of the time, aligned spins are preferred.

### 10.7.2 X-ray diffraction

You may wonder how so much is known about the crystal structure of solids in view of the fact that the atoms are much too small to be seen with visible light. In addition, because of the fact that the energy levels get smeared out into bands, like in figure 10.11, solids do not have those tell-tale line spectra that are so useful for analyzing atoms and molecules.

To be precise, while the energy levels of the outer electrons of the atoms get smeared out, those of the inner electrons do not do so significantly, and these do produce line spectra. But since the energy levels of the inner electrons are very high, transitions involving inner electrons do not produce visible light, but X-rays.

There is a very powerful other technique for studying the crystal structure of atoms, however, and it also involves X-rays. In this technique, called X-ray diffraction, an X-ray is trained on a crystal from various angles, and the way the crystal scatters the X-ray is determined.

There is no quantum mechanics needed to describe how this works, but a brief description may be of value anyway. If you want to work in nanotechnology, you will inevitably run up against experimental work, and X-ray diffraction is a key technique. Having some idea of how it works and what it can do can be useful.

First a very basic understanding is needed of what is an X-ray. An X-ray is a propagating wave of electromagnetic radiation just like a beam of visible light. The only difference between them is that an X-ray is much more energetic. Whether it is light or an X-ray, an electromagnetic wave is physically a combination of electric and magnetic fields that propagate in a given direction with the speed of light.

Figure 10.27: Depiction of an electromagnetic ray.
Figure 10.27 gives a sketch of how the strength of the electric field varies along the propagation direction of a simple monochromatic wave; the magnetic field is similar, but 90 degrees out of phase. Above that, a sketch is given how such rays will be visualized in this subsection: the positive maxima will be indicated by encircled plus signs, and the negative minima by encircled minus signs. Both these maxima and minima propagate along the line with the speed of light; the picture is just a snapshot at an arbitrary time.

The distance between two successive maxima is called the wave length $\lambda$. If the wave length is in the narrow range from about 4000 to $7000 \AA$, it is visible light. But such a wave length is much too large to distinguish atoms, since atom sizes are in the order of a few $\AA$. Electromagnetic waves with the required wave lengths of a few $\AA$ fall in what is called the X-ray range.

The wave number $\kappa$ is the reciprocal of the wave length within a normalization factor $2 \pi: \kappa=2 \pi / \lambda$. The wave number vector $\vec{\kappa}$ has the magnitude of the wave number $\kappa$ and points in the direction of propagation of the wave.

Next consider a plane of atoms in a crystal, and imagine that it forms a perfectly flat mirror, as in figure 10.28 . No, there are no physical examples of flat atoms known to science. But just imagine there would be, OK? Now shine an X-ray from the left onto this crystal layer and examine the diffracted wave that comes back from it. Assume Huygens' principle that the scattered rays come off in all directions, and that the scattering is elastic, meaning that the energy, hence wave length, stays the same.

Under those conditions, a detector A, placed at a position to catch the rays scattered to the same angle as the angle $\theta$ of the incident beam, will observe a

Figure 10.28: Law of reflection in elastic scattering from a plane.
strong signal. All the maxima in the electric field of the rays arrive at detector A at the same time, reinforcing each other. They march in lock-step. So a strong positive signal will exist at detector A at their arrival. Similarly, the minima march in lock-step, arriving at $A$ at the same time and producing a strong signal, now negative. Detector A will record a strong, fluctuating, electric field.

Detector B, at a position where the angle of reflection is unequal to the angle of incidence, receives similar rays, but both positive and negative values of the electric field arrive at B at the same time, killing each other off. So detector B will not see an observable signal. That is the law of reflection: there is only a detectable diffracted wave at a position where the angle of reflection equals the angle of incidence. (Those angles are usually measured from the normal to the surface instead of from the surface itself, but not in Bragg diffraction.)

For visible light, this is actually a quite reasonable analysis of a mirror, since an atom-size surface roughness is negligible compared to the wave length of visible light. For X-rays, it is not so hot, partly because a layer of atoms is not flat on the scale of the wave length of the X-ray. But worse, a single layer of atoms does not reflect an X-ray by any appreciable amount. That is the entire point of medical X-rays; they can penetrate millions of layers of atoms to show what is below. A single layer is nothing to them.

For X-rays to be diffracted in an appreciable amount, it must be done by many parallel layers of atoms, not just one, as in figure 10.29. The layers must furthermore have a very specific spacing $d$ for the maxima and minima from different layers to arrive at the detector at the same time. Note that the angular position of the detector is already determined by the law of reflection, in order to get whatever little there can be gotten from each plane separately.

Figure 10.29: Scattering from multiple "planes of atoms."
(Also note that whatever variations in phase there are in the signals arriving at the detector in figure 10.29 are artifacts: for graphical reasons the detector is much closer to the specimen than it should be. The spacing between planes should be on the order of $\AA$, while the detector should be a macroscopic distance away from the specimen.)

The spacing between planes needed to get a decent combined signal strength at the detector is known to satisfy the Bragg law:

$$
\begin{equation*}
2 d \sin \theta=n \lambda \tag{10.16}
\end{equation*}
$$

where $n$ is a natural number. A derivation will be given below. One immediate consequence is that to get X-ray diffraction, the wave length $\lambda$ of the X-ray cannot be more than twice the spacing between the planes of atoms. That requires wave lengths no longer than of the order of Ångstroms. Visible light does not qualify.

The above story is, of course, not very satisfactory. For one, layers of atoms are not flat planes on the scale of the required X-ray wave lengths. And how come that in one direction the atoms have continuous positions and in another discrete? Furthermore, it is not obvious what to make of the results. Observing a refracted X-ray at some angular location may suggest that there is some reflecting plane in the crystal at an angle deducible from the law of reflection, but many different planes of atoms exist in a crystal. If a large number of measurements are done, typically by surrounding the specimen by detectors and rotating it while shining an X-ray on it, how is the crystal structure to be deduced from that overwhelming amount of information?

Clearly, a mathematical analysis is needed, and actually it is not very complicated. First a mathematical expression is needed for the signal along the ray; it can be taken to be a complex exponential
where $s$ is the distance traveled along the ray from a suitable chosen starting position, $t$ the time, and $c$ the speed of light. The real part of the exponential can be taken as the electric field, with a suitable constant, and the imaginary part as the magnetic field, with another constant. The only important point here is that if there is a difference in travel distance $\Delta s$ between two rays, their signals at the detector will be out of phase by a factor $e^{i \kappa \Delta s}$. Unless this factor is one, which requires $\kappa \Delta s$ to be zero or a whole multiple of $2 \pi$, there will be at least some cancelation of signals at the detector.

Figure 10.30: Difference in travel distance when scattered from $P$ rather than O.

So, how much is the phase factor $e^{\mathrm{i} \kappa \Delta s}$ ? Figure 10.30 shows one ray that is scattered at a chosen reference point $O$ in the crystal, and another ray that is scattered at another point P . The position vector of P relative to origin O is $\vec{r}$. Now the difference in travel distance for the second ray to reach P versus the first one to reach O is given by the component of vector $\vec{r}$ in the direction of the incoming wave vector $\vec{k}$. This component can be found as a dot product with the unit vector in the direction of $\vec{\kappa}$ :

$$
\Delta s_{1}=\vec{r} \cdot \frac{\vec{\kappa}}{\kappa} \quad \text { so } \quad e^{\mathrm{i} \kappa \Delta s_{1}}=e^{\mathrm{i} k \cdot \vec{r}}
$$

The difference in travel distance for the second ray to reach the detector from point P versus the first from O is similarly given as

$$
\Delta s_{2}=-\vec{r} \cdot \frac{\vec{k}^{\prime}}{\kappa} \quad \text { so } \quad e^{\mathrm{i} \kappa \Delta s_{2}}=e^{-\mathrm{i} \vec{\kappa}^{\prime} \cdot \vec{r}}
$$

assuming that the detector is sufficiently far away from the crystal that the rays can be assumed to travel to the detector in parallel.

The net result is then that the phase factor with which the ray from P arrives at the detector compared to the ray from O is

This result may be used to check the law of reflection and Bragg's law above
First of all, for the law of reflection of figure 10.28, the positions of the scattering points P vary continuously through the horizontal plane. That means that the phase factor of the rays received at the detector will normally also vary continuously from positive to negative back to positive etcetera, leading to largescale cancelation of the net signal. The one exception is when $\vec{\kappa}-\vec{\kappa}^{\prime}$ happens to be normal to the reflecting plane, since a dot product with a normal vector is always zero. For $\vec{\kappa}-\vec{\kappa}^{\prime}$ to be normal to the plane, its horizontal component must be zero, meaning that the horizontal components of $\vec{\kappa}$ and $\vec{\kappa}^{\prime}$ must be equal, and for that to be true, their angles with the horizontal plane must be equal, since the vectors have the same length. So the law of reflection is obtained.

Next for Bragg's law of figure 10.29, the issue is the phase difference between successive crystal planes. So the vector $\vec{r}$ in this case can be assumed to point from one crystal plane to the next. Since from the law of reflection, it is already known that $\vec{\kappa}-\vec{\kappa}^{\prime}$ is normal to the planes, the only component of $\vec{r}$ of importance is the vertical one, and that is the crystal plane spacing $d$. It must be multiplied by the vertical component of $\vec{\kappa}-\vec{\kappa}^{\prime}$, (its only component), which is according to basic trig is equal to $-2 \kappa \sin \theta$. The phase factor between successive planes is therefore $e^{-\mathrm{i} d 2 \kappa \sin \theta}$. The argument of the exponential is obviously negative, and then the only possibility for the phase factor to be one is if the argument is a whole multiple $n$ times -i2 $\pi$. So for signals from different crystal planes to arrive at the detector in phase,

$$
d 2 \kappa \sin \theta=n 2 \pi .
$$

Substitute $\kappa=2 \pi / \lambda$ and you have Bragg's law.
Now how about diffraction from a real crystal? Well, assume that every location in the crystal elastically scatters the incoming wave by a small amount that is proportional to the electron density $n$ at that point. (This $n$ not to be confused with the $n$ in Bragg's law.) Then the total signal $D$ received by the detector can be written as

$$
D=C \int_{\text {all } \vec{r}} n(\vec{r}) e^{\mathrm{i}\left(\vec{k}-\vec{r}^{\prime}\right) \cdot \vec{r}} \mathrm{~d}^{3} \vec{r}
$$

where $C$ is some constant. Now the electron density is periodic on crystal lattice scale, so according to section 10.3 .10 it can be written as a Fourier series, giving the signal as

$$
D=C \sum_{\text {all } \vec{k}_{\vec{n}}} \int_{\text {all } \vec{r}} n_{\overrightarrow{k_{\vec{n}}}} e^{\mathrm{i}\left(\vec{k}_{\vec{n}}+\vec{k}-\vec{k}^{\prime}\right) \cdot \vec{r}} \mathrm{~d}^{3} \vec{r}
$$

where the $\vec{k}_{\vec{n}}$ wave number vectors form the reciprocal lattice and the numbers $n_{\overrightarrow{k_{\vec{n}}}}$ are constants. Because the volume integration above extends over countless lattice cells, there will be massive cancelation of signal unless the exponential is
constant, which requires that the factor multiplying the position coordinate is zero:

$$
\begin{equation*}
\vec{k}_{\vec{n}}=\vec{\kappa}^{\prime}-\vec{\kappa} \tag{10.17}
\end{equation*}
$$

So the changes in the x-ray wave number vector $\vec{\kappa}$ for which there is a detectable signal tell you the reciprocal lattice vectors. (Or at least the ones for which $n_{\overrightarrow{k_{\vec{n}}}}$ is not zero because of some symmetry.) After you infer the reciprocal lattice vectors it is easy to figure out the primitive vectors of the physical crystal you are analyzing. Furthermore, the relative strength of the received signal tells you the magnitude of the Fourier coefficient $n_{\overrightarrow{\vec{n}_{\vec{n}}}}$ of the electron density. Obviously, all of this is very specific and powerful information, far above trying to make some sense out of mere collections of flat planes and their spacings.

One interesting additional issue has to do with what incoming wave vectors $\vec{\kappa}$ are diffracted, regardless of where the diffracted wave ends up. To answer it, just eliminate $\vec{k}^{\prime}$ from the above equation by finding its square and noting that $\vec{\kappa}^{\prime} \cdot \vec{\kappa}^{\prime}$ is $\kappa^{2}$ since the magnitude of the wave number does not change in elastic scattering. It produces

$$
\begin{equation*}
\vec{\kappa} \cdot \vec{k}_{\vec{n}}=-\frac{1}{2} \vec{k}_{\vec{n}} \cdot \vec{k}_{\vec{n}} \tag{10.18}
\end{equation*}
$$

For this equation to be satisfied, the X-ray wave number vector $\vec{\kappa}$ must be in the Bragg plane between $-\vec{k}_{\vec{n}}$ and the origin. For example, for a simple cubic crystal, $\vec{\kappa}$ must be in one of the Bragg planes shown in cross section in figure 10.24. One general consequence is that the wave number vector $\kappa$ must at least be long enough to reach the surface of the first Brillouin zone for any Bragg diffraction to occur. That determines the maximum wave length of usable Xrays according to $\lambda=2 \pi / \kappa$. You may recall that the Bragg planes are also the surfaces of the Brillouin zone segments and the surfaces along which the electron energy states develop discontinuities if there is a lattice potential. They sure get around.

Historically, Bragg diffraction was important to show that particles are indeed associated with wave functions, as de Broglie had surmised. When Davisson and Germer bombarded a crystal with a beam of single-momentum electrons, they observed Bragg diffraction just like for electromagnetic waves. Assuming for simplicity that the momentum of the electrons is in the $z$-direction and that uncertainty in momentum can be ignored, the eigenfunctions of the momentum operator $\widehat{p}_{z}=\hbar \partial / \mathrm{i} \partial z$ are proportional to $e^{\mathrm{i} \kappa z}$, where $\hbar \kappa$ is the $z$-momentum eigenvalue. From the known momentum of the electrons, Davisson and Germer could compute the wave number $\kappa$ and verify that the electrons suffered Bragg diffraction according to that wave number. (The value of $\hbar$ was already known from Planck's blackbody spectrum, and from the Planck-Einstein relation that the energy of the photons of electromagnetic radiation equals $\hbar \omega$ with $\omega$ the angular frequency.)

Chapter 6 mentioned the Maxwell-Boltzmann, Fermi-Dirac, and Bose-Einstein energy distributions of systems of weakly interacting particles. This chapter explains these results and then goes on to put quantum mechanics and thermodynamics in context.

It is assumed that you have had a course in basic thermodynamics. If not, rejoice, you are going to get one now. The exposition depends relatively strongly upon the material in chapter 5.7-5.9 and chapter 6.1-6.16.

This chapter will be restricted to systems of particles that are all the same. Such a system is called a "pure substance." Water would be a pure substance, but air not really; air is mostly nitrogen, but the $20 \%$ oxygen can probably not be ignored. That would be particularly important under cryogenic conditions in which the oxygen condenses out first.

The primary quantum system to be studied in detail will be a macroscopic number of weakly interacting particles, especially particles in a box. Nontrivial interactions between even a few particles are very hard to account for correctly, and for a macroscopic system, that becomes much more so: just a millimol has well over $10^{20}$ particles. By ignoring particle interactions, the system can be described in terms of single-particle energy eigenstates, allowing some real analysis to be done.

However, a system of strictly noninteracting unperturbed particles would be stuck into the initial energy eigenstate, or the initial combination of such states, according to the Schrödinger equation. To get such a system to settle down into a physically realistic configuration, it is necessary to include the effects of the unavoidable real life perturbations, (molecular motion of the containing box, ambient electromagnetic field, cosmic rays, whatever.) The effects of such small random perturbations will be accounted for using reasonable assumptions. In particular, it will be assumed that they tend to randomly stir up things a bit over time, taking the system out of any physically unlikely state it may be

## Basic and Quantum Thermodynamics

stuck in and making it settle down into the macroscopically stable one, called "thermal equilibrium."

### 11.1 Temperature

This book frequently uses the word "temperature," but what does that really mean? It is often said that temperature is some measure of the kinetic energy of the molecules, but that is a dubious statement. It is OK for a thin noble gas, where the kinetic energy per atom is $\frac{3}{2} k_{\mathrm{B}} T$ with $k_{\mathrm{B}}=1.3806510^{-23} \mathrm{~J} / \mathrm{K}$ the Boltzmann constant and $T$ the (absolute) temperature in degrees Kelvin. But the valence electrons in an metal typically have kinetic energies many times greater than $\frac{3}{2} k_{\mathrm{B}} T$. And when the absolute temperature becomes zero, the kinetic energy of a system of particles does not normally become zero, since the uncertainty principle does not allow that.

In reality, the temperature of a system is not a measure of its thermal kinetic energy, but of its "hotness." So, to understand temperature, you first have to understand hotness. A system A is hotter than a system B, (and B is colder than $A$, ) if heat energy flows from A to B if they are brought into thermal contact. If no heat flows, A and B are equally hot. Temperature is a numerical value defined so that, if two systems A and B are equally hot, they have the same value for the temperature.

The so-called "zeroth law of thermodynamics" ensures that this definition makes sense. It says that if systems A and B have the same temperature, and systems B and C have the same temperature, then systems A and C have the same temperature. Otherwise system B would have two temperatures: A and $C$ would have different temperatures, and $B$ would have the same temperature as each of them.

The systems are supposed to be in thermal equilibrium. For example, a solid chunk of matter that is hotter on its inside than its outside simply does not have a (single) temperature, so there is no point in talking about it.

The requirement that systems that are equally hot must have the same value of the temperature does not say anything about what that value must be. Definitions of the actual values have historically varied. A good one is to compute the temperature of a system A using an ideal gas B at equal temperature as system A. Then $\frac{3}{2} k_{\mathrm{B}} T$ can simply be defined to be the mean translational kinetic energy of the molecules of ideal gas B. That kinetic energy, in turn, can be computed from the pressure and density of the gas. With this definition of the temperature scale, the temperature is zero in the ground state of ideal gas B . The reason is that a highly accurate ideal gas means very few atoms or molecules in a very roomy box. With the vast uncertainty in position that the roomy box provides to the ground-state, the uncertainty-demanded kinetic energy is vanishingly small. So $k_{\mathrm{B}} T$ will be zero.

[^3]

$\square$

$\square$

[^4]

[^5]It then follows that all ground states are at absolute zero temperature, regardless how large their kinetic energy. The reason is that all ground states must have the same temperature: if two systems in their ground states are brought in thermal contact, no heat can flow: neither ground state can sacrifice any more energy, the ground state energy cannot be reduced.

However, the "ideal gas thermometer" is limited by the fact that the temperatures it can describe must be positive. There are some unstable systems that in a technical and approximate, but meaningful, sense have negative absolute temperatures [4]. Unlike what you might expect, (aren't negative numbers less than positive ones?) such systems are hotter than any normal system. Systems of negative temperature will give off heat regardless of how searingly hot the normal system that they are in contact with is.

In this chapter a definition of temperature scale will be given based on the quantum treatment. Various equivalent definitions will pop up. Eventually, section 11.14 .4 will establish it is the same as the ideal gas temperature scale.

You might wonder why the laws of thermodynamics are numbered from zero. The reason is historical; the first, second, and third laws were already firmly established before in the early twentieth century it was belatedly recognized that an explicit statement of the zeroth law was really needed. If you are already familiar with the second law, you might think it implies the zeroth, but things are not quite that simple.

What about these other laws? The "first law of thermodynamics" is simply stolen from general physics; it states that energy is conserved. The second and third laws will be described in sections 11.8 through 11.10.

### 11.2 Single-Particle versus System States

The purpose of this section is to describe the generic form of the energy eigenfunctions of a system of weakly interacting particles.

The total number of particles will be indicated by $I$. If the interactions between the $I$ particles are ignored, any energy eigenfunction of the complete system of $I$ particles can be written in terms of single-particle energy eigenfunctions $\psi_{1}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \psi_{2}^{\mathrm{p}}\left(\vec{r}, S_{z}\right), \ldots$

The basic case is that of noninteracting particles in a box, like discussed in chapter 6.2. For such particles the single-particle eigenfunctions take the spatial form

$$
\psi_{n}^{\mathrm{p}}=\sqrt{\frac{8}{\ell_{x} \ell_{y} \ell_{z}}} \sin \left(k_{x} x\right) \sin \left(k_{y} y\right) \sin \left(k_{z} z\right)
$$

where $k_{x}, k_{y}$, and $k_{z}$ are constants, called the "wave number components." Different values for these constants correspond to different single-particle eigen-
functions, with single-particle energy

$$
E_{n}^{\mathrm{p}}=\frac{\hbar^{2}}{2 m}\left(k_{x}^{2}+k_{y}^{2}+k_{z}^{2}\right)=\frac{\hbar^{2}}{2 m} k^{2}
$$

The single-particle energy eigenfunctions will in this chapter be numbered as $n$ $=1,2,3, \ldots, N$. Higher values of index $n$ correspond to eigenfunctions of equal or higher energy $E_{n}^{\mathrm{p}}$.

The single-particle eigenfunctions do not always correspond to a particle in a box. For example, particles caught in a magnetic trap, like in the Bose-Einstein condensation experiments of 1995, might be better described using harmonic oscillator eigenfunctions. Or the particles might be restricted to move in a lower-dimensional space. But a lot of the formulae you can find in literature and in this chapter are in fact derived assuming the simplest case of noninteracting particles in a roomy box.

The details of the single-particle energy eigenfunctions are not really that important in this chapter. What is more interesting are the energy eigenfunctions $\psi_{q}^{\mathrm{S}}$ of complete systems of particles. It will be assumed that these system eigenfunctions are numbered using a counter $q$, but the way they are numbered also does not really make a difference to the analysis.

As long as the interactions between the particles are weak, energy eigenfunctions of the complete system can be found as products of the single-particle ones. As an important example, at absolute zero temperature, all particles will be in the single-particle ground state $\psi_{1}^{\mathrm{p}}$, and the system will be in its ground state

$$
\psi_{1}^{\mathrm{S}}=\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{5}, S_{z 5}\right) \ldots \psi_{1}^{\mathrm{p}}\left(\vec{r}_{I}, S_{z I}\right)
$$

where $I$ is the total number of particles in the system. This does assume that the single-particle ground state energy $E_{1}^{\mathrm{p}}$ is not degenerate. More importantly, it assumes that the $I$ particles are not identical fermions. According to the exclusion principle, at most one fermion can go into a single-particle state. (For spin $1 / 2$ fermions like electrons, two can go into a single spatial state, one in the spin-up version, and the other in the spin-down one.)

Statistical thermodynamics, in any case, is much more interested in temperatures that are not zero. Then the system will not be in the ground state, but in some combination of system eigenfunctions of higher energy. As a completely arbitrary example of such a system eigenfunction, take the following one, describing $I=36$ different particles:

$$
\psi_{q}^{\mathrm{S}}=\psi_{24}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{7}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right) \psi_{6}^{\mathrm{p}}\left(\vec{r}_{5}, S_{z 5}\right) \ldots \psi_{54}^{\mathrm{p}}\left(\vec{r}_{36}, S_{z 36}\right)
$$

This system eigenfunction has an energy that is the sum of the 36 single-particle eigenstate energies involved:

$$
E_{q}^{\mathrm{S}}=E_{24}^{\mathrm{p}}+E_{4}^{\mathrm{p}}+E_{7}^{\mathrm{p}}+E_{1}^{\mathrm{p}}+E_{6}^{\mathrm{p}}+\ldots+E_{54}^{\mathrm{p}}
$$

Figure 11.1: Graphical depiction of an arbitrary system energy eigenfunction for 36 distinguishable particles.

To understand the arguments in this chapter, it is essential to visualize the system energy eigenfunctions as in figure 11.1. In this figure the single-particle states are shown as boxes, and the particles that are in those particular singleparticle states are shown inside the boxes. In the example, particle 1 is inside the $\psi_{24}^{\mathrm{p}}$ box, particle 2 is inside the $\psi_{4}^{\mathrm{p}}$ one, etcetera. It is just the reverse from the mathematical expression above: the mathematical expression shows for each particle in turn what the single-particle eigenstate of that particle is. The figure shows for each type of single-particle eigenstate in turn what particles are in that eigenstate.

To simplify the analysis, in the figure single-particle eigenstates of about the same energy have been grouped together on "shelves." (As a consequence, a subscript to a single-particle energy $E^{\text {p }}$ may refer to either a single-particle eigenfunction number $n$ or to a shelf number $s$, depending on context.) The number of single-particle states on a shelf is intended to roughly simulate the density of states of the particles in a box as described in chapter 6.3. The larger the energy, the more single-particle states there are at that energy; it increases like the square root of the energy. This may not be true for other situations, such as when the particles are confined to a lower-dimensional space, compare chapter 6.12. Various formulae given here and in literature may need to be adjusted then.

Of course, in normal nonnano applications, the number of particles will be astronomically larger than 36 particles; the example is just a small illustration. Even a millimol of particles means on the order of $10^{20}$ particles. And unless the temperature is incredibly low, those particles will extend to many more single-particle states than the few shown in the figure.

Next, note that you are not going to have something like $10^{20}$ different types of particles. Instead they are more likely to all be helium atoms, or all electrons or so. If their wave functions overlap nontrivially, that makes a big difference because of the symmetrization requirements of the system wave function.

Consider first the case that the $I$ particles are all identical bosons, like plain helium atoms. In that case the wave function must be symmetric, unchanged, under the exchange of any two of the bosons, and the example wave function above is not. If, for example, particles 2 and 5 are exchanged, it turns the example wave function from

$$
\psi_{q}^{\mathrm{S}}=\psi_{24}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{7}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right) \psi_{6}^{\mathrm{p}}\left(\vec{r}_{5}, S_{z 5}\right) \ldots \psi_{54}^{\mathrm{p}}\left(\vec{r}_{36}, S_{z 36}\right)
$$

into

$$
\psi_{\underline{q}}^{\mathrm{S}}=\psi_{24}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{6}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{7}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{5}, S_{z 5}\right) \ldots \psi_{54}^{\mathrm{p}}\left(\vec{r}_{36}, S_{z 36}\right)
$$

and that is simply a different wave function, because the states are different, independent functions. In terms of the pictorial representation figure 11.1, swapping the numbers " 2 " and " 5 " in the particles changes the picture.

Figure 11.2: Graphical depiction of an arbitrary system energy eigenfunction for 36 identical bosons.

As chapter 5.7 explained, to eliminate the problem that exchanging particles 2 and 5 changes the wave function, the original and exchanged wave functions must be combined together. And to eliminate the problem for any two particles, all wave functions that can be obtained by merely swapping numbers must be combined together equally into a single wave function multiplied by a single undetermined coefficient. In terms of figure 11.1, we need to combine the wave functions with all possible permutations of the numbers inside the particles into
one. And if all permutations of the numbers are equally included, then those numbers no longer add any nontrivial additional information; they may as well be left out. That makes the pictorial representation of an example system wave function for identical bosons as shown in figure 11.2.

Figure 11.3: Graphical depiction of an arbitrary system energy eigenfunction for 33 identical fermions.

For identical fermions, the situation is similar, except that the different wave functions must be combined with equal or opposite sign, depending on whether it takes an odd or even number of particle swaps to turn one into the other. And such wave functions only exist if the $I$ single-particle wave functions involved are all different. That is the Pauli exclusion principle. The pictorial representation figure 11.2 for bosons is totally unacceptable for fermions since it uses many of the single-particle states for more than one particle. There can be at most one fermion in each type of single-particle state. An example of a wave function that is acceptable for a system of identical fermions is shown in figure 11.3.

Looking at the example pictorial representations for systems of bosons and fermions, it may not be surprising that such particles are often called "indistinguishable." Of course, in classical quantum mechanics, there is still an electron 1 , an electron 2, etcetera; they are mathematically distinguished. Still, it is convenient to use the term "distinguishable" for particles for which the symmetrization requirements can be ignored.

The prime example is the atoms of an ideal gas in a box; almost by definition, the interactions between such atoms are negligible. And that allows the quantum results to be referred back to the well-understood properties of ideal gases obtained in classical physics. Probably you would like to see all results follow naturally from quantum mechanics, not classical physics, and that would be very nice indeed. But it would be very hard to follow up on. As Baierlein [4,
p. 109] notes, real-life physics adopts whichever theoretical approach offers the easiest calculation or the most insight. This book's approach really is to formulate as much as possible in terms of the quantum-mechanical ideas discussed here. But do be aware that it is a much more messy world when you go out there.

### 11.3 How Many System Eigenfunctions?

The fundamental question from which all of quantum statistics springs is a very basic one: How many system energy eigenstates are there with given generic properties? This section will address that question.

Of course, by definition each system energy eigenfunction is unique. Figures 11.1-11.3 give examples of such unique energy eigenfunctions for systems of distinguishable particles, indistinguishable bosons, and indistinguishable fermions. But trying to get accurate data on each individual eigenfunction just does not work. That is much too big a challenge.

Quantum statistics must satisfy itself by figuring out the probabilities on groups of system eigenfunctions with similar properties. To do so, the singleparticle energy eigenstates are best grouped together on shelves of similar energy, as illustrated in figures 11.1-11.3. Doing so allows for more answerable questions such as: "How many system energy eigenfunctions $\psi_{q}^{\mathrm{S}}$ have $I_{1}$ out of the $I$ total particles on shelf 1, another $I_{2}$ on shelf 2, etcetera?" 'In other words, if $\vec{I}$ stands for a given set of shelf occupation numbers $\left(I_{1}, I_{2}, I_{3}, \ldots\right)$, then what is the number $Q_{\vec{I}}$ of system eigenfunctions $\psi_{q}^{\mathrm{S}}$ that have those shelf occupation numbers?

That question is answerable with some clever mathematics; it is a big thing in various textbooks. However, the suspicion is that this is more because of the "neat" mathematics than because of the actual physical insight that these derivations provide. In this book, the derivations are shoved away into $\{D .56\}$. But here are the results. (Drums please.) The system eigenfunction counts for distinguishable particles, bosons, and fermions are:

$$
\begin{align*}
Q_{\vec{I}}^{\mathrm{d}} & =I!\prod_{\text {all } s} \frac{N_{s}^{I_{s}}}{\left(I_{s}\right)!}  \tag{11.1}\\
Q_{\vec{I}}^{\mathrm{b}} & =\prod_{\text {all } s} \frac{\left(I_{s}+N_{s}-1\right)!}{\left(I_{s}\right)!\left(N_{s}-1\right)!}  \tag{11.2}\\
Q_{\vec{I}}^{\mathrm{f}} & =\prod_{\text {all } s} \frac{\left(N_{s}\right)!}{\left(I_{s}\right)!\left(N_{s}-I_{s}\right)!} \tag{11.3}
\end{align*}
$$

where $\Pi$ means the product of all the terms of the form shown to its right that can be obtained by substituting in every possible value of the shelf number $s$. That is just like $\Sigma$ would mean the sum of all these terms. For example, for distinguishable particles

$$
Q_{\vec{I}}^{\mathrm{d}}=I!\frac{N_{1}^{I_{1}}}{\left(I_{1}\right)!} \frac{N_{2}^{I_{2}}}{\left(I_{2}\right)!} \frac{N_{3}^{I_{3}}}{\left(I_{3}\right)!} \frac{N_{4}^{I_{4}}}{\left(I_{4}\right)!} \cdots
$$

where $N_{1}$ is the number of single-particle energy states on shelf 1 and $I_{1}$ the number of particles on that shelf, $N_{2}$ the number of single-particle energy states on shelf 2 and $I_{2}$ the number of particles on that shelf, etcetera. Also an exclamation mark indicates the factorial function, defined as

$$
n!=\prod_{\underline{n}=1}^{n} \underline{n}=1 \times 2 \times 3 \times \ldots \times n
$$

For example, $5!=1 \times 2 \times 3 \times 4 \times 5=120$. The eigenfunction counts may also involve 0 !, which is defined to be 1 , and $n$ ! for negative $n$, which is defined to be infinity. The latter is essential to ensure that the eigenfunction count is zero as it should be for fermion eigenfunctions that try to put more particles on a shelf than there are states on it.

This section is mainly concerned with explaining qualitatively why these system eigenfunction counts matter physically. And to do so, a very simple model system having only three shelves will suffice.

Figure 11.4: Illustrative small model system having 4 distinguishable particles. The particular eigenfunction shown is arbitrary.

The first example is illustrated in quantum-mechanical terms in figure 11.4. Like the other examples, it has only three shelves, and it has only $I=4$ distinguishable particles. Shelf 1 has $N_{1}=1$ single-particle state with energy $E_{1}^{\mathrm{p}}$ $=1$ (arbitrary units), shelf 2 has $N_{2}=3$ single-particle states with energy $E_{2}^{\mathrm{p}}$ $=2$, (note that $3 \approx 2 \sqrt{2}$ ), and shelf 3 has $N_{3}=4 \sqrt{4}=8$ single-particle states with energy $E_{3}^{\mathrm{p}}=4$. One major deficiency of this model is the small number of particles and states, but that will be fixed in the later examples. More seriously is that there are no shelves with energies above $E_{3}^{\mathrm{p}}=4$. To mitigate
that problem, for the time being the average energy per particle of the system eigenfunctions will be restricted to no more than 2.5 . This will leave shelf 3 largely empty, reducing the effects of the missing shelves of still higher energy.

Figure 11.5: The number of system energy eigenfunctions for a simple model system with only three energy shelves. Positions of the squares indicate the numbers of particles on shelves 2 and 3 ; darkness of the squares indicates the relative number of eigenfunctions with those shelf numbers. Left: system with 4 distinguishable particles, middle: 16, right: 64 .

Now the question is, how many energy eigenfunctions are there for a given set of shelf occupation numbers $\vec{I}=\left(I_{1}, I_{2}, I_{3}\right)$ ? The answer, as given by (11.1), is shown graphically in the left graph of figure 11.5. Darker squares indicate more eigenfunctions with those shelf occupation numbers. The oblique line in figure 11.5 is the line above which the average energy per particle exceeds the chosen limit of 2.5.

Some example observations about the figure may help to understand it. For example, there is only one system eigenfunction with all 4 particles on shelf 1 , i.e. with $I_{1}=4$ and $I_{2}=I_{3}=0$; it is

$$
\psi_{1}^{\mathrm{S}}=\psi_{1}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right)
$$

This is represented by the white square at the origin in the left graph of figure 11.5 .

As another example, the darkest square in the left graph of figure 11.5 represents system eigenfunctions that have shelf numbers $\vec{I}=(1,2,1)$, i.e. $I_{1}=1, I_{2}$ $=2, I_{3}=1$ : one particle on shelf 1 , two particles on shelf 2 , and one particle on shelf 3 . A completely arbitrary example of such a system energy eigenfunction,

$$
\psi_{3}^{\mathrm{p}}\left(\vec{r}_{1}, S_{z 1}\right) \psi_{1}^{\mathrm{p}}\left(\vec{r}_{2}, S_{z 2}\right) \psi_{4}^{\mathrm{p}}\left(\vec{r}_{3}, S_{z 3}\right) \psi_{8}^{\mathrm{p}}\left(\vec{r}_{4}, S_{z 4}\right),
$$

is the one depicted in figure 11.4. It has particle 1 in single-particle state $\psi_{3}^{\mathrm{p}}$, which is on shelf 2 , particle 2 in $\psi_{1}^{\mathrm{p}}$, which is on shelf 1 , particle 3 in $\psi_{4}^{\mathrm{p}}$ which is on shelf 2 , and particle 4 in $\psi_{8}^{\mathrm{p}}$, which is on shelf 3 . But there are a lot more system eigenfunctions with the same shelf occupation numbers; in fact, there are

$$
4 \times 3 \times 8 \times 3 \times 3=864
$$

such eigenfunctions, since there are 4 possible choices for the particle that goes on shelf 1 , times a remaining 3 possible choices for the particle that goes on shelf 3 , times 8 possible choices $\psi_{5}^{\mathrm{p}}$ through $\psi_{12}^{\mathrm{p}}$ for the single-particle eigenfunction on shelf 3 that that particle can go into, times 3 possible choices $\psi_{2}^{\mathrm{p}}$ through $\psi_{4}^{\mathrm{p}}$ that each of the remaining two particles on shelf 2 can go into.

Next, consider a system four times as big. That means that there are four times as many particles, so $I=16$ particles, in a box that has four times the volume. If the volume of the box becomes 4 times as large, there are four times as many single-particle states on each shelf, since the number of states per unit volume at a given single-particle energy is constant, compare (6.6). Shelf 1 now has 4 states, shelf 2 has 12 , and shelf 3 has 32 . The number of energy states for given shelf occupation numbers is shown as grey tones in the middle graph of figure 11.5. Now the number of system energy eigenfunctions that have all particles on shelf 1 is not one, but $4^{16}$ or 4294967296 , since there are 4 different states on shelf 1 that each of the 16 particles can go into. That is obviously quite lot of system eigenfunctions, but it is dwarfed by the darkest square, states with shelf occupation numbers $\vec{I}=(4,6,6)$. There are about $1.410^{24}$ system energy eigenfunctions with those shelf occupation numbers. So the $\vec{I}=(16,0,0)$ square at the origin stays lily-white despite having over 4 billion energy eigenfunctions.

If the system size is increased by another factor 4 , to 64 particles, the number of states with occupation numbers $\vec{I}=(64,0,0)$, all particles on shelf 1 , is $1.210^{77}$, a tremendous number, but totally humiliated by the $2.710^{138}$ eigenfunctions that have occupation numbers $\vec{I}=(14,27,23)$. Taking the ratio of these two numbers shows that there are $2.310^{61}$ energy eigenfunctions with shelf numbers $(14,27,23)$ for each eigenfunction with shelf numbers $(64,0,0)$. By the time the system reaches, say, $10^{20}$ particles, still less than a millimol, the number of system energy eigenstates for each set of occupation numbers is astronomical, but so are the differences between the shelf numbers that have the most and those that have less. The tick marks in figure 11.5 indicate that for large systems, the darkest square will have $40 \%$ of the particles on shelf 2 , $37 \%$ on shelf 3 , and the remaining $23 \%$ on shelf 1 .

These general trends do not just apply to this simple model system; they are typical:

The number of system energy eigenfunctions for a macroscopic system is astronomical, and so are the differences in numbers.

Another trend illustrated by figure 11.5 has to do with the effect of system energy. The system energy of an energy eigenfunction is given in terms of its shelf numbers by

$$
E^{\mathrm{S}}=I_{1} E_{1}^{\mathrm{p}}+I_{2} E_{2}^{\mathrm{p}}+I_{3} E_{3}^{\mathrm{p}}
$$

so all eigenfunctions with the same shelf numbers have the same system energy. In particular, the squares just below the oblique cut-off line in figure 11.5 have
the highest system energy. It is seen that these shelf numbers also have by far the most energy eigenfunctions:

The number of system energy eigenfunctions with a higher energy typically dwarfs the number of system eigenfunctions with a lower energy.

Figure 11.6: Number of energy eigenfunctions on the oblique energy line in the previous figure. (The curves are mathematically interpolated to allow a continuously varying fraction of particles on shelf 2.) Left: 4 particles, middle: 64, right: 1,024.

Next assume that the system has exactly the energy of the oblique cut-off line in figure 11.5, with zero uncertainty. The number of energy eigenstates $Q_{\vec{I}}$ on that oblique line is plotted in figure 11.6 as a function of the fraction of particles $I_{2} / I$ on shelf 2 . (To get a smooth continuous curve, the values have been mathematically interpolated in between the integer values of $I_{2}$. The continuous function that interpolates $n$ ! is called the gamma function; see the notations section under "!" for details.) The maximum number of energy eigenstates occurs at about $I_{2} / I=40 \%$, corresponding to $I_{3}=37 \%$ and $I_{1}$ $=23 \%$. This set of occupation numbers, $\left(I_{1}, I_{2}, I_{3}\right)=(0.23,0.40,0.37) I$, is called the "most probable set of occupation numbers." If you pick an eigenfunction at random, you have more chance of getting one with that set of occupation numbers than one with a different given set of occupation numbers.

To be sure, if the number of particles is large, the chances of picking any eigenfunction with an exact set of occupation numbers is small. But note how the "spike" in figure 11.6 becomes narrower with increasing number of particles. You may not pick an eigenfunction with exactly the most probable set of shelf numbers, but you are quite sure to pick one with shelf numbers very close to it. By the time the system size reaches, say, $10^{20}$ particles, the spike becomes for all practical purposes a mathematical line. Then essentially all eigenfunctions have very precisely $23 \%$ of their particles on shelf 1 at energy $E_{1}^{\mathrm{p}}, 40 \%$ on shelf 2 at energy $E_{2}^{\mathrm{p}}$, and $37 \%$ on shelf 3 at energy $E_{3}^{\mathrm{p}}$.

Since there is only an incredibly small fraction of eigenfunctions that do not have very accurately the most probable occupation numbers, it seems intuitively obvious that in thermal equilibrium, the physical system must have the same distribution of particle energies. Why would nature prefer one of those extremely
rare eigenfunctions that do not have these occupation numbers, rather than one of the vast majority that do? In fact, $\{\mathrm{N} .23\}$,

> It is a fundamental assumption of statistical mechanics that in thermal equilibrium, all system energy eigenfunctions with the same energy have the same probability.

So the most probable set of shelf numbers, as found from the count of eigenfunctions, gives the distribution of particle energies in thermal equilibrium.

This then is the final conclusion: the particle energy distribution of a macroscopic system of weakly interacting particles at a given energy can be obtained by merely counting the system energy eigenstates. It can be done without doing any physics. Whatever physics may want to do, it is just not enough to offset the vast numerical superiority of the eigenfunctions with very accurately the most probable shelf numbers.

### 11.4 Particle-Energy Distribution Functions

The objective in this section is to relate the Maxwell-Boltzmann, Bose-Einstein, and Fermi-Dirac particle energy distributions of chapter 6 to the conclusions obtained in the previous section. The three distributions give the number of particles that have given single-particle energies.

In terms of the picture developed in the previous sections, they describe how many particles are on each energy shelf relative to the number of single-particle states on the shelf. The distributions also assume that the number of shelves is taken large enough that their energy can be assumed to vary continuously.

According to the conclusion of the previous section, for a system with given energy it is sufficient to find the most probable set of energy shelf occupation numbers, the set that has the highest number of system energy eigenfunctions. That gives the number of particles on each energy shelf that is the most probable. As the previous section demonstrated by example, the fraction of eigenfunctions that have significantly different shelf occupation numbers than the most probable ones is so small for a macroscopic system that it can be ignored.

Therefore, the basic approach to find the three distribution functions is to first identify all sets of shelf occupation numbers $\vec{I}$ that have the given energy, and then among these pick out the set that has the most system eigenfunctions $Q_{\vec{I}}$. There are some technical issues with that, $\{\mathrm{N} .24\}$, but they can be worked out, as in derivation $\{D .57\}$.

The final result is, of course, the particle energy distributions from chapter 6 :

$$
\iota^{\mathrm{b}}=\frac{1}{e^{\left(E^{\mathrm{P}}-\mu\right) / k_{\mathrm{B}} T}-1} \quad \iota^{\mathrm{d}}=\frac{1}{e^{\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T}} \quad \iota^{\mathrm{f}}=\frac{1}{e^{\left(E^{\mathrm{P}}-\mu\right) / k_{\mathrm{B}} T}+1}
$$

Here $\iota$ indicates the number of particles per single-particle state, more precisely, $\iota=I_{s} / N_{s}$. This ratio is independent of the precise details of how the shelves are selected, as long as their energies are closely spaced. However, for identical bosons it does assume that the number of single-particle states on a shelf is large. If that assumption is problematic, the more accurate formulae in derivation $\{\mathrm{D} .57\}$ should be consulted. The main case for which there is a real problem is for the ground state in Bose-Einstein condensation.

It may be noted that " $T$ " in the above distribution laws is a temperature, but the derivation in the note did not establish it is the same temperature scale that you would get with an ideal-gas thermometer. That will be shown in section 11.14.4. For now note that $T$ will normally have to be positive. Otherwise the derived energy distributions would have the number of particles become infinity at infinite shelf energies. For some weird system for which there is an upper limit to the possible single-particle energies, this argument does not apply, and negative temperatures cannot be excluded. But for particles in a box, arbitrarily large energy levels do exist, see chapter 6.2, and the temperature must be positive.

The derivation also did not show that $\mu$ in the above distributions is the chemical potential as is defined in general thermodynamics. That will eventually be shown in derivation $\{$ D. 61$\}$. Note that for particles like photons that can be readily created or annihilated, there is no chemical potential; $\mu$ entered into the derivation $\{$ D. 57$\}$ through the constraint that the number of particles of the system is a given. A look at the note shows that the formulae still apply for such transient particles if you simply put $\mu=0$.

For permanent particles, increasingly large negative values of the chemical potential $\mu$ decrease the number of particles at all energies. Therefore large negative $\mu$ corresponds to systems of very low particle densities. If $\mu$ is sufficiently negative that $e^{\left(E^{\mathrm{P}}-\mu\right) / k_{\mathrm{B}} T}$ is large even for the single-particle ground state, the $\pm 1$ that characterize the Fermi-Dirac and Bose-Einstein distributions can be ignored compared to the exponential, and the three distributions become equal:

The symmetrization requirements for bosons and fermions can be ignored under conditions of very low particle densities.

These are ideal gas conditions, section 11.14.4
Decreasing the temperature will primarily thin out the particle numbers at high energies. In this sense, yes, temperature reductions are indeed to some extent associated with (kinetic) energy reductions.

### 11.5 The Canonical Probability Distribution

The particle energy distribution functions in the previous section were derived assuming that the energy is given. In quantum-mechanical terms, it was as-
sumed that the energy had a definite value. However, that cannot really be right, for one because of the energy-time uncertainty principle.

Assume for a second that a lot of boxes of particles are carefully prepared, all with a system energy as precise as it can be made. And that all these boxes are then stacked together into one big system. In the combined system of stacked boxes, the energy is presumably quite unambiguous, since the random errors are likely to cancel each other, rather than add up systematically. In fact, simplistic statistics would expect the relative error in the energy of the combined system to decrease like the square root of the number of boxes.

But for the carefully prepared individual boxes, the future of their lack of energy uncertainty is much bleaker. Surely a single box in the stack may randomly exchange a bit of energy with the other boxes. Of course, when a box acquires much more energy than the others, the exchange will no longer be random, but almost certainly go from the hotter box to the cooler ones. Still, it seems unavoidable that quite a lot of uncertainty in the energy of the individual boxes would result. The boxes still have a precise temperature, being in thermal equilibrium with the larger system, but no longer a precise energy.

Then the appropriate way to describe the individual boxes is no longer in terms of given energy, but in terms of probabilities. The proper expression for the probabilities is "deduced" in derivation $\{$ D. 58$\}$. It turns out that when the temperature $T$, but not the energy of a system is certain, the system energy eigenfunctions $\psi_{q}^{S}$ can be assigned probabilities of the form

$$
\begin{equation*}
P_{q}=\frac{1}{Z} e^{-E_{q}^{\mathrm{S}} / k_{\mathrm{B}} T} \tag{11.4}
\end{equation*}
$$

where $k_{\mathrm{B}}=1.3806510^{-23} \mathrm{~J} / \mathrm{K}$ is the Boltzmann constant. This equation for the probabilities is called the Gibbs "canonical probability distribution." Feynman [18, p. 1] calls it the summit of statistical mechanics.

The exponential by itself is called the "Boltzmann factor." The normalization factor $Z$, which makes sure that the probabilities all together sum to one, is called the "partition function." It equals

$$
\begin{equation*}
Z=\sum_{\text {all } q} e^{-E_{q}^{\mathrm{S}} / k_{\mathrm{B}} T} \tag{11.5}
\end{equation*}
$$

You might wonder why a mere normalization factor warrants its own name. It turns out that if an analytical expression for the partition function $Z(T, V, I)$ is available, various quantities of interest may be found from it by taking suitable partial derivatives. Examples will be given in subsequent sections.

The canonical probability distribution conforms to the fundamental assumption of quantum statistics that eigenfunctions of the same energy have the same probability. However, it adds that for system eigenfunctions with different energies, the higher energies are less likely. Massively less likely, to be sure, because
the system energy $E_{q}^{S}$ is a macroscopic energy, while the energy $k_{\mathrm{B}} T$ is a microscopic energy level, roughly the kinetic energy of a single atom in an ideal gas at that temperature. So the Boltzmann factor decays extremely rapidly with energy.

Figure 11.7: Probabilities of shelf-number sets for the simple 64 particle model system if there is uncertainty in energy. More probable shelf-number distributions are shown darker. Left: identical bosons, middle: distinguishable particles, right: identical fermions. The temperature is the same as in the previous two figures.

So, what happens to the simple model system from section 11.3 when the energy is no longer certain, and instead the probabilities are given by the canonical probability distribution? The answer is in the middle graphic of figure 11.7. Note that there is no longer a need to limit the displayed energies; the strong exponential decay of the Boltzmann factor takes care of killing off the high energy eigenfunctions. The rapid growth of the number of eigenfunctions does remain evident at lower energies where the Boltzmann factor has not yet reached enough strength.

There is still an oblique energy line in figure 11.7, but it is no longer limiting energy; it is merely the energy at the most probable shelf occupation numbers. Equivalently, it is the "expectation energy" of the system, defined following the ideas of chapter 4.4.1 as

$$
\langle E\rangle \equiv \sum_{\text {all } q} P_{q} E_{q}^{\mathrm{S}} \equiv E
$$

because for a macroscopic system size, the most probable and expectation values are the same. That is a direct result of the black blob collapsing towards a single point for increasing system size: in a macroscopic system, essentially all system eigenfunctions have the same macroscopic properties.

In thermodynamics, the expectation energy is called the "internal energy" and indicated by $E$ or $U$. This book will use $E$, dropping the angular brackets. The difference in notation from the single-particle/shelf/system energies is that the internal energy is plain $E$ with no subscripts or superscripts.

Figure 11.7 also shows the shelf occupation number probabilities if the example 64 particles are not distinguishable, but identical bosons or identical fermions. The most probable shelf numbers are not the same, since bosons and fermions have different numbers of eigenfunctions than distinguishable particles, but as the figure shows, the effects are not dramatic at the shown temperature, $k_{\mathrm{B}} T=1.85$ in the arbitrary energy units.

### 11.6 Low Temperature Behavior

The three-shelf simple model used to illustrate the basic ideas of quantum statistics qualitatively can also be used to illustrate the low temperature behavior that was discussed in chapter 6. To do so, however, the first shelf must be taken to contain just a single, nondegenerate ground state.

Figure 11.8: Probabilities of shelf-number sets for the simple 64 particle model system if shelf 1 is a nondegenerate ground state. Left: identical bosons, middle: distinguishable particles, right: identical fermions. The temperature is the same as in the previous figures.

In that case, figure 11.7 of the previous section turns into figure 11.8. Neither of the three systems sees much reason to put any measurable amount of particles in the first shelf. Why would they, it contains only one single-particle state out of 177 ? In particular, the most probable shelf numbers are right at the $45^{\circ}$ limiting line through the points $I_{2}=I, I_{3}=0$ and $I_{2}=0, I_{3}=I$ on which $I_{1}=0$. Actually, the mathematics of the system of bosons would like to put a negative number of bosons on the first shelf, and must be constrained to put zero on it.

If the temperature is lowered however, as in figure 11.9 things change, especially for the system of bosons. Now the mathematics of the most probable state wants to put a positive number of bosons on shelf 1, and a large fraction of them to boot, considering that it is only one state out of 177 . The most probable distribution drops way below the $45^{\circ}$ limiting line. The mathematics for distinguishable particles and fermions does not yet see any reason to panic, and still leaves shelf 1 largely empty.

Figure 11.9: Like the previous figure, but at a lower temperature.

Figure 11.10: Like the previous figures, but at a still lower temperature.

When the temperature is lowered still much lower, as shown in figure 11.10, almost all bosons drop into the ground state and the most probable state is right next to the origin $I_{2}=I_{3}=0$. In contrast, while the system of distinguishable particles does recognize that high-energy shelf 3 becomes quite unreachable with the available amount of thermal energy, it still has a quite significant fraction of the particles on shelf 2 . And the system of fermions will never drop to shelf 1, however low the temperature. Because of the Pauli exclusion principle, only one fermion out of the 64 can ever go on shelf one, and only $48,75 \%$. can go on shelf 2 . The remaining $23 \%$ will stay on the high-energy shelf however low the temperature goes.

If you still need convincing that temperature is a measure of hotness, and not of thermal kinetic energy, there it is. The three systems of figure 11.10 are all at the same temperature, but there are vast differences in their kinetic energy. In thermal contact at very low temperatures, the system of fermions runs off with almost all the energy, leaving a small morsel of energy for the system of distinguishable particles, and the system of bosons gets practically nothing.

It is really weird. Any distribution of shelf numbers that is valid for distinguishable particles is exactly as valid for bosons and vice/versa; it is just the number of eigenfunctions with those shelf numbers that is different. But when the two systems are brought into thermal contact at very low temperatures, the distinguishable particles get all the energy. It is just as possible from an energy
conservation and quantum mechanics point of view that all the energy goes to the bosons instead of to the distinguishable particles. But it becomes astronomically unlikely because there are so few eigenfunctions like that. (Do note that it is assumed here that the temperature is so low that almost all bosons have dropped in the ground state. As long as the temperatures do not become much smaller than the one of Bose-Einstein condensation, the energies of systems of bosons and distinguishable particles remain quite comparable, as in figure 11.9.)

### 11.7 The Basic Thermodynamic Variables

This section introduces the most important basic players in thermodynamics.
The primary thermodynamic property introduced so far is the temperature. Recall that temperature is a measure of the hotness of the substance, a measure of how eager it is to dump energy onto other systems. Temperature is called an "intensive variable;" it is the same for two systems that differ only in size.

The total number of particles $I$ or the total volume of their box $V$ are not intensive variables; they are "extensive variables," variables that increase in value proportional to the system size. Often, however, you are only interested in the properties of your substance, not the amount. In that case, intensive variables can be created by taking ratios of the extensive ones; in particular, $I / V$ is an intensive variable called the "particle density." It is the number of particles per unit volume. If you restrict your attention to only one half of your box with particles, the particle density is still the same, with half the particles in half the volume.

Note that under equilibrium conditions, it suffices to know the temperature and particle density to fully fix the state that a given system is in. More generally, the rule is that:

Two intensive variables must be known to fully determine the inten-
sive properties of a simple substance in thermal equilibrium.
(To be precise, in a two-phase equilibrium like a liquid-vapor mixture, pressure and temperature are related, and would not be sufficient to determine something like net specific volume. They do still suffice to determine the specific volumes of the liquid and vapor parts individually, in any case.) If the amount of substance is also desired, knowledge of at least one extensive variable is required, making three variables that must be known in total.

Since the number of particles will have very large values, for macroscopic work the particle density is often not very convenient, and somewhat differently defined, but completely equivalent variables are used. The most common are the (mass) "density" $\rho$, found by multiplying the particle density with the singleparticle mass $m, \rho \equiv m I / V$, or its reciprocal, the "specific volume" $v \equiv V / m I$.

The density is the system mass per unit system volume, and the specific volume is the system volume per unit system mass.

Alternatively, to keep the values for the number of particles in check, they may be expressed in "moles," multiples of Avogadro's number

$$
I_{\mathrm{A}} \approx 6.022110^{23}
$$

That produces the "molar density" $\bar{\rho} \equiv I / I_{\mathrm{A}} V$ and "molar specific volume" $\bar{v} \equiv$ $V I_{\mathrm{A}} / I$. In thermodynamic textbooks, the use of kilo mol (kmol) instead of mol has become quite standard (but then, so has the use of kilo Newton instead of Newton.) The conversion factor between molar and nonmolar specific quantities is called the "molar mass" $M$; it is applied according to its units of $\mathrm{kg} / \mathrm{kmol}$. Note that thermo books for engineers may misname $M$ to be the "molecular mass". The numerical value of the molar mass is roughly the total number of protons and neutrons in the nuclei of a single molecule; in fact, the weird number of particles given by Avogadro's number was chosen to achieve this.

So what else is there? Well, there is the energy of the system. In view of the uncertainty in energy, the appropriate system energy is defined as the expectation value,

$$
\begin{equation*}
E=\sum_{\text {all } q} P_{q} E_{q}^{\mathrm{S}} \tag{11.6}
\end{equation*}
$$

where $P_{q}$ is the canonical probability of (11.4), (11.5). Quantity $E$ is called the "internal energy." In engineering thermodynamics books, it is usually indicated by $U$, but this is physics. The intensive equivalent $e$ is found by dividing by the system mass; $e=E / m I$. Note the convention of indicating extensive variables by a capital and their intensive value per unit mass with the corresponding lower case letter. A specific quantity on a molar basis is lower case with a bar above it.

As a demonstration of the importance of the partition function mentioned in the previous section, if the partition function (11.5) is differentiated with respect to temperature, you get

$$
\left(\frac{\partial Z}{\partial T}\right)_{V \text { constant }}=\frac{1}{k_{\mathrm{B}} T^{2}} \sum_{\text {all } q} E_{q}^{\mathrm{S}} e^{-E_{q}^{\mathrm{S}} / k_{\mathrm{B}} T}
$$

(The volume of the system should be held constant in order that the energy eigenfunctions do not change.) Dividing both sides by $Z$ turns the derivative in the left hand side into that of the logarithm of $Z$, and the sum in the right hand side into the internal energy $E$, and you get

$$
\begin{equation*}
E=k_{\mathrm{B}} T^{2}\left(\frac{\partial \ln Z}{\partial T}\right)_{V \text { constant }} \tag{11.7}
\end{equation*}
$$

Next there is the "pressure" $P$, being the force with which the substance pushes on the surfaces of the box it is in per unit surface area. To identify $P$ quantum mechanically, first consider a system in a single energy eigenfunction $E_{q}^{S}$ for certain. If the volume of the box is slightly changed, there will be a corresponding slight change in the energy eigenfunction $E_{q}^{S}$, (the boundary conditions of the Hamiltonian eigenvalue problem will change), and in particular its energy will slightly change. Energy conservation requires that the change in energy $\mathrm{d} E_{q}^{S}$ is offset by the work done by the containing walls on the substance. Now the work done by the wall pressure on the substance equals

$$
-P \mathrm{~d} V
$$

(The force is pressure times area and is normal to the area; the work is force times displacement in the direction of the force; combining the two, area times displacement normal to that area gives change in volume. The minus sign is because the displacement must be inwards for the pressure force on the substance to do positive work.) So for the system in a single eigenstate, the pressure equals $P=-\mathrm{d} E_{q}^{\mathrm{S}} / \mathrm{d} V$. For a real system with uncertainty in energy, the pressure is defined as the expectation value:

$$
\begin{equation*}
P=-\sum_{\text {all } q} P_{q} \frac{\mathrm{~d} E_{q}^{\mathrm{S}}}{\mathrm{~d} V} \tag{11.8}
\end{equation*}
$$

It may be verified by simple substitution that this, too may be obtained from the partition function, now by differentiating with respect to volume keeping temperature constant:

$$
\begin{equation*}
P=k_{\mathrm{B}} T\left(\frac{\partial \ln Z}{\partial V}\right)_{T \text { constant }} \tag{11.9}
\end{equation*}
$$

While the final quantum mechanical definition of the pressure is quite sound, it should be pointed out that the original definition in terms of force was very artificial. And not just because force is a poor quantum variable. Even if a system in a single eigenfunction could be created, the walls of the system would have to be idealized to assume that the energy change equals the work $-P \mathrm{~d} V$. For example, if the walls of the box would consist of molecules that were hotter than the particles inside, the walls too would add energy to the system, and take it out of its single energy eigenstate to boot. And even macroscopically, for pressure times area to be the force requires that the system is in thermal equilibrium. It would not be true for a system evolving in a violent way.

Often a particular combination of the variables defined above is very convenient; the"enthalpy" $H$ is defined as

$$
\begin{equation*}
H=E+P V \tag{11.10}
\end{equation*}
$$

Enthalpy is not a fundamentally new variable, just a combination of existing ones.

Assuming that the system evolves while staying at least approximately in thermal equilibrium, the "first law of thermodynamics" can be stated macroscopically as follows:

$$
\begin{equation*}
\mathrm{d} E=\delta Q-P \mathrm{~d} V \tag{11.11}
\end{equation*}
$$

In words, the internal energy of the system changes by the amount $\delta Q$ of heat added plus the amount $-P \mathrm{~d} V$ of work done on the system. It is just energy conservation expressed in thermodynamic terms. (And it assumes that other forms of energy than internal energy and work done while expanding can be ignored.)

Note the use of a straight d for the changes in internal energy $E$ and volume $V$, but a $\delta$ for the heat energy added. It reflects that $\mathrm{d} E$ and $\mathrm{d} V$ are changes in properties of the system, but $\delta Q$ is not; $\delta Q$ is a small amount of energy exchanged between systems, not a property of any system. Also note that while popularly you might talk about the heat within a system, it is standard in thermodynamics to refer to the thermal energy within a system as internal energy, and reserve the term "heat" for exchanged thermal energy.

Just two more variables. The "specific heat at constant volume" $C_{v}$ is defined as the heat that must be added to the substance for each degree temperature change, per unit mass and keeping the volume constant. In terms of the first law on a unit mass basis,

$$
\mathrm{d} e=\delta q-P \mathrm{~d} v
$$

it means that $C_{v}$ is defined as $\delta q / \mathrm{d} T$ when $\mathrm{d} v=0$. So $C_{v}$ is the derivative of the specific internal energy $e$ with respect to temperature. To be specific, since specifying $e$ normally requires two intensive variables, $C_{v}$ is the partial derivative of $e$ keeping specific volume constant:

$$
\begin{equation*}
C_{v} \equiv\left(\frac{\partial e}{\partial T}\right)_{v} \tag{11.12}
\end{equation*}
$$

Note that in thermodynamics the quantity being held constant while taking the partial derivative is shown as a subscript to parentheses enclosing the derivative. You did not see that in calculus, but that is because in mathematics, they tend to choose a couple of independent variables and stick with them. In thermodynamics, two independent variables are needed, (assuming the amount of substance is a given), but the choice of which two changes all the time. Therefore, listing what is held constant in the derivatives is crucial.

The specific heat at constant pressure $C_{p}$ is defined similarly as $C_{v}$, except that pressure, instead of volume, is being held constant. According to the first law above, the heat added is now $d e+P \mathrm{~d} v$ and that is the change in enthalpy $h=e+P v$. There is the first practical application of the enthalpy already! It
follows that

$$
\begin{equation*}
C_{p} \equiv\left(\frac{\partial h}{\partial T}\right)_{P} \tag{11.13}
\end{equation*}
$$

### 11.8 Intro to the Second Law

Take a look around you. You are surrounded by air molecules. They are all over the place. Isn't that messy? Suppose there would be water all over the room wouldn't you do something about it? Wouldn't it be much neater to compress all those air atoms together and put them in a glass? (You may want to wear a space suit while doing this.)

The reality, of course, is that if you put all the air atoms in a glass, the high pressure would cause the air to explode out of the glass and it would scatter all over the room again. All your efforts would be for naught. It is like the clothes of a ten-year old. Nature likes messiness. In fact, if messiness is properly defined, and it will be in section 11.10, nature will always increase messiness as much as circumstances and the laws of physics allow. The properly defined messiness is called "entropy." It is not to be confused with enthalpy, which is a completely different concept altogether.

Entropy provides an unrelenting arrow of time. If you take a movie and run it backwards, it simply does not look right, since you notice messiness getting smaller, rather than larger. The movie of a glass of water slipping out of your hand and breaking on the floor becomes, if run backwards, a spill of water and pieces of glass combining together and jumping into your hand. It does not happen. Messiness always increases. Even if you mop up the water and glue the pieces of broken glass back together, it does not work. While you reduce the messiness of the glass of water, you need to perform effort, and it turns out that this always increases messiness elsewhere more than the messiness of the glass of water is reduced.

It has big consequences. Would it not be nice if your car could run without using gas? After all, there is lots of random kinetic energy in the air molecules surrounding your car. Why not scope up some of that kinetic energy out of the air and use it to run your car? It does not work because it would decrease messiness in the universe, that's why. It would turn messy random molecular motion into organized motion of the engine of your car, and nature refuses to do it. And there you have it, the second law of thermodynamics, or at least the version of it given by Kelvin and Planck:

You cannot just take random thermal energy out of a substance and turn it into useful work.

You expected a physical law to be a formula, instead of a verbal statement like that? Well, you are out of luck for now.

To be sure, if the air around your car is hotter than the ground below it, then it is possible with some ingenuity to set up a flow of heat from the air to the ground, and you can then divert some of this flow of heat and turn it into useful work. But that is not an unlimited free supply of energy; it stops as soon as the temperatures of air and ground have become equal. The temperature difference is an expendable energy source, much like oil in the ground is; you are not simply scooping up random thermal energy out of a substance. If that sounds like a feeble excuse, consider the following: after the temperature difference is gone, the air molecules still have almost exactly the same thermal energy as before, and the ground molecules have more. But you cannot get any of it out anymore as usable energy. Zero. (Practically speaking, the amount of energy you would get out of the temperature difference is not going to get you to work in time anyway, but that is another matter.)

Would it not be nice if your fridge would run without electricity? It would really save on the electricity bill. But it cannot be done; that is the Clausius statement of the second law:

You cannot move heat the wrong way, from cold to hot, without doing work.
It is the same thing as the Kelvin-Planck statement, of course. If you could really have a fridge that ran for free, you could use it to create a temperature difference, and you could use that temperature difference to run your car. So your car would run for free. Conversely, if your car could run for free, you could use the cigarette lighter socket to run your fridge for free.

As patent offices all over the world can confirm, the second law has been solidly verified by countless masses of clever inventors all over the centuries doing everything possible to get around it. All have failed, however ingenious their tricks trying to fool nature. And don't forget about the most brilliant scientists of the last few centuries who have also tried wistfully and failed miserably, usually by trying to manipulate nature on the molecular level. The two verbal statements of the second law may not seem to have much mathematical precision, but they do. If you find a kink in either one's armor, however small, the fabric of current science and technology comes apart. Fabulous riches will be yours, and you will also be the most famous scientist of all time.

### 11.9 The Reversible Ideal

The statements of the previous section describing the second law are clearly common sense: yes, you still need to plug in your fridge, and no, you cannot skip the periodic stop at a gas station. What a surprise!

They seem to be fairly useless beyond that. For example, they say that it takes electricity to run our fridge, but they do not say it how much. It might be a megawatt, it might be a nanowatt.

Enter human ingenuity. With a some cleverness the two simple statements of the second law can be greatly leveraged, allowing an entire edifice to be constructed upon their basis.

A first insight is that if we are limited by nature's unrelenting arrow of time, then it should pay to study devices that almost ignore that arrow. If you make a movie of a device, and it looks almost exactly right when run backwards, the device is called (almost exactly) "reversible." An example is a mechanism that is carefully designed to move with almost no friction. If set into motion, the motion will slow down only a negligible amount during a short movie. When that movie is run backwards in time, at first glance it seems perfectly fine. If you look more carefully, you will see a slight problem: in the backward movie, the device is speeding up slightly, instead of slowing down due to friction as it should. But it is almost right: it would require only a very small amount of additional energy to speed up the actual device running backwards as it does in the reversed movie.

Dollar signs may come in front of your eyes upon reading that last sentence: it suggest that almost reversible devices may require very little energy to run. In context of the second law it suggests that it may be worthwhile to study refrigeration devices and engines that are almost reversible.

The second major insight is to look where there is light. Why not study, say, a refrigeration device that is simple enough that it can be analyzed in detail? At the very minimum it will give a standard against which other refrigeration devices can be compared. And so it will be done.

Low temperature side $T_{\mathrm{L}}$. (Fridge.)
Figure 11.11: Schematic of the Carnot refrigeration cycle.
The theoretically simple refrigeration device is called a "Carnot cycle" refrigeration device, or Carnot heat pump. A schematic is shown in figure 11.11. A substance, the refrigerant, is circulating through four devices, with the objective of transporting heat out of the fridge, dumping it into the kitchen. In the discussed device, the refrigerant will be taken to be some ideal gas with a
constant specific heat like maybe helium. You would not really want to use an ideal gas as refrigerant in a real refrigerator, but the objective here is not to make a practical refrigerator that you can sell for a profit. The purpose here is to create a device that can be analyzed precisely, and an ideal gas is described by simple mathematical formulae discussed in basic physics classes.

Consider the details of the device. The refrigerant enters the fridge at a temperature colder than the inside of the fridge. It then moves through a long piping system, allowing heat to flow out of the fridge into the colder refrigerant inside the pipes. This piping system is called a heat exchanger. The first reversibility problem arises: heat flow is most definitely irreversible. Heat flow seen backwards would be flow from colder to hotter, and that is wrong. The only thing that can be done to minimize this problem as much as possible is to minimize the temperature differences. The refrigerant can be sent in just slightly colder than the inside of the fridge. Of course, if the temperature difference is small, the surface through which the heat flows into the refrigerant will have to be very large to take any decent amount of heat away. One impractical aspect of Carnot cycles is that they are huge; that piping system cannot be small. Be that as it may, the theoretical bottom line is that the heat exchange in the fridge can be approximated as (almost) isothermal.

After leaving the inside of the refrigerator, the refrigerant is compressed to increase its temperature to slightly above that of the kitchen. This requires an amount $W_{C}$ of work to be done, indicating the need for electricity to run the fridge. To avoid irreversible heat conduction in the compression process, the compressor is thermally carefully insulated to eliminate any heat exchange with its surroundings. Also, the compressor is very carefully designed to be almost frictionless. It has expensive bearings that run with almost no friction. Additionally, the refrigerant itself has "viscosity;" it experiences internal friction if there are significant gradients in its velocity. That would make the work required to compress it greater than the ideal $-P \mathrm{~d} V$, and to minimize that effect, the velocity gradients can be minimized by using lots of refrigerant. This also has the effect of minimizing any internal heat conduction within the refrigerant that may arise. Viscosity is also an issue in the heat exchangers, because the pressure differences cause velocity increases. With lots of refrigerant, the pressure changes over the heat exchangers are also minimized.

Now the refrigerant is sent to a heat exchanger open to the kitchen air. Since it enters slightly hotter than the kitchen, heat will flow out of the refrigerant into the kitchen. Again, the temperature difference must be small for the process to be almost reversible. Finally, the refrigerant is allowed to expand, which reduces its temperature to below that inside the fridge. The expansion occurs within a carefully designed turbine, because the substance does an amount of work $W_{T}$ while expanding reversibly, and the turbine captures that work. It is used to run a high-quality generator and recover some of the electric power $W_{C}$ needed to run the compressor. Then the refrigerant reenters the fridge and the
cycle repeats.
If this Carnot refrigerator is analyzed theoretically, $\{\mathrm{D} .59\}$, a very simple result is found. The ratio of the heat $Q_{\mathrm{H}}$ dumped by the device into the kitchen to the heat $Q_{\mathrm{L}}$ removed from the refrigerator is exactly the same as the ratio of the temperature of the kitchen $T_{\mathrm{H}}$ to that of the fridge $T_{\mathrm{L}}$ :

$$
\begin{equation*}
\text { For an ideal cycle: } \frac{Q_{\mathrm{H}}}{Q_{\mathrm{L}}}=\frac{T_{\mathrm{H}}}{T_{\mathrm{L}}} \tag{11.14}
\end{equation*}
$$

That is a very useful result, because the net work $W=W_{C}-W_{T}$ that must go into the device is, by conservation of energy, the difference between $Q_{\mathrm{H}}$ and $Q_{\mathrm{L}}$. A "coefficient of performance" can be defined that is the ratio of the heat $Q_{\mathrm{L}}$ removed from the fridge to the required power input $W$ :

$$
\begin{equation*}
\text { For an ideal refrigeration cycle: } \beta \equiv \frac{Q_{\mathrm{L}}}{W}=\frac{T_{\mathrm{L}}}{T_{\mathrm{H}}-T_{\mathrm{L}}} \tag{11.15}
\end{equation*}
$$

Actually, some irreversibility is unavoidable in real life, and the true work required will be more. The formula above gives the required work if everything is truly ideal.

The same device can be used in winter to heat the inside of your house. Remember that heat was dumped into the kitchen. So, just cross out "kitchen" at the high temperature side in figure 11.11 and write in "house." And cross out "fridge" and write in "outside." The device removes heat from the outside and dumps it into your house. It is the exact same device, but it is used for a different purpose. That is the reason that it is no longer called a "refrigeration cycle" but a "heat pump." For an heat pump, the quantity of interest is the amount of heat dumped at the high temperature side, into your house. So an alternate coefficient of performance is now defined as

$$
\begin{equation*}
\text { For an ideal heat pump: } \beta^{\prime} \equiv \frac{Q_{\mathrm{H}}}{W}=\frac{T_{\mathrm{H}}}{T_{\mathrm{H}}-T_{\mathrm{L}}} \tag{11.16}
\end{equation*}
$$

The formula above is ideal. Real-life performance will be less, so the work required will be more.

It is interesting to note that if you take an amount $W$ of electricity and dump it into a simple resistance heater, it adds exactly an amount $W$ of heat to your house. If you dump that same amount of electricity into a Carnot heat pump that uses it to pump in heat from the outside, the amount of heat added to your house will be much larger than $W$. For example, if it is $300 \mathrm{~K}\left(27^{\circ} \mathrm{C}\right)$ inside and $275 \mathrm{~K}\left(2^{\circ} \mathrm{C}\right)$ outside, the amount of heat added is $300 / 25=12 \mathrm{~W}$, twelve times the amount you got from the resistance heater!

If you run the Carnot refrigeration cycle in reverse, as in figure 11.12, all arrows reverse and it turns into a "heat engine." The device now takes in

High temperature side $T_{\mathrm{H}}$. (Fuel combustion.)

Low temperature side $T_{\mathrm{L}}$. (Environment.)
Figure 11.12: Schematic of the Carnot heat engine.
heat at the high temperature side and outputs a net amount of work. The high temperature side is the place where you are burning the fuel. The low temperature may be cooling water from the local river. The Kelvin-Planck statement says that the device will not run unless some of the heat from the combustion is dumped to a lower temperature. In a car engine, the exhaust and radiator are the ones that take much of the heat away. Since the device is almost reversible, the numbers for transferred heats and net work do not change much from the nonreversed version. But the purpose is now to create work, so the "thermal efficiency" of a heat engine is defined as

$$
\begin{equation*}
\text { For an ideal heat engine: } \eta_{\mathrm{th}} \equiv \frac{W}{Q_{\mathrm{H}}}=\frac{T_{\mathrm{H}}-T_{\mathrm{L}}}{T_{\mathrm{H}}} \tag{11.17}
\end{equation*}
$$

Unfortunately, this is always less than one. And to get close to that, the engine must operate hot; the temperature at which the fuel is burned must be very hot.
(Note that slight corrections to the strictly reversed refrigeration process are needed; in particular, for the heat engine process to work, the substance must now be slightly colder than $T_{\mathrm{H}}$ at the high temperature side, and slightly hotter than $T_{\mathrm{L}}$ at the low temperature side. Heat cannot flow from colder to hotter. But since these are small changes, the mathematics is almost the same. In particular, the numerical values for $Q_{\mathrm{H}}$ and $Q_{\mathrm{L}}$ will be almost unchanged, though the heat now goes the opposite way.)

The final issue to be resolved is whether other devices could not be better than the Carnot ones. For example, could not a generic heat pump be more efficient than the reversible Carnot version in heating a house? Well, put them into different windows, and see. (The Carnot one will need the big window.) Assume that both devices are sized to produce the same heat flow into the house. On second thought, since the Carnot machine is reversible, run it in

High temperature side $T_{\mathrm{H}}$. (House.)

Low temperature side $T_{\mathrm{L}}$. (Outside.)
Figure 11.13: A generic heat pump next to a reversed Carnot one with the same heat delivery.
reverse; that can be done without changing its numbers for the heat fluxes and net work noticeably, and it will show up the differences between the devices.

The idea is shown in figure 11.13. Note that the net heat flow into the house is now zero, confirming that running the Carnot in reverse really shows the differences between the devices. Net heat is exchanged with the outside air and there is net work. Enter Kelvin-Planck. According to Kelvin-Planck, heat cannot simply be taken out of the outside air and converted into useful net work. The net work being taken out of the air will have to be negative. So the work required for the generic heat pump will need to be greater than that recovered by the reversed Carnot one, the excess ending up as heat in the outside air. So, the generic heat pump requires more work than a Carnot one running normally. No device can therefore be more efficient than the Carnot one. The best case is that the generic device, too, is reversible. In that case, neither device can win, because the generic device can be made to run in reverse instead of the Carnot one. That is the case where both devices are so perfectly constructed that whatever work goes into the generic device is almost $100 \%$ recovered by the reversed Carnot machine, with negligible amounts of work being turned into heat by friction or other irreversibility and ending up in the outside air.

The conclusion is that:
All reversible devices exchanging heat at a given high temperature $T_{\mathrm{H}}$ and low temperature $T_{\mathrm{L}}$, (and nowhere else,) have the same efficiency. Irreversible devices have less.

To see that it is true for refrigeration cycles too, just note that because of conservation of energy, $Q_{\mathrm{L}}=Q_{\mathrm{H}}-W$. It follows that, considered as a refrigeration cycle, not only does the generic heat pump above require more work, it also
removes less heat from the cold side. To see that it applies to heat engines too, just place a generic heat engine next to a reversed Carnot one producing the same power. The net work is then zero, and the heat flow $Q_{\mathrm{H}}$ of the generic device better be greater than that of the Carnot cycle, because otherwise net heat would flow from cold to hot, violating the Clausius statement. The heat flow $Q_{\mathrm{H}}$ is a measure of the amount of fuel burned, so the irreversible generic device uses more fuel.

Practical devices may exchange heat at more than two temperatures, and can be compared to a set of Carnot cycles doing the same. It is then seen that it is bad news; for maximum theoretical efficiency of a heat engine, you prefer to exchange heat at the highest available temperature and the lowest available temperature, and for heat pumps and refrigerators, at the lowest available high temperature and the highest available low temperature. But real-life and theory are of course not the same.

Since the efficiency of the Carnot cycle has a unique relation to the temperature ratio between the hot and cold sides, it is possible to define the temperature scale using the Carnot cycle. The only thing it takes is to select a single reference temperature to compare with, like water at its triple point. This was in fact proposed by Kelvin as a conceptual definition, to be contrasted with earlier definitions based on thermometers containing mercury or a similar fluid whose volume expansion is read-off. While a substance like mercury expands in volume very much linearly with the (Kelvin) temperature, it does not expand exactly linearly with it. So slight variations in temperature would occur based on which substance is arbitrarily selected for the reference thermometer. On the other hand, the second law requires that all substances used in the Carnot cycle will give the same Carnot temperature, with no deviation allowed. It may be noted that the definition of temperature used in this chapter is completely consistent with the Kelvin one, because "all" substances includes ideal gasses.

### 11.10 Entropy

With the cleverest inventors and the greatest scientists relentlessly trying to fool nature and circumvent the second law, how come nature never once gets confused, not even by the most complicated, convoluted, unusual, ingenious schemes? Nature does not outwit them by out-thinking them, but by maintaining an accounting system that cannot be fooled. Unlike human accounting systems, this accounting system does not assign a monetary value to each physical system, but a measure of messiness called "entropy." Then, in any transaction within or between systems, nature simply makes sure that this entropy is not being reduced; whatever entropy one system gives up must always be less than what the other system receives.

So what can this numerical grade of messiness called entropy be? Surely, it
must be related somehow to the second law as stated by Clausius and Kelvin and Planck, and to the resulting Carnot engines that cannot be beat. Note that the Carnot engines relate heat added to temperature. In particular an infinitesimally small Carnot engine would take in an infinitesimal amount $\delta Q_{\mathrm{H}}$ of heat at a temperature $T_{\mathrm{H}}$ and give up an infinitesimal amount $\delta Q_{\mathrm{L}}$ at a temperature $T_{\mathrm{L}}$. This is done so that $\delta Q_{\mathrm{H}} / \delta Q_{\mathrm{L}}=T_{\mathrm{H}} / T_{\mathrm{L}}$, or separating the two ends of the device, $\delta Q_{\mathrm{H}} / T_{\mathrm{H}}=\delta Q_{\mathrm{L}} / T_{\mathrm{L}}$. The quantity $\delta Q / T$ is the same at both sides, except that one is going in and the other out. Might this, then, be the change in messiness? After all, for the ideal reversible machine no messiness can be created, otherwise in the reversed process, messiness would be reduced. Whatever increase in messiness one side receives, the other side must give up, and $\delta Q / T$ fits the bill for that.

If $\delta Q / T$ gives the infinitesimal change in messiness, excuse, entropy, then it should be possible to find the entropy of a system by integration. In particular, choosing some arbitrary state of the system as reference, the entropy of a system in thermal equilibrium can be found as:

$$
\begin{equation*}
S \equiv S_{\text {ref }}+\int_{\text {reference state }}^{\text {desired state }} \frac{\delta Q}{T} \quad \text { along any reversible path } \tag{11.18}
\end{equation*}
$$

Figure 11.14: Comparison of two different integration paths for finding the entropy of a desired state. The two different integration paths are in black and the yellow lines are reversible adiabatic process lines.

The entropy as defined above is a specific number for a system in thermal equilibrium, just like its pressure, temperature, particle density, and internal energy are specific numbers. You might think that you could get a different value for the entropy by following a different process path from the reference state to the desired state. But the second law prevents that. To see why, consider the pressure-volume diagram in figure 11.14. Two different reversible processes are shown leading from the reference state to a desired state. A bundle of reversible adiabatic process lines is also shown; those are graphical representations of processes in which there is no heat exchange between the system and its surroundings. The bundle of adiabatic lines chops the two process
paths into small pieces, of almost constant temperature, that pairwise have the same value of $\delta Q / T$. For, if a piece like AB would have a lower value for $\delta Q / T$ than the corresponding piece CD , then a heat engine running the cycle CDBAC would lose less of the heat $\delta Q_{\mathrm{H}}$ at the low temperature side than the Carnot ideal, hence have a higher efficiency than Carnot and that is not possible. Conversely, if AB would have a higher value for $\delta Q / T$ than CD , then a refrigeration device running the cycle ABDCA would remove more heat from the low side than Carnot, again not possible. So all the little segments pairwise have the same value for $\delta Q / T$, which means the complete integrals must also be the same. It follows that the entropy for a system in thermal equilibrium is uniquely defined.

So what happens if the reference and final states are still the same, but there is a slight glitch for a single segment AB , making the process over that one segment irreversible? In that case, the heat engine argument no longer applies, since it runs through the segment AB in reversed order, and irreversible processes cannot be reversed. The refrigeration cycle argument says that the amount of heat $\delta Q$ absorbed by the system will be less; more of the heat $\delta Q$ going out at the high temperature side CD will come from the work done, and less from the heat removed at the cold side. The final entropy is still the same, because it only depends on the final state, not on the path to get there. So during the slight glitch, the entropy of the system increased more than $\delta Q / T$. In general:

$$
\begin{equation*}
\mathrm{d} S \geqslant \frac{\delta Q}{T} \tag{11.19}
\end{equation*}
$$

where $=$ applies if the change is reversible and $>$ if it is not.
Note that the above formula is only valid if the system has an definite temperature, as in this particular example. Typically this is simply not true in irreversible processes; for example, the interior of the system might be hotter than the outside. The real importance of the above formula is to confirm that the defined entropy is indeed a measure of messiness and not of order; reversible processes merely shuffle entropy around from one system to the next, but irreversible processes increase the net entropy content in the universe.

So what about the entropy of a system that is not in thermal equilibrium? Equation (11.18) only applies for systems in thermal equilibrium. In order for nature not to become confused in its entropy accounting system, surely entropy must still have a numerical value for nonequilibrium systems. If the problem is merely temperature or pressure variations, where the system is still in approximate thermal equilibrium locally, you could just integrate the entropy per unit volume over the volume. But if the system is not in thermal equilibrium even on macroscopically small scales, it gets much more difficult. For example, air crossing a typical shock wave (sonic boom) experiences a significant increase in pressure over an extremely short distance. Better bring out the quantum
mechanics trick box. Or at least molecular dynamics
Still, some important general observations can be made without running to a computer. An "isolated" system is a system that does not interact with its surroundings in any way. Remember the example where the air inside a room was collected and neatly put inside a glass? That was an example of an isolated system. Presumably, the doors of the room were hermetically sealed. The walls of the room are stationary, so they do not perform work on the air in the room. And the air comes rushing back out of the glass so quickly that there is really no time for any heat conduction through the walls. If there is no heat conduction with the outside, then there is no entropy exchange with the outside. So the entropy of the air can only increase due to irreversible effects. And that is exactly what happens: the air exploding out of the glass is highly irreversible, (no, it has no plans to go back in), and its entropy increases rapidly. Quite quickly however, the air spreads again out over the entire room and settles down. Beyond that point, the entropy remains further constant.

An isolated system evolves to the state of maximum possible entropy and then stays there.

The state of maximum possible entropy is the thermodynamically stable state a system will assume if left alone.

A more general system is an "adiabatic" or "insulated" system. Work may be performed on such a system, but there is still no heat exchange with the surroundings. That means that the entropy of such a system can again only increase due to reversibility. A simple example is a thermos bottle with a cold drink inside. If you continue shaking this thermos bottle violently, the cold drink will heat up due to its viscosity, its internal friction, and it will not stay a cold drink for long. Its entropy will increase while you are shaking it.

The entropy of adiabatic systems can only increase.
But, of course, that of an open system may not. It is the recipe of life, $\{\mathrm{N} .25\}$.
You might wonder why this book on quantum mechanics included a concise, but still very lengthy classical description of the second law. It is because the evidence for the second law is so much more convincing based on the macroscopic evidence than on the microscopic one. Macroscopically, the most complex systems can be accurately observed, microscopically, the quantum mechanics of only the most simplistic systems can be rigorously solved. And whether we can observe the solution is still another matter.

However, given the macroscopic fact that there really is an accounting measure of messiness called entropy, the question becomes what is its actual microscopic nature? Surely, it must have a relatively simple explanation in terms of the basic microscopic physics? For one, nature never seems to get confused about what it is, and for another, you really would expect something that is
clearly so fundamental to nature to be relatively esthetic when expressed in terms of mathematics.

And that thought is all that is needed to guess the true microscopic nature of entropy. And guessing is good, because it gives a lot of insight why entropy is what it is. And to ensure that the final result is really correct, it can be cross checked against the macroscopic definition (11.18) and other known facts about entropy.

The first guess is about what physical microscopic quantity would be involved. Now microscopically, a simple system is described by energy eigenfunctions $\psi_{q}^{\mathrm{S}}$, and there is nothing messy about those. They are the systematic solutions of the Hamiltonian eigenvalue problem. But these eigenfunctions have probabilities $P_{q}$, being the square magnitudes of their coefficients, and they are a different story. A system of a given energy could in theory exist neatly as a single energy eigenfunction with that energy. But according to the fundamental assumption of quantum statistics, this simply does not happen. In thermal equilibrium, every single energy eigenfunction of the given energy achieves about the same probability. Instead of nature neatly leaving the system in the single eigenfunction it may have started out with, it gives every Johnny-come-lately state about the same probability, and it becomes a mess.

If the system is in a single eigenstate for sure, the probability $P_{q}$ of that one eigenstate is one, and all others are zero. But if the probabilities are equally spread out over a large number, call it $N$, of eigenfunctions, then each eigenfunction receives a probability $P_{q}=1 / N$. So your simplest thought would be that maybe entropy is the average value of the probability. In particular, just like the average energy is $\sum P_{q} E_{q}^{\mathrm{S}}$, the average probability would be $\sum P_{q}^{2}$. It is always the sum of the values for which you want the average times their probability. You second thought would be that since $\sum P_{q}^{2}$ is one for the single eigenfunction case, and $1 / N$ for the spread out case, maybe the entropy should be $-\sum P_{q}^{2}$ in order that the single eigenfunction case has the lower value of messiness. But macroscopically it is known that you can keep increasing entropy indefinitely by adding more and more heat, and the given expression starts at minus one and never gets above zero.

So try a slightly more general possibility, that the entropy is the average of some function of the probability, as in $S=\sum P_{q} f\left(P_{q}\right)$. The question is then, what function? Well, macroscopically it is also known that entropy is additive, the values of the entropies of two systems simply add up. It simplifies nature's task of maintaining a tight accounting system on messiness. For two systems with probabilities $P_{q}$ and $P_{r}$,

$$
S=\sum_{q} P_{q} f\left(P_{q}\right)+\sum_{r} P_{r} f\left(P_{r}\right)
$$

This can be rewritten as

$$
S=\sum_{q} \sum_{r} P_{q} P_{r} f\left(P_{q}\right)+\sum_{q} \sum_{r} P_{q} P_{r} f\left(P_{r}\right) .
$$

since probabilities by themselves must sum to one. On the other hand, if you combine two systems, the probabilities multiply, just like the probability of throwing a 3 with your red dice and a 4 with your black dice is $\frac{1}{6} \times \frac{1}{6}$. So the combined entropy should also be equal to

$$
S=\sum_{q} \sum_{r} P_{q} P_{r} f\left(P_{q} P_{r}\right)
$$

Comparing this with the previous equation, you see that $f\left(P_{q} P_{r}\right)$ must equal $f\left(P_{q}\right)+f\left(P_{r}\right)$. The function that does that is the logarithmic function. More precisely, you want minus the logarithmic function, since the logarithm of a small probability is a large negative number, and you need a large positive messiness if the probabilities are spread out over a large number of states. Also, you will need to throw in a factor to ensure that the units of the microscopically defined entropy are the same as the ones in the macroscopical definition. The appropriate factor turns out to be the Boltzmann constant $k_{\mathrm{B}}=1.3806510^{-23}$ $\mathrm{J} / \mathrm{K}$; note that this factor has absolutely no effect on the physical meaning of entropy; it is just a matter of agreeing on units.

The microscopic definition of entropy has been guessed:

$$
\begin{equation*}
S=-k_{\mathrm{B}} \sum P_{q} \ln \left(P_{q}\right) \tag{11.20}
\end{equation*}
$$

That wasn't too bad, was it?
At absolute zero temperature, the system is in the ground state. That means that probability $P_{q}$ of the ground state is 1 and all other probabilities are zero. Then the entropy is zero, because $\ln (1)=0$. The fact that the entropy is zero at absolute zero is known as the "third law of thermodynamics," \{A.35\}.

At temperatures above absolute zero, many eigenfunctions will have nonzero probabilities. That makes the entropy positive, because logarithms of numbers less than one are negative. (It should be noted that $P_{q} \ln P_{q}$ becomes zero when $P_{q}$ becomes zero; the blow up of $\ln P_{q}$ is no match for the reduction in magnitude of $P_{q}$. So highly improbable states will not contribute significantly to the entropy despite their relatively large values of the logarithm.)

To put the definition of entropy on a less abstract basis, assume that you schematize the system of interest into unimportant eigenfunctions that you give zero probability, and a remaining $N$ important eigenfunctions that all have the same average probability $1 / N$. Sure, it is crude, but it is just to get an idea. In this simple model, the entropy is $k_{\mathrm{B}} \ln (N)$, proportional to the logarithm of the number of quantum states that have an important probability. The more
states, the higher the entropy. This is what you will find in popular expositions, And it would actually be correct for systems with zero indeterminacy in energy, if they existed.

The next step is to check the expression. Derivations are given in $\{$ D. 60$\}$, but here are the results. For systems in thermal equilibrium, is the entropy the same as the one given by the classical integration (11.18)? Check. Does the entropy exist even for systems that are not in thermal equilibrium? Check, quantum mechanics still applies. For a system of given energy, is the entropy smallest when the system is in a single energy eigenfunction? Check, it is zero then. For a system of given energy, is the entropy the largest when all eigenfunctions of that energy have the same probability, as the fundamental assumption of quantum statistics suggests? Check. For a system with given expectation energy but uncertainty in energy, is the entropy highest when the probabilities are given by the canonical probability distribution? Check. For two systems in thermal contact, is the entropy greatest when their temperatures have become equal? Check.

Feynman $[18$, p. 8$]$ gives an argument to show that the entropy of an isolated system always increases with time. Taking the time derivative of (11.20),

$$
\frac{\mathrm{d} S}{\mathrm{~d} t}=-k_{\mathrm{B}} \sum_{q}\left[\ln \left(P_{q}\right)+1\right] \frac{\mathrm{d} P_{q}}{\mathrm{~d} t}=-k_{\mathrm{B}} \sum_{q} \sum_{r}\left[\ln \left(P_{q}\right)+1\right] R_{q r}\left[P_{r}-P_{q}\right]
$$

the final equality being from time-dependent perturbation theory, with $R_{q r}=$ $R_{r q}>0$ the transition rate from state $q$ to state $p$. In the double summation, a typical term with indices $q$ and $r$ combines with the term having the reversed indices as

$$
k_{\mathrm{B}}\left[\ln \left(P_{r}\right)+1-\ln \left(P_{q}\right)-1\right] R_{q r}\left[P_{r}-P_{q}\right]
$$

and that is always greater that zero because the terms in the square brackets have the same sign: if $P_{q}$ is greater/less than $P_{r}$ then so is $\ln \left(P_{q}\right)$ greater/less than $\ln \left(P_{r}\right)$. However, given the dependence of time-dependent perturbation theory on linearization and worse, the "measurement" wild card, chapter 7.6 you might consider this more a validation of time dependent perturbation theory than of the expression for entropy. Then there is the problem of ensuring that a perturbed and measured system is adiabatic.

In any case, it may be noted that the checks on the expression for entropy, as given above, cut both ways. If you accept the expression for entropy, the canonical probability distribution follows. They are consistent, and in the end, it is just a matter of which of the two postulates you are more willing to accept as true.

### 11.11 The Big Lie of Distinguishable Particles

If you try to find the entropy of the system of distinguishable particles that produces the Maxwell-Boltzmann distribution, you are in for an unpleasant surprise. It just cannot be done. The problem is that the number of eigenfunctions for $I$ distinguishable particles is typically roughly $I$ ! larger than for $I$ identical bosons or fermions. If the typical number of states becomes larger by a factor $I$ !, the logarithm of the number of states increases by $I \ln I$, (using the Stirling formula), which is no longer proportional to the size of the system $I$, but much larger than that. The specific entropy would blow up with system size.

What gives? Now the truth must be revealed. The entire notion of distinguishable particles is a blatant lie. You are simply not going to have $10^{23}$ distinguishable particles in a box. Assume they would be $10^{23}$ different molecules. It would a take a chemistry handbook of $10^{21}$ pages to list them, one line for each. Make your system size 1000 times as big, and the handbook gets 1000 times thicker still. That would be really messy! When identical bosons or fermions are far enough apart that their wave functions do no longer overlap, the symmetrization requirements are no longer important for most practical purposes. But if you start counting energy eigenfunctions, as entropy does, it is a different story. Then there is no escaping the fact that the particles really are, after all, indistinguishable forever.

### 11.12 The New Variables

The new kid on the block is the entropy $S$. For an adiabatic system the entropy is always increasing. That is highly useful information, if you want to know what thermodynamically stable final state an adiabatic system will settle down into. No need to try to figure out the complicated time evolution leading to the final state. Just find the state that has the highest possible entropy $S$, that will be the stable final state.

But a lot of systems of interest are not well described as being adiabatic. A typical alternative case might be a system in a rigid box in an environment that is big enough, and conducts heat well enough, that it can at all times be taken to be at the same temperature $T_{\text {surr }}$. Also assume that initially the system itself is in some state 1 at the ambient temperature $T_{\text {surr }}$, and that it ends up in a state 2 again at that temperature. In the evolution from 1 to 2 , however, the system temperature could be be different from the surroundings, or even undefined, no thermal equilibrium is assumed. The first law, energy conservation, says that the heat $Q_{12}$ added to the system from the surroundings equals the change in internal energy $E_{2}-E_{1}$ of the system. Also, the entropy change in the isothermal environment will be $-Q_{12} / T_{\text {surr }}$, so the system entropy
change $S_{2}-S_{1}$ must be at least $Q_{12} / T_{\text {surr }}$ in order for the net entropy in the universe not to decrease. From that it can be seen by simply writing it out that the "Helmholtz free energy"

$$
\begin{equation*}
F=E-T S \tag{11.21}
\end{equation*}
$$

is smaller for the final system 2 than for the starting one 1 . In particular, if the system ends up into a stable final state that can no longer change, it will be the state of smallest possible Helmholtz free energy. So, if you want to know what will be the final fate of a system in a rigid, heat conducting, box in an isothermal environment, just find the state of lowest possible Helmholtz energy. That will be the one.

A slightly different version occurs even more often in real applications. In these the system is not in a rigid box, but instead its surface is at all times exposed to ambient atmospheric pressure. Energy conservation now says that the heat added $Q_{12}$ equals the change in internal energy $E_{2}-E_{1}$ plus the work done expanding against the atmospheric pressure, which is $P_{\text {surr }}\left(V_{2}-\right.$ $V_{1}$ ). Assuming that both the initial state 1 and final state 2 are at ambient atmospheric pressure, as well as at ambient temperature as before, then it is seen that the quantity that decreases is the "Gibbs free energy"

$$
\begin{equation*}
G=H-T S \tag{11.22}
\end{equation*}
$$

in terms of the enthalpy $H$ defined as $H=E+P V$. As an example, phase equilibria are at the same pressure and temperature. In order for them to be stable, the phases need to have the same specific Gibbs energy. Otherwise all particles would end up in whatever phase has the lower Gibbs energy. Similarly, chemical equilibria are often posed at an ambient pressure and temperature.

There are a number of differential expressions that are very useful in doing thermodynamics. The primary one is obtained by combining the differential first law (11.11) with the differential second law (11.19) for reversible processes:

$$
\begin{equation*}
\mathrm{d} E=T \mathrm{~d} S-P \mathrm{~d} V \tag{11.23}
\end{equation*}
$$

This no longer involves the heat transferred from the surroundings, just state variables of the system itself. The equivalent one using the enthalpy $H$ instead of the internal energy $E$ is

$$
\begin{equation*}
\mathrm{d} H=T \mathrm{~d} S+V \mathrm{~d} P \tag{11.24}
\end{equation*}
$$

The differentials of the Helmholtz and Gibbs free energies are, after cleaning up with the two expressions immediately above:

$$
\begin{equation*}
\mathrm{d} F=-S \mathrm{~d} T-P \mathrm{~d} V \tag{11.25}
\end{equation*}
$$

and

$$
\begin{equation*}
\mathrm{d} G=-S \mathrm{~d} T+V \mathrm{~d} P \tag{11.26}
\end{equation*}
$$

Expression (11.25) shows that the work obtainable in an isothermal reversible process is given by the decrease in Helmholtz free energy. That is why Helmholtz called it "free energy" in the first place. The Gibbs free energy is applicable to steady flow devices such as compressors and turbines; the first law for these devices must be corrected for the "flow work" done by the pressure forces on the substance entering and leaving the device. The effect is to turn $P \mathrm{~d} V$ into $-V \mathrm{~d} P$ as the differential for the actual work obtainable from the device. (This assumes that the kinetic and/or potential energy that the substance picks up while going through the device is a not a factor.)

Maxwell noted that, according to the total differential of calculus, the coefficients of the differentials in the right hand sides of (11.23) through (11.26) must be the partial derivatives of the quantity in the left hand side:

$$
\left.\begin{array}{llll}
\left(\frac{\partial E}{\partial S}\right)_{V} & =T & \left(\frac{\partial E}{\partial V}\right)_{S}=-P & \left(\frac{\partial T}{\partial V}\right)_{S}
\end{array}=-\left(\frac{\partial P}{\partial S}\right)_{V}\right)
$$

The final equation in each line can be verified by substituting in the previous two and noting that the order of differentiation does not make a difference. Those are called the "Maxwell relations." They have a lot of practical uses. For example, either of the final equations in the last two lines allows the entropy to be found if the relationship between the "normal" variables $P, V$, and $T$ is known, assuming that at least one data point at every temperature is already available. Even more important from an applied point of view, the Maxwell relations allow whatever data you find about a substance in literature to be stretched thin. Approximate the derivatives above with difference quotients, and you can compute a host of information not initially in your table or graph.

There are two even more remarkable relations along these lines. They follow from dividing (11.23) and (11.24) by $T$ and rearranging so that $S$ becomes the
quantity differentiated. That produces

$$
\begin{array}{rlrl}
\left(\frac{\partial S}{\partial T}\right)_{V}=\frac{1}{T}\left(\frac{\partial E}{\partial T}\right)_{V} & \left(\frac{\partial S}{\partial V}\right)_{T}= & \frac{1}{T}\left(\frac{\partial E}{\partial V}\right)_{T} & +\frac{P}{T} \\
\left(\frac{\partial E}{\partial V}\right)_{T} & =T^{2}\left(\frac{\partial P / T}{\partial T}\right)_{V} \\
\left(\frac{\partial S}{\partial T}\right)_{P}=\frac{1}{T}\left(\frac{\partial H}{\partial T}\right)_{P} & \left(\frac{\partial S}{\partial P}\right)_{T}=\frac{1}{T}\left(\frac{\partial H}{\partial P}\right)_{T} & -\frac{V}{T} \\
\left(\frac{\partial H}{\partial P}\right)_{T} & =-T^{2}\left(\frac{\partial V / T}{\partial T}\right)_{P}^{P} \tag{11.32}
\end{array}
$$

What is so remarkable is the final equation in each case: they do not involve entropy in any way, just the "normal" variables $P, V, T, H$, and $E$. Merely because entropy exists, there must be relationships between these variables which seemingly have absolutely nothing to do with the second law.

As an example, consider an ideal gas, more precisely, any substance that satisfies the ideal gas law

$$
\begin{equation*}
P v=R T \quad \text { with } \quad R=\frac{k_{\mathrm{B}}}{m}=\frac{R_{\mathrm{u}}}{M} \quad R_{\mathrm{u}}=8.314472 \mathrm{~kJ} / \mathrm{kmol} \mathrm{~K} \tag{11.33}
\end{equation*}
$$

The constant $R$ is called the specific gas constant; it can be computed from the ratio of the Boltzmann constant $k_{\mathrm{B}}$ and the mass of a single molecule $m$. Alternatively, it can be computed from the "universal gas constant" $R_{\mathrm{u}}=I_{\mathrm{A}} k_{\mathrm{B}}$ and the molar mass $M=I_{\mathrm{A}} m$. For an ideal gas like that, the equations above show that the internal energy and enthalpy are functions of temperature only. And then so are the specific heats $C_{v}$ and $C_{p}$, because those are their temperature derivatives:

$$
\begin{equation*}
\text { For ideal gases: } e, h, C_{v}, C_{p}=e, h, C_{v}, C_{p}(T) \quad C_{P}=C_{v}+R \tag{11.34}
\end{equation*}
$$

(The final relation is because $C_{P}=\mathrm{d} h / \mathrm{d} T=\mathrm{d}(e+P v) / \mathrm{d} T$ with $\mathrm{d} e / \mathrm{d} T=C_{v}$ and $P v=R T$.) Ideal gas tables can therefore be tabulated by temperature only, there is no need to include a second independent variable. You might think that entropy should be tabulated against both varying temperature and varying pressure, because it does depend on both pressure and temperature. However, the Maxwell equation (11.30) may be used to find the entropy at any pressure as long as it is listed for just one pressure, say for one bar.

There is a sleeper among the Maxwell equations; the very first one, in (11.27). Turned on its head, it says that

$$
\begin{equation*}
\frac{1}{T}=\left(\frac{\partial S}{\partial E}\right)_{V \text { and other external parameters fixed }} \tag{11.35}
\end{equation*}
$$

This can be used as a definition of temperature. Note that in taking the derivative, the volume of the box, the number of particles, and other external parameters, like maybe an external magnetic field, must be held constant. To understand qualitatively why the above derivative defines a temperature, consider two systems $A$ and $B$ for which $A$ has the larger temperature according to the definition above. If these two systems are brought into thermal contact, then net messiness increases when energy flows from high temperature system $A$ to low temperature system $B$, because system $B$, with the higher value of the derivative, increases its entropy more than $A$ decreases its.

Of course, this new definition of temperature is completely consistent with the ideal gas one; it was derived from it. However, the new definition also works fine for negative temperatures. Assume a system $A$ has a negative temperature according to he definition above. Then its messiness (entropy) increases if it gives up heat. That is in stark contrast to normal substances at positive temperatures that increase in messiness if they take in heat. So assume that system $A$ is brought into thermal contact with a normal system $B$ at a positive temperature. Then $A$ will give off heat to $B$, and both systems increase their messiness, so everyone is happy. It follows that $A$ will give off heat however hot is the normal system it is brought into contact with. While the temperature of $A$ may be negative, it is hotter than any substance with a normal positive temperature!

And now the big question: what is that "chemical potential" you hear so much about? Nothing new, really. For a pure substance with a single constituent like this chapter is supposed to discuss, the chemical potential is just the specific Gibbs free energy on a molar basis, $\bar{\mu}=\bar{g}$. More generally, if there is more than one constituent the chemical potential $\bar{\mu}_{c}$ of each constituent $c$ is best defined as

$$
\begin{equation*}
\bar{\mu}_{c} \equiv\left(\frac{\partial G}{\partial \bar{\imath}_{c}}\right)_{P, T} \tag{11.36}
\end{equation*}
$$

(If there is only one constituent, then $G=\bar{q} \bar{g}$ and the derivative does indeed produce $\bar{g}$. Note that an intensive quantity like $\bar{g}$, when considered to be a function of $P, T$, and $\bar{\imath}$, only depends on the two intensive variables $P$ and $T$, not on the amount of particles $\bar{\imath}$ present.) If there is more than one constituent, and assuming that their Gibbs free energies simply add up, as in

$$
G=\bar{\imath}_{1} \bar{g}_{1}+\bar{\imath} \bar{g}_{2}+\ldots=\sum_{c} \bar{\imath}_{c} \bar{g}_{c},
$$

then the chemical potential $\bar{\mu}_{c}$ of each constituent is simply the molar specific Gibbs free energy $\bar{g}_{c}$ of that constituent,

The partial derivatives described by the chemical potentials are important for figuring out the stable equilibrium state a system will achieve in an isothermal, isobaric, environment, i.e. in an environment that is at constant temperature
and pressure. As noted earlier in this section, the Gibbs free energy must be as small as it can be in equilibrium at a given temperature and pressure. Now according to calculus, the full differential for a change in Gibbs free energy is

$$
\mathrm{d} G\left(P, T, \bar{\imath}_{1}, \bar{\imath}_{2}, \ldots\right)=\frac{\partial G}{\partial T} \mathrm{~d} T+\frac{\partial G}{\partial P} \mathrm{~d} P+\frac{\partial G}{\partial \bar{\imath}_{1}} \mathrm{~d} \bar{\imath}_{1}+\frac{\partial G}{\partial \bar{\imath}_{2}} \mathrm{~d} \bar{\imath}_{2}+\ldots
$$

The first two partial derivatives, which keep the number of particles fixed, were identified in the discussion of the Maxwell equations as $-S$ and $V$; also the partial derivatives with respect to the numbers of particles of the constituent have been defined as the chemical potentials $\bar{\mu}_{c}$. Therefore more shortly,

$$
\mathrm{d} G=-S \mathrm{~d} T+V \mathrm{~d} P+\bar{\mu}_{1} \mathrm{~d} \bar{\imath}_{1}+\bar{\mu}_{2} \mathrm{~d} \bar{\imath}_{2}+\ldots=-S \mathrm{~d} T+V \mathrm{~d} P+\sum_{c} \bar{\mu}_{c} \mathrm{~d} \bar{\imath}_{c}
$$

$\qquad$
This generalizes (11.26) to the case that the numbers of constituents change. At equilibrium at given temperature and pressure, the Gibbs energy must be minimal. It means that $\mathrm{d} G$ must be zero whenever $\mathrm{d} T=\mathrm{d} P=0$, regardless of any infinitesimal changes in the amounts of the constituents. That gives a condition on the fractions of the constituents present.

Note that there are typically constraints on the changes $\mathrm{d} \bar{\imath}_{c}$ in the amounts of the constituents. For example, in a liquid-vapor "phase equilibrium," any additional amount of particles $\mathrm{d} \bar{\imath}_{\mathrm{f}}$ that condenses to liquid must equal the amount $-\mathrm{d} \overline{\mathrm{v}}_{\mathrm{g}}$ of particles that disappears from the vapor phase. (The subscripts follow the unfortunate convention liquid=fluid $=\mathrm{f}$ and vapor=gas=g. Don't ask.) Putting this relation in (11.37) it can be seen that the liquid and vapor phase must have the same chemical potential, $\bar{\mu}_{\mathrm{f}}=\bar{\mu}_{\mathrm{g}}$. Otherwise the Gibbs free energy would get smaller when more particles enter whatever is the phase of lowest chemical potential and the system would collapse completely into that phase alone.

The equality of chemical potentials suffices to derive the famous ClausiusClapeyron equation relating pressure changes under two-phase, or "saturated," conditions to the corresponding temperature changes. For, the changes in chemical potentials must be equal too, $\mathrm{d} \mu_{\mathrm{f}}=\mathrm{d} \mu_{\mathrm{g}}$, and substituting in the differential (11.26) for the Gibbs free energy, taking it on a molar basis since $\bar{\mu}=\bar{g}$,

$$
-\bar{s}_{\mathrm{f}} \mathrm{~d} T+\bar{v}_{\mathrm{f}} \mathrm{~d} P=-\bar{s}_{\mathrm{g}} \mathrm{~d} T+\bar{v}_{\mathrm{g}} \mathrm{~d} P
$$

and rearranging gives the Clausius-Clapeyron equation:

$$
\frac{\mathrm{d} P}{\mathrm{~d} T}=\frac{s_{\mathrm{g}}-s_{\mathrm{f}}}{v_{\mathrm{g}}-v_{\mathrm{f}}}
$$

Note that since the right-hand side is a ratio, it does not make a difference whether you take the entropies and volumes on a molar basis or on a mass
basis. The mass basis is shown since that is how you will typically find the entropy and volume tabulated. Typical engineering thermodynamic textbooks will also tabulate $s_{\mathrm{fg}}=s_{\mathrm{g}}-s_{\mathrm{f}}$ and $v_{\mathrm{fg}}=v_{\mathrm{g}}-v_{\mathrm{f}}$, making the formula above very convenient.

In case your tables do not have the entropies of the liquid and vapor phases, they often still have the "latent heat of vaporization," also known as "enthalpy of vaporization" or similar, and in engineering thermodynamics books typically indicated by $h_{\mathrm{fg}}$. That is the difference between the enthalpy of the saturated liquid and vapor phases, $h_{\mathrm{fg}}=h_{\mathrm{g}}-h_{\mathrm{f}}$. If saturated liquid is turned into saturated vapor by adding heat under conditions of constant pressure and temperature, (11.24) shows that the change in enthalpy $h_{\mathrm{g}}-h_{\mathrm{f}}$ equals $T\left(s_{\mathrm{g}}-s_{\mathrm{f}}\right)$. So the Clausius-Clapeyron equation can be rewritten as

$$
\begin{equation*}
\frac{\mathrm{d} P}{\mathrm{~d} T}=\frac{h_{\mathrm{fg}}}{T\left(v_{\mathrm{g}}-v_{\mathrm{f}}\right)} \tag{11.38}
\end{equation*}
$$

Because $T \mathrm{~d} s$ is the heat added, the physical meaning of the latent heat of vaporization is the heat needed to turn saturated liquid into saturated vapor while keeping the temperature and pressure constant.

For chemical reactions, like maybe

$$
2 \mathrm{H}_{2}+\mathrm{O}_{2} \Longleftrightarrow 2 \mathrm{H}_{2} \mathrm{O}
$$

the changes in the amounts of the constituents are related as

$$
\mathrm{d} \bar{\imath}_{\mathrm{H}_{2}}=-2 \mathrm{~d} \bar{r} \quad \mathrm{~d} \bar{\imath}_{\mathrm{O}_{2}}=-1 \mathrm{~d} \bar{r} \quad \mathrm{~d} \bar{\imath}_{\mathrm{H}_{2} \mathrm{O}}=2 \mathrm{~d} \bar{r}
$$

where $\mathrm{d} \bar{r}$ is the additional number of times the forward reaction takes place from the starting state. The constants $-2,-1$, and 2 are called the "stoichiometric coefficients." They can be used when applying the condition that at equilibrium, the change in Gibbs energy due to an infinitesimal amount of further reactions $\mathrm{d} \bar{r}$ must be zero.

However, chemical reactions are often posed in a context of constant volume rather than constant pressure, for one because it simplifies the reaction kinematics. For constant volume, the Helmholtz free energy must be used instead of the Gibbs one. Does that mean that a second set of chemical potentials is needed to deal with those problems? Fortunately, the answer is no, the same chemical potentials will do for Helmholtz problems. To see why, note that by definition $F=G-P V$, so $\mathrm{d} F=\mathrm{d} G-P \mathrm{~d} V-V \mathrm{~d} P$, and substituting for $\mathrm{d} G$ from (11.37), that gives
$\mathrm{d} F=-S \mathrm{~d} T-P \mathrm{~d} V+\bar{\mu}_{1} \mathrm{~d} \bar{\imath}_{1}+\bar{\mu}_{2} \mathrm{~d} \bar{\imath}_{2}+\ldots=-S \mathrm{~d} T-P \mathrm{~d} V+\sum_{c} \bar{\mu}_{c} \mathrm{~d} \bar{\imath}_{c}$

Under isothermal and constant volume conditions, the first two terms in the right hand side will be zero and $F$ will be minimal when the differentials with respect to the amounts of particles add up to zero.

Does this mean that the chemical potentials are also specific Helmholtz free energies, just like they are specific Gibbs free energies? Of course the answer is no, and the reason is that the partial derivatives of $F$ represented by the chemical potentials keep extensive volume $V$, instead of intensive molar specific volume $\bar{v}$ constant. A single-constituent molar specific Helmholtz energy $\bar{f}$ can be considered to be a function $\bar{f}(T, \bar{v})$ of temperature and molar specific volume, two intensive variables, and then $F=\bar{\imath} \bar{f}(T, \bar{v})$, but $(\partial \bar{\imath} \bar{f}(T, V / \bar{\imath}) / \partial \bar{\imath})_{T V}$ does not simply produce $\bar{f}$, even if $(\partial \bar{\imath} \bar{g}(T, P) / \partial \bar{\imath})_{T P}$ produces $\bar{g}$.

### 11.13 Microscopic Meaning of the Variables

The new variables introduced in the previous section assume the temperature to be defined, hence there must be thermodynamic equilibrium in some meaningful sense. That is important for identifying their microscopic descriptions, since the canonical expression $P_{q}=e^{-E_{q}^{S} / k t} / Z$ can be used for the probabilities of the energy eigenfunctions.

Consider first the Helmholtz free energy:

$$
F=E-T S=\sum_{q} P_{q} E_{q}^{\mathrm{S}}+T k_{\mathrm{B}} \sum_{q} P_{q} \ln \left(e^{-E_{q}^{\mathrm{S}} / k_{\mathrm{B}} T} / Z\right)
$$

This can be simplified by taking apart the logarithm, and noting that the probabilities must sum to one, $\sum_{q} P_{q}=1$, to give

$$
\begin{equation*}
F=-k_{\mathrm{B}} T \ln Z \tag{11.40}
\end{equation*}
$$

That makes strike three for the partition function $Z$, since it already was able to produce the internal energy $E$, (11.7), and the pressure $P$, (11.9). Knowing $Z$ as a function of volume $V$, temperature $T$, and number of particles $I$ is all that is needed to figure out the other variables. Indeed, knowing $F$ is just as good as knowing the entropy $S$, since $F=E-T S$. It illustrates why the partition function is much more valuable than you might expect from a mere normalization factor of the probabilities.

For the Gibbs free energy, add $P V$ from (11.9):

$$
\begin{equation*}
G=-k_{\mathrm{B}} T\left[\ln Z-V\left(\frac{\partial \ln Z}{\partial V}\right)_{T}\right] \tag{11.41}
\end{equation*}
$$

Dividing by the number of moles gives the molar specific Gibbs energy $\bar{g}$, equal to the chemical potential $\bar{\mu}$.

How about showing that this chemical potential is the same one as in the Maxwell-Boltzmann, Fermi-Dirac, and Bose-Einstein distribution functions for weakly interacting particles? It is surprisingly difficult to show it; in fact, it cannot be done for distinguishable particles for which the entropy does not exist. It further appears that the best way to get the result for bosons and fermions is to elaborately re-derive the two distributions from scratch, each separately, using a new approach. Note that they were already derived twice earlier, once for given system energy, and once for the canonical probability distribution. So the dual derivations in $\{$ D. 61$\}$ make three. Please note that whatever this book tells you thrice is absolutely true.

### 11.14 Application to Particles in a Box

This section applies the ideas developed in the previous sections to weakly interacting particles in a box. This allows some of the details of the "shelves" in figures 11.1 through 11.3 to be filled in for a concrete case.

For particles in a macroscopic box, the single-particle energy levels $E^{\mathrm{p}}$ are so closely spaced that they can be taken to be continuously varying. The one exception is the ground state when Bose-Einstein condensation occurs; that will be ignored for now. In continuum approximation, the number of single-particle energy states in a macroscopically small energy range $\mathrm{d} E^{\mathrm{p}}$ is approximately, following (6.6),

$$
\begin{equation*}
\mathrm{d} N=V n_{s} \mathcal{D} \mathrm{~d} E^{\mathrm{p}}=V \frac{n_{s}}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \sqrt{E^{\mathrm{p}}} \mathrm{~d} E^{\mathrm{p}} \tag{11.42}
\end{equation*}
$$

Here $n_{s}=2 s+1$ is the number of spin states.
Now according to the derived distributions, the number of particles in a single energy state at energy $E^{\text {p }}$ is

$$
\iota=\frac{1}{e^{\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T} \pm 1}
$$

where the plus sign applies for fermions and the minus sign for bosons. The term can be ignored completely for distinguishable particles.

To get the total number of particles, just integrate the particles per state $\iota$ over all states:

$$
I=\int_{E^{\mathrm{p}}=0}^{\infty} \iota V n_{s} \mathcal{D} \mathrm{~d} E^{\mathrm{p}}=V \frac{n_{s}}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \int_{E^{\mathrm{p}}=0}^{\infty} \frac{\sqrt{E^{\mathrm{p}}}}{e^{\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T} \pm 1} \mathrm{~d} E^{\mathrm{p}}
$$

and to get the total energy, integrate the energy of each single-particle state times the number of particles in that state over all states:

$$
E=\int_{E^{\mathrm{p}}=0}^{\infty} E^{\mathrm{p}} \iota n_{s} V \mathcal{D} \mathrm{~d} E^{\mathrm{p}}=V \frac{n_{s}}{4 \pi^{2}}\left(\frac{2 m}{\hbar^{2}}\right)^{3 / 2} \int_{E^{\mathrm{p}}=0}^{\infty} \frac{E^{\mathrm{p}} \sqrt{E^{\mathrm{p}}}}{e^{\left(E^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T} \pm 1} \mathrm{~d} E^{\mathrm{p}}
$$

The expression for the number of particles can be nondimensionalized by rearranging and taking a root to give

$$
\begin{equation*}
\frac{\frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}}{k_{\mathrm{B}} T}=\left(\frac{n_{s}}{4 \pi^{2}} \int_{u=0}^{\infty} \frac{\sqrt{u} \mathrm{~d} u}{e^{u-u_{0}} \pm 1}\right)^{2 / 3} \quad u \equiv \frac{E^{\mathrm{p}}}{k_{\mathrm{B}} T} \quad u_{0} \equiv \frac{\mu}{k_{\mathrm{B}} T} \tag{11.43}
\end{equation*}
$$

Note that the left hand side is a nondimensional ratio of a typical quantum microscopic energy, based on the average particle spacing $\sqrt[3]{V / I}$, to the typical classical microscopic energy $k_{\mathrm{B}} T$. This ratio is a key nondimensional number governing weakly interacting particles in a box. To put the typical quantum energy into context, a single particle in its own volume of size $V / I$ would have a ground state energy $3 \pi^{2} \hbar^{2} / 2 m(V / I)^{2 / 3}$.

Some references, [4], define a "thermal de Broglie wavelength" $\lambda_{\text {th }}$ by writing the classical microscopic energy $k_{\mathrm{B}} T$ in a quantum-like way:

$$
k_{\mathrm{B}} T \equiv 4 \pi \frac{\hbar^{2}}{2 m} \frac{1}{\lambda_{\mathrm{th}}^{2}}
$$

In some simple cases, you can think of this as roughly the quantum wavelength corresponding to the momentum of the particles. It allows various results that depend on the nondimensional ratio of energies to be reformulated in terms of a nondimensional ratio of lengths, as in

$$
\frac{\frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}}{k_{\mathrm{B}} T}=\frac{1}{4 \pi}\left[\frac{\lambda_{\mathrm{th}}}{(V / I)^{1 / 3}}\right]^{2}
$$

Since the ratio of energies is fully equivalent, and has an unambiguous meaning, this book will refrain from making theory harder than needed by defining superfluous quantities. But in practice, thinking in terms of numerical values that are lengths is likely to be more intuitive than energies, and then the numerical value of the thermal wavelength would be the one to keep in mind.

Note that (11.43) provides a direct relationship between the ratio of typical quantum/classical energies on one side, and $u_{0}$, the ratio of atomic chemical potential $\mu$ to typical classical microscopic energy $k_{\mathrm{B}} T$ on the other side. While the two energy ratios are not the same, (11.43) makes them equivalent for systems of weakly interacting particles in boxes. Know one and you can in principle compute the other.

The expression for the system energy may be nondimensionalized in a similar way to get

$$
\begin{equation*}
\frac{E}{I k_{\mathrm{B}} T}=\int_{u=0}^{\infty} \frac{u \sqrt{u} \mathrm{~d} u}{e^{u-u_{0}} \pm 1} / \int_{u=0}^{\infty} \frac{\sqrt{u} \mathrm{~d} u}{e^{u-u_{0}} \pm 1} \quad u \equiv \frac{E^{\mathrm{p}}}{k_{\mathrm{B}} T} \quad u_{0} \equiv \frac{\mu}{k_{\mathrm{B}} T} \tag{11.4}
\end{equation*}
$$

The integral in the bottom arises when getting rid of the ratio of energies that forms using (11.43).

The quantity in the left hand side is the nondimensional ratio of the actual system energy over the system energy if every particle had the typical classical energy $k_{\mathrm{B}} T$. It too is a unique function of $u_{0}$, and as a consequence, also of the ratio of typical microscopic quantum and classical energies.

### 11.14.1 Bose-Einstein condensation

Bose-Einstein condensation is said to have occurred when in a macroscopic system the number of bosons in the ground state becomes a finite fraction of the number of particles $I$. It happens when the temperature is lowered sufficiently or the particle density is increased sufficiently or both.

According to derivation $\{$ D. 57$\}$, the number of particles in the ground state is given by

$$
\begin{equation*}
I_{1}=\frac{N_{1}-1}{e^{\left(E_{1}^{\mathrm{p}}-\mu\right) / k_{\mathrm{B}} T}-1} \tag{11.45}
\end{equation*}
$$

In order for this to become a finite fraction of the large number of particles $I$ of a macroscopic system, the denominator must become extremely small, hence the exponential must become extremely close to one, hence $\mu$ must come extremely close to the lowest energy level $E_{1}^{\mathrm{p}}$. To be precise, $E_{1}-\mu$ must be small of order $k_{\mathrm{B}} T / I$; smaller than the classical microscopic energy by the humongous factor I. In addition, for a macroscopic system of weakly interacting particles in a box, $E_{1}^{\mathrm{p}}$ is extremely close to zero, (it is smaller than the microscopic quantum energy defined above by a factor $I^{2 / 3}$.) So condensation occurs when $\mu \approx E_{1}^{\mathrm{p}} \approx$ 0 , the approximations being extremely close. If the ground state is unique, $N_{1}$ $=1$, Bose-Einstein condensation simply occurs when $\mu=E_{1}^{\mathrm{p}} \approx 0$.

You would therefore expect that you can simply put $u_{0}=\mu / k_{\mathrm{B}} T$ to zero in the integrals (11.43) and (11.44). However, if you do so (11.43) fails to describe the number of particles in the ground state; it only gives the number of particles $I-I_{1}$ not in the ground state:

$$
\begin{equation*}
\frac{\frac{\hbar^{2}}{2 m}\left(\frac{I-I_{1}}{V}\right)^{2 / 3}}{k_{\mathrm{B}} T}=\left(\frac{n_{s}}{4 \pi^{2}} \int_{u=0}^{\infty} \frac{\sqrt{u} \mathrm{~d} u}{e^{u}-1}\right)^{2 / 3} \quad \text { for } \mathrm{BEC} \tag{11.46}
\end{equation*}
$$

To see that the number of particles in the ground state is indeed not included in the integral, note that while the integrand does become infinite when $u \downarrow 0$, it becomes infinite proportionally to $1 / \sqrt{u}$, which integrates as proportional to $\sqrt{u}$, and $\sqrt{u_{1}}=\sqrt{E_{1}^{\mathrm{p}} / k_{\mathrm{B}} T}$ is vanishingly small, not finite. Arguments given in derivation $\{$ D. 57$\}$ do show that the only significant error occurs for the ground state; the above integral does correctly approximate the number of particles not in the ground state when condensation has occurred.

The value of the integral can be found in mathematical handbooks, [41, p. 201, with typo], as $\frac{1}{2}!\zeta\left(\frac{3}{2}\right)$ with $\zeta$ the so-called Riemann zeta function, due to, who else, Euler. Euler showed that it is equal to a product of terms ranging over all prime numbers, but you do not want to know that. All you want to know is that $\zeta\left(\frac{3}{2}\right) \approx 2.612$ and that $\frac{1}{2}!=\frac{1}{2} \sqrt{\pi}$.

The Bose-Einstein temperature $T_{B}$ is the temperature at which Bose-Einstein condensation starts. That means it is the temperature for which $I_{1}=0$ in the expression above, giving

$$
\begin{equation*}
\frac{\frac{\hbar^{2}}{2 m}\left(\frac{I-I_{1}}{V}\right)^{2 / 3}}{k_{\mathrm{B}} T}=\frac{\frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}}{k_{\mathrm{B}} T_{B}}=\left(\frac{n_{s}}{8 \pi^{3 / 2}} \zeta\left(\frac{3}{2}\right)\right)^{2 / 3} \quad T \leqslant T_{B} \tag{11.47}
\end{equation*}
$$

It implies that for a given system of bosons, at Bose-Einstein condensation there is a fixed numerical ratio between the microscopic quantum energy based on particle density and the classical microscopic energy $k_{\mathrm{B}} T_{B}$. That also illustrates the point made at the beginning of this subsection that both changes in temperature and changes in particle density can produce Bose-Einstein condensation.

The first equality in the equation above can be cleaned up to give the fraction of bosons in the ground state as:

$$
\begin{equation*}
\frac{I_{1}}{I}=1-\left(\frac{T}{T_{B}}\right)^{3 / 2} \quad T \leqslant T_{B} \tag{11.48}
\end{equation*}
$$

### 11.14.2 Fermions at low temperatures

Another application of the integrals (11.43) and (11.44) is to find the Fermi energy $E_{\mathrm{F}}^{\mathrm{p}}$ and internal energy $E$ of a system of weakly interacting fermions for vanishing temperature.

For low temperatures, the nondimensional energy ratio $u_{0}=\mu / k_{\mathrm{B}} T$ blows up, since $k_{\mathrm{B}} T$ becomes zero and the chemical potential $\mu$ does not; $\mu$ becomes the Fermi energy $E_{\mathrm{F}}^{\mathrm{p}}$, chapter 6.10. To deal with the blow up, the integrals can be rephrased in terms of $u / u_{0}=E^{\mathrm{p}} / \mu$, which does not blow up.

In particular, the ratio (11.43) involving the typical microscopic quantum energy can be rewritten by taking a factor $u_{0}^{3 / 2}$ out of the integral and root and to the other side to give:

$$
\frac{\frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}}{\mu}=\left(\frac{n_{s}}{4 \pi^{2}} \int_{u / u_{0}=0}^{\infty} \frac{\sqrt{u / u_{0}} \mathrm{~d}\left(u / u_{0}\right)}{e^{u_{0}\left[\left(u / u_{0}\right)-1\right]}+1}\right)^{2 / 3}
$$

Now since $u_{0}$ is large, the exponential in the denominator becomes extremely large for $u / u_{0}>1$, making the integrand negligibly small. Therefore the upper limit of integration can be limited to $u / u_{0}=1$. In that range, the exponential
is vanishingly small, except for a negligibly small range around $u / u_{0}=1$, so it can be ignored. That gives

$$
\frac{\frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}}{\mu}=\left(\frac{n_{s}}{4 \pi^{2}} \int_{u / u_{0}=0}^{1} \sqrt{u / u_{0}} \mathrm{~d}\left(u / u_{0}\right)\right)^{2 / 3}=\left(\frac{n_{s}}{6 \pi^{2}}\right)^{2 / 3}
$$

It follows that the Fermi energy is

$$
E_{\mathrm{F}}^{\mathrm{p}}=\left.\mu\right|_{T=0}=\left(\frac{6 \pi^{2}}{n_{s}}\right)^{2 / 3} \frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}
$$

Physicist like to define a "Fermi temperature" as the temperature where the classical microscopic energy $k_{\mathrm{B}} T$ becomes equal to the Fermi energy. It is

$$
\begin{equation*}
T_{\mathrm{F}}=\frac{1}{k_{\mathrm{B}}}\left(\frac{6 \pi^{2}}{n_{s}}\right)^{2 / 3} \frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3} \tag{11.49}
\end{equation*}
$$

It may be noted that except for the numerical factor, the expression for the Fermi temperature $T_{\mathrm{F}}$ is the same as that for the Bose-Einstein condensation temperature $T_{B}$ given in the previous subsection.

Electrons have $n_{s}=2$. For the valence electrons in typical metals, the Fermi temperatures are in the order of ten thousands of degrees Kelvin. The metal will melt before it is reached. The valence electrons are pretty much the same at room temperature as they are at absolute zero.

The integral (11.44) can be integrated in the same way and then shows that $E=\frac{3}{5} I \mu=\frac{3}{5} I E_{\mathrm{F}}^{\mathrm{p}}$. In short, at absolute zero, the average energy per particle is $\frac{3}{5}$ times $E_{\mathrm{F}}^{\mathrm{p}}$, the maximum single-particle energy.

It should be admitted that both of the results in this subsection have been obtained more simply in chapter 6.10. However, the analysis in this subsection can be used to find the corrected expressions when the temperature is fairly small but not zero, $\{\mathrm{D} .62\}$, or for any temperature by brute-force numerical integration. One result is the specific heat at constant volume of the freeelectron gas for low temperatures:

$$
\begin{equation*}
C_{v}=\frac{\pi^{2}}{2} \frac{k_{\mathrm{B}} T}{E_{\mathrm{F}}^{\mathrm{p}}} \frac{k_{\mathrm{B}}}{m}(1+\ldots) \tag{11.50}
\end{equation*}
$$

where $k_{\mathrm{B}} / m$ is the gas constant $R$. All low-temperature expansions proceed in powers of $\left(k_{\mathrm{B}} T / E_{\mathrm{F}}^{\mathrm{p}}\right)^{2}$, so the dots in the expression for $C_{v}$ above are of that order. The specific heat vanishes at zero temperature and is typically small.

### 11.14.3 A generalized ideal gas law

While the previous subsections produced a lot of interesting information about weakly interacting particles near absolute zero, how about some info about
conditions that you can check in a T-shirt? And how about something mathematically simple, instead of elaborate integrals that produce weird functions?

Well, there is at least one. By definition, (11.8), the pressure is the expectation value of $-\mathrm{d} E_{q}^{S} / \mathrm{d} V$ where the $E_{q}^{S}$ are the system energy eigenvalues. For weakly interacting particles in a box, chapter 6.2 found that the single particle energies are inversely proportional to the squares of the linear dimensions of the box, which means proportional to $V^{-2 / 3}$. Then so are the system energy eigenfunctions, since they are sums of single-particle ones: $E_{q}^{S}=$ constant $V^{-2 / 3}$ Differentiating produces $\mathrm{d} E_{q}^{\mathrm{S}} / \mathrm{d} V=-\frac{2}{3} E_{q}^{\mathrm{S}} / V$ and taking the expectation value

$$
\begin{equation*}
P V=\frac{2}{3} E \tag{11.51}
\end{equation*}
$$

This expression is valid for weakly interacting bosons and fermions even if the symmetrization requirements cannot be ignored.

### 11.14.4 The ideal gas

The weakly interacting particles in a box can be approximated as an ideal gas if the number of particles is so small, or the box so large, that the average number of particles in an energy state is much less than one.

Since the number of particles per energy state is given by

$$
\iota=\frac{1}{e^{\left(E^{\mathrm{P}}-\mu\right) / k_{\mathrm{B}} T} \pm 1}
$$

ideal gas conditions imply that the exponential must be much greater than one, and then the $\pm 1$ can be ignored. That means that the difference between fermions and bosons, which accounts for the $\pm 1$, can be ignored for an ideal gas. Both can be approximated by the distribution derived for distinguishable particles.

The energy integral (11.44) can now easily be done; the $e^{u_{0}}$ factor divides away and an integration by parts in the numerator produces $E=\frac{3}{2} I k_{\mathrm{B}} T$. Plug it into the generalized ideal gas law (11.51) to get the normal "ideal gas law"

$$
\begin{equation*}
P V=I k_{\mathrm{B}} T \quad \Longleftrightarrow \quad P v=R T \quad R \equiv \frac{k_{\mathrm{B}}}{m} \tag{11.52}
\end{equation*}
$$

Also, following (11.34),

$$
e=\frac{3}{2} \frac{k_{\mathrm{B}}}{m} T=C_{v} T \quad h=\frac{5}{2} \frac{k_{\mathrm{B}}}{m} T=C_{p} T \quad C_{v}=\frac{3}{2} R \quad C_{p}=\frac{5}{2} R
$$

but note that these formulae are specific to the simplistic ideal gases described by the model, (like noble gases.) For ideal gases with more complex molecules,
like air, the specific heats are not constants, but vary with temperature, as discussed in section 11.15.

The ideal gas equation is identical to the one derived in classical physics. That is important since it establishes that what was defined to be the temperature in this chapter is in fact the ideal gas temperature that classical physics defines.

The integral (11.43) can be done using integration by parts and a result found in the notations under "!". It gives an expression for the single-particle chemical potential $\mu$ :

$$
-\frac{\mu}{k_{\mathrm{B}} T}=\frac{3}{2} \ln \left[k_{\mathrm{B}} T / 4 \pi n_{s}^{-2 / 3} \frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}\right]
$$

Note that the argument of the logarithm is essentially the ratio between the classical microscopic energy and the quantum microscopic energy based on average particle spacing. This ratio has to be big for an accurate ideal gas, to get the exponential in the particle energy distribution $\iota$ to be big.

Next is the specific entropy $s$. Recall that the chemical potential is just the Gibbs free energy. By the definition of the Gibbs free energy, the specific entropy $s$ equals $(h-g) / T$. Now the specific Gibbs energy is just the Gibbs energy per unit mass, in other words, $\mu / m$ while $h / T=C_{p}$ as above. So

$$
\begin{equation*}
s=C_{v} \ln \left[k_{\mathrm{B}} T / 4 \pi n_{s}^{-2 / 3} \frac{\hbar^{2}}{2 m}\left(\frac{I}{V}\right)^{2 / 3}\right]+C_{p} \tag{11.53}
\end{equation*}
$$

In terms of classical thermodynamics, $V / I$ is $m$ times the specific volume $v$. So classical thermodynamics takes the logarithm above apart as

$$
s=C_{v} \ln (T)+R \ln (v)+\text { some combined constant }
$$

and then promptly forgets about the constant, damn units.

### 11.14.5 Blackbody radiation

This section takes a closer look at blackbody radiation, discussed earlier in chapter 6.8. Blackbody radiation is the basic model for absorption and emission of electromagnetic radiation. Electromagnetic radiation includes light and a wide range of other radiation, like radio waves, microwaves, and X-rays. All surfaces absorb and emit radiation; otherwise we would not see anything. But "black" surfaces are the most easy to understand theoretically.

No, a black body need not look black. If its temperature is high enough, it could look like the sun. What defines an ideal black body is that it absorbs, (internalizes instead of reflects,) all radiation that hits it. But it may be emitting
its own radiation at the same time. And that makes a difference. If the black body is cool, you will need your infrared camera to see it; it would look really black to the eye. It is not reflecting any radiation, and it is not emitting any visible amount either. But if it is at the temperature of the sun, better take out your sunglasses. It is still absorbing all radiation that hits it, but it is emitting large amounts of its own too, and lots of it in the visible range.

So where do you get a nearly perfectly black surface? Matte black paint? A piece of blackboard? Soot? Actually, pretty much all materials will reflect in some range of wave lengths. You get the blackest surface by using no material at all. Take a big box and paint its interior the blackest you can. Close the box, then drill a very tiny hole in its side. From the outside, the area of the hole will be truly, absolutely black. Whatever radiation enters there is gone. Still, when you heat the box to very high temperatures, the hole will shine bright.

While any radiation entering the hole will most surely be absorbed somewhere inside, the inside of the box itself is filled with electromagnetic radiation, like a gas of photons, produced by the hot inside surface of the box. And some of those photons will manage to escape through the hole, making it shine.

The amount of photons in the box may be computed from the Bose-Einstein distribution with a few caveats. The first is that there is no limit on the number of photons; photons will be created or absorbed by the box surface to achieve thermal equilibrium at whatever level is most probable at the given temperature. This means the chemical potential $\mu$ of the photons is zero, as you can check from the derivations in notes $\{$ D. 57$\}$ and $\{$ D. 58$\}$.

The second caveat is that the usual density of states (6.6) is nonrelativistic. It does not apply to photons, which move at the speed of light. For photons you must use the density of modes (6.7).

The third caveat is that there are only two independent spin states for a photon. As a spin-one particle you would expect that photons would have the spin values 0 and $\pm 1$, but the zero value does not occur in the direction of propagation, addendum $\{$ A. 21.6$\}$. Therefore the number of independent states that exist is two, not three. A different way to understand this is classical: the electric field can only oscillate in the two independent directions normal to the direction of propagation, (13.10); oscillation in the direction of propagation itself is not allowed by Maxwell's laws because it would make the divergence of the electric field nonzero. The fact that there are only two independent states has already been accounted for in the density of modes (6.7).

The energy per unit box volume and unit frequency range found under the above caveats is Planck's blackbody spectrum already given in chapter 6.8:

$$
\begin{equation*}
\rho(\omega) \equiv \frac{\mathrm{d}(E / V)}{\mathrm{d} \omega}=\frac{\hbar}{\pi^{2} c^{3}} \frac{\omega^{3}}{e^{\hbar \omega / k_{\mathrm{B}} T}-1} \tag{11.54}
\end{equation*}
$$

The expression for the total internal energy per unit volume is called the "Stefan-Boltzmann formula." It is found by integration of Planck's spectrum
over all frequencies just like for the Stefan-Boltzmann law in chapter 6.8:

$$
\begin{equation*}
\frac{E}{V}=\frac{\pi^{2}}{15 \hbar^{3} c^{3}}\left(k_{\mathrm{B}} T\right)^{4} \tag{11.55}
\end{equation*}
$$

The number of particles may be found similar to the energy, by dropping the $\hbar \omega$ energy per particle from the integral. It is, [41, 36.24, with typo]:

$$
\begin{equation*}
\frac{I}{V}=\frac{2 \zeta(3)}{\pi^{2} \hbar^{3} c^{3}}\left(k_{\mathrm{B}} T\right)^{3} \quad \zeta(3) \approx 1.202 \tag{11.56}
\end{equation*}
$$

Taking the ratio with (11.55), the average energy per photon may be found:

$$
\begin{equation*}
\frac{E}{I}=\frac{\pi^{4}}{30 \zeta(3)} k_{\mathrm{B}} T \approx 2.7 k_{\mathrm{B}} T \tag{11.57}
\end{equation*}
$$

The temperature has to be roughly 9000 K for the average photon to become visible light. That is one reason a black body will look black at a room temperature of about 300 K . The solar surface has a temperature of about 6000 K , so the visible light photons it emits are more energetic than average, but there are still plenty of them.

The entropy $S$ of the photon gas follows from integrating $\int \mathrm{d} E / T$ using (11.55), starting from absolute zero and keeping the volume constant:

$$
\begin{equation*}
\frac{S}{V}=\frac{4 \pi^{2}}{45 \hbar^{3} c^{3}} k_{\mathrm{B}}\left(k_{\mathrm{B}} T\right)^{3} \tag{11.58}
\end{equation*}
$$

Dividing by (11.56) shows the average entropy per photon to be

$$
\begin{equation*}
\frac{S}{I}=\frac{2 \pi^{4}}{45 \zeta(3)} k_{\mathrm{B}} \tag{11.59}
\end{equation*}
$$

independent of temperature.
The generalized ideal gas law (11.51) does not apply to the pressure exerted by the photon gas, because the energy of the photons is $\hbar c k$ and that is proportional to the wave number instead of its square. The corrected expression is:

$$
\begin{equation*}
P V=\frac{1}{3} E \tag{11.60}
\end{equation*}
$$

### 11.14.6 The Debye model

To explain the heat capacity of simple solids, Debye modeled the energy in the crystal vibrations very much the same way as the photon gas of the previous subsection. This subsection briefly outlines the main ideas.

For electromagnetic waves propagating with the speed of light $c$, substitute acoustical waves propagating with the speed of sound $c_{\mathrm{s}}$. For photons with energy $\hbar \omega$, substitute phonons with energy $\hbar \omega$. Since unlike electromagnetic waves, sound waves can vibrate in the direction of wave propagation, for the number of spin states substitute $n_{s}=3$ instead of 2 ; in other words, just multiply the various expressions for photons by 1.5.

The critical difference for solids is that the number of modes, hence the frequencies, is not infinitely large. Since each individual atom has three degrees of freedom (it can move in three individual directions), there are 3I degrees of freedom, and reformulating the motion in terms of acoustic waves does not change the number of degrees of freedom. The shortest wave lengths will be comparable to the atom spacing, and no waves of shorter wave length will exist. As a result, there will be a highest frequency $\omega_{\max }$. The "Debye temperature" $T_{D}$ is defined as the temperature at which the typical classical microscopic energy $k_{\mathrm{B}} T$ becomes equal to the maximum quantum microscopic energy $\hbar \omega_{\max }$

$$
\begin{equation*}
k_{\mathrm{B}} T_{D}=\hbar \omega_{\max } \tag{11.61}
\end{equation*}
$$

The expression for the internal energy becomes, from (6.11) times 1.5:

$$
\begin{equation*}
\frac{E}{V}=\int_{0}^{\omega_{\max }} \frac{3 \hbar}{2 \pi^{2} c_{\mathrm{s}}^{3}} \frac{\omega^{3}}{e^{\hbar \omega / k_{\mathrm{B}} T}-1} \mathrm{~d} \omega \tag{11.62}
\end{equation*}
$$

If the temperatures are very low the exponential will make the integrand zero except for very small frequencies. Then the upper limit is essentially infinite compared to the range of integration. That makes the energy proportional to $T^{4}$ just like for the photon gas and the heat capacity is therefore proportional to $T^{3}$. At the other extreme, when the temperature is large, the exponential in the bottom can be expanded in a Taylor series and the energy becomes proportional to $T$, making the heat capacity constant.

The maximum frequency, hence the Debye temperature, can be found from the requirement that the number of modes is $3 I$, to be applied by integrating (6.7), or an empirical value can be used to improve the approximation for whatever temperature range is of interest. Literature values are often chosen to approximate the low temperature range accurately, since the model works best for low temperatures. If integration of (6.7) is used at high temperatures, the law of Dulong and Petit results, as described in section 11.15.

More sophisticated versions of the analysis exist to account for some of the very nontrivial differences between crystal vibrations and electromagnetic waves. They will need to be left to literature.

### 11.15 Specific Heats

The specific heat of a substance describes its absorption of heat in terms of its temperature change. In particular, the specific heat at constant volume, $C_{v}$, of a substance is the thermal energy that gets stored internally in the substance per unit temperature rise and per unit amount of substance.

As a first example, consider simple monatomic ideal gases, and in particular noble gases. Basic physics, or section 11.14.4, shows that for an ideal gas, the molecules have $\frac{1}{2} k_{\mathrm{B}} T$ of translational kinetic energy in each of the three directions of a Cartesian coordinate system, where $k_{\mathrm{B}}=1.38 \quad 10^{-23} \mathrm{~J} / \mathrm{K}$ is Boltzmann's constant. So the specific heat per molecule is $\frac{3}{2} k_{\mathrm{B}}$ or $1.5 k_{\mathrm{B}}$. For a kmol (i.e. $6.0210^{26}$ ) of molecules instead of one, $k_{\mathrm{B}}$ becomes the "universal gas constant" $R_{\mathrm{u}}=8.31 \mathrm{~kJ} / \mathrm{kmol}$ K. Hence for a

$$
\begin{equation*}
\text { monatomic ideal gas: } \bar{C}_{v}=1.5 R_{\mathrm{u}} \approx 12.5 \mathrm{~kJ} / \mathrm{kmol} \mathrm{~K} \tag{11.63}
\end{equation*}
$$

on a kmol basis. As figure 11.15 shows, this is very accurate for noble gases, including helium. (To get the more usual specific heat $C_{v}$ per kilogram instead of kmol, divide by the molar mass $M$. For example, for helium with two protons and two neutrons in its nucleus, the molar mass is about $4 \mathrm{~kg} / \mathrm{kmol}$, so divide by 4 . In thermo books, you will probably find the molar mass values you need mislisted as "molecular mass," without units. Just use the values and ignore the name and the missing units of $\mathrm{kg} / \mathrm{kmol}$. See the notations for more.)

Many important ideal gases, such as hydrogen, as well as the oxygen and nitrogen that make up air, are diatomic. Now if we assume that the two atoms are point-size masses somehow rigidly connected to each other, we still have that the center of the entire molecule can move in three different directions, accounting for $\frac{3}{2} k_{\mathrm{B}}$ of kinetic translational energy. But at any given time, the molecule can also be conducting rotational motion around its center in two independent directions, both orthogonal to the connecting line between the atoms. (For point masses, rotation around the connecting axis would not do anything.) Classical physics, in particular the "equipartition theorem," would then predict that each of the two rotational motions has $\frac{1}{2} k_{\mathrm{B}}$ of kinetic energy too, raising the total specific heat to $\frac{5}{2} k_{\mathrm{B}}$ or $2.5 k_{\mathrm{B}}$. Well, figure 11.15 shows that at room temperature, about 300 K , this is quite accurate for common diatomic gases like the nitrogen and oxygen in air.

But note that these experimental data show that there are problems, both at very low temperatures, and at very high ones. And there are major theoretical problems too. Surely the connection between the atoms is not going to be infinitely rigid. Allowing for that, we now have two individual atoms that can each move in three different directions independently of each other. That raises the kinetic energy to $\frac{6}{2} k_{\mathrm{B}}$. And assuming that the connecting force varies linearly with elongation, there would be another $\frac{1}{2} k_{\mathrm{B}}$ of potential energy, making the
total energy $\frac{7}{2} k_{\mathrm{B}}$. But figure 11.15 shows that the common diatomic gasses only approach values like that well above room temperature.

It was all a big problem for classical physics. Not to mention that, as Maxwell noted, if you really take classical theory at face value, things get far, far, worse still, since the individual internal parts of the atoms, like the individual electrons and quarks in the nuclei, would each have to absorb their own thermal energy too. This should produce enormously high specific heats.

Figure 11.15: Specific heat at constant volume of gases. Temperatures from absolute zero to $1,200 \mathrm{~K}$. Data from NIST-JANAF and AIP.

Hydrogen in particular was a mystery before the advent of quantum mechanics: at low temperatures it would behave as a monatomic gas, with a specific heat of $\frac{3}{2} k_{\mathrm{B}}$ per molecule, figure 11.15. That meant that the molecule had to be translating only, like a monatomic gas. How could the random thermal motion not cause any angular rotation of the two atoms around their mutual center of gravity, nor vibration of the atoms towards and away from each other?

Quantum mechanics solved this problem. In quantum mechanics the angular momentum of the molecule, and so the corresponding kinetic energy, as well as the harmonic oscillation energy, are quantized. For hydrogen at low temperatures, the typical available thermal energy $\frac{1}{2} k_{\mathrm{B}} T$ is not enough to reach even the first level above the ground state for either energy. No thermal energy can therefore be put into rotation of the molecule, nor into internal vibration. So hydrogen does indeed have the specific heat of monatomic gases at low temperatures, weird as it may seem. The rotational and vibrational motions are "frozen out."

At normal temperatures, there is enough thermal energy to reach the states where the molecule rotates normal to the line connecting the atoms, and the
specific heat becomes
typical diatomic ideal gas: $\bar{C}_{v}=2.5 R_{\mathrm{u}} \approx 20.8 \mathrm{~kJ} / \mathrm{kmol} \mathrm{K}$.
Actual values for hydrogen, nitrogen and oxygen at room temperature are 2.47, 2.50, and $2.53 R_{\mathrm{u}}$.

For high enough temperature, the vibrational modes will start becoming active, and the specific heats will start inching up towards $3.5 R_{\mathrm{u}}$ (and beyond), figure 11.15. But it takes to temperatures of 1000 K (hydrogen), 600 K (nitrogen), or 400 K (oxygen) before there is a $5 \%$ deviation from the $2.5 R_{\mathrm{u}}$ value.

These differences may be understood qualitatively if the motion is modeled as a simple harmonic oscillator as discussed in chapter 4.1. The energy levels of an harmonic oscillator are apart by an amount $\hbar \omega$, where $\omega$ is the angular frequency. And the frequency of a harmonic oscillator $\omega=\sqrt{c / m}$, where $c$ is the effective stiffness and $m$ the effective mass of the vibrational motion. So light atoms that are bound together tightly will require a lot of thermal energy to reach the first nontrivial vibrational state. Hydrogen is much lighter than nitrogen or oxygen, so the required energy $\hbar \omega$ should be quite large. This explains the high temperature before vibration become important for hydrogen. The molar masses of nitrogen and oxygen are similar, but nitrogen is bound with a triple bond, and oxygen only a double one. So nitrogen has the higher effective stiffness of the two and vibrates less readily.

Following this reasoning, you would expect fluorine, which is held together with only a single covalent bond, to have a higher specific heat still, and figure 11.15 confirms it. And chlorine and bromine, also held together by a single covalent bond, but heavier than fluorine, approach the classical value $3.5 R_{\mathrm{u}}$ fairly closely at normal temperatures: $\mathrm{Cl}_{2}$ has $3.08 R_{\mathrm{u}}$ and $\mathrm{Br}_{2} 3.34 R_{\mathrm{u}}$.

For solids, the basic classical idea in terms of atomic motion would be that there would be $\frac{3}{2} R_{\mathrm{u}}$ per atom in kinetic energy and $\frac{3}{2} R_{\mathrm{u}}$ in potential energy:

$$
\begin{equation*}
\text { law of Dulong and Petit: } \bar{C}_{v}=3 R_{\mathrm{u}} \approx 25 \mathrm{~kJ} / \mathrm{kmol} \mathrm{K.} \tag{11.65}
\end{equation*}
$$

Not only is 3 a nice round number, it actually works well for a lot of relatively simple solids at room temperature. For example, aluminum is $2.91 R_{\mathrm{u}}$, copper 2.94 , gold 3.05, iron 3.02.

Note that typically for solids $\bar{C}_{p}$, the heat added per unit temperature change at constant pressure is given instead of $\bar{C}_{v}$. However, unlike for gases, the difference between $\bar{C}_{p}$ and $\bar{C}_{v}$ is small for solids and most liquids and will be ignored here.

Dulong and Petit also works for liquid water if you take it per kmol of atoms, rather than kmol of molecules, but not for ice. Ice has $4.6 R_{\mathrm{u}}$ per kmol of molecules and $1.5 R_{\mathrm{u}}$ per kmol of atoms. For molecules, certainly there is an obvious problem in deciding how many pieces you need to count as independently moving units. A value of $900 R_{\mathrm{u}}$ for paraffin wax (per molecule) found at

Wikipedia may sound astonishing, until you find elsewhere at Wikipedia that its chemical formula is $\mathrm{C}_{25} \mathrm{H}_{52}$. It is still quite capable of storing a lot of heat per unit weight too, in any case, but nowhere close to hydrogen. Putting $\frac{5}{2} k_{\mathrm{B}} T$ in a molecule with the tiny molecular mass of just about two protons is the real way to get a high heat content per unit mass.

Complex molecules may be an understandable problem for the law of Dulong and Petit, but how come that diamond has about $0.73 R_{\mathrm{u}}$, and graphite 1.02 $R_{\mathrm{u}}$, instead of 3 as it should? No molecules are involved there. The values of boron at $1.33 R_{\mathrm{u}}$ and beryllium at $1.98 R_{\mathrm{u}}$ are much too low too, though not as bad as diamond or graphite.

Figure 11.16: Specific heat at constant pressure of solids. Temperatures from absolute zero to $1,200 \mathrm{~K}$. Carbon is diamond; graphite is similar. Water is ice and liquid. Data from NIST-JANAF, CRC, AIP, Rohsenow et al.

Actually, it turns out, figure 11.16, that at much higher temperatures diamond does agree nicely with the Dulong and Petit value. Conversely, if the elements that agree well with Dulong and Petit at room temperature are cooled to low temperatures, they too have a specific heat that is much lower than the Dulong and Petit value. For example, at 77 K , aluminum has $1.09 R_{\mathrm{u}}$, copper 1.5 , and diamond 0.01 .

It turns out that for all of them a characteristic temperature can by found above which the specific heat is about the Dulong and Petit value, but below which the specific heat starts dropping precariously. This characteristic temperature is called the Debye temperature. For example, aluminum, copper, gold, and iron have Debye temperatures of $394,315,170$, and 460 K , all near or below room temperature, and their room temperature specific heats agree reasonably with the Dulong and Petit value. Conversely, diamond, boron, and beryllium
have Debye temperatures of 1860,1250 , and 1000 K , and their specific heats are much too low at room temperature.

The lack of heat capacity below the Debye temperature is again a matter of "frozen out" vibrational modes, like the freezing out of the vibrational modes that gave common diatomic ideal gases a heat capacity of only $\frac{5}{2} R_{\mathrm{u}}$ instead of $\frac{7}{2} R_{\mathrm{u}}$. Note for example that carbon, boron and beryllium are light atoms, and that the diamond structure is particularly stiff, just the properties that froze out the vibrational modes in diatomic gas molecules too. However, the actual description is more complex than for a gas: if all vibrations were frozen out in a solid, there would be nothing left.

Atoms in a solid cannot be considered independent harmonic oscillators like the pairs of atoms in diatomic molecules. If an atom in a solid moves, its neighbors are affected. The proper way to describe the motion of the atoms is in terms of crystal-wide vibrations, such as those that in normal continuum mechanics describe acoustical waves. There are three variants of such waves, corresponding to the three independent directions the motion of the atoms can take with respect to the propagation direction of the wave. The atoms can move in the same direction, like in the acoustics of air in a pipe, or in a direction normal to it, like surface waves in water. Those are called longitudinal and transverse waves respectively. If there is more than one atom in the basis from which the solid crystal is formed, the atoms in a basis can also vibrate relative to each other's position in high-frequency vibrations called optical modes. However, after such details are accounted for, the classical internal energy of a solid is still the Dulong and Petit value.

Enter quantum mechanics. Just like quantum mechanics says that the energy of vibrating electromagnetic fields of frequency $\omega$ comes in discrete units called photons, with energy $\hbar \omega$, it says that the energy of crystal vibrations comes in discrete units called "phonons" with energy $\hbar \omega$. As long as the typical amount of heat energy, $k_{\mathrm{B}} T$, is larger than the largest of such phonon energies, the fact that the energy levels are discrete make no real difference, and classical analysis works fine. But for lower temperatures, there is not enough energy to create the high-energy phonons and the specific heat will be less. The representative temperature $T_{D}$ at which the heat energy $k_{\mathrm{B}} T_{D}$ becomes equal to the highest phonon energies $\hbar \omega$ is the Debye temperature. (The Debye analysis is not exact except for low energies, and the definitions of Debye temperature vary somewhat. See section 11.14.6 for more details.)

Quantum mechanics did not just solve the low temperature problems for heat capacity; it also solved the electron problem. That problem was that classically electrons in at least metals too should have $\frac{3}{2} k_{\mathrm{B}} T$ of kinetic energy, since electrical conduction meant that they moved independently of the atoms. But observations showed it was simply not there. The quantum mechanical explanation was the Fermi-Dirac distribution of figure 6.11: only a small fraction of the electrons have free energy states above them within a distance of order
$k_{\mathrm{B}} T$, and only these can take on heat energy. Since so few electrons are involved, the amount of energy they absorb is negligible except at very low temperatures. At very low temperatures, the energy in the phonons becomes very small, and the conduction electrons in metals then do make a difference.

Also, when the heat capacity due to the atom vibrations levels off to the Dulong and Petit value, that of the valence electrons keeps growing. Furthermore, at higher temperatures the increased vibrations lead to increased deviations in potential from the harmonic oscillator relationship. Wikipedia, Debye model, says anharmonicity causes the heat capacity to rise further; apparently authoritative other sources say that it can either increase or decrease the heat capacity. In any case, typical solids do show an increase of the heat capacity above the Dulong and Petit value at higher temperatures, figure 11.16.

## Chapter 12

## Angular momentum

The quantum mechanics of angular momentum is fascinating. It is also very basic to much of quantum mechanics. It is a model for dealing with other systems of particles

In chapter 5.4 , it was already mentioned that angular momentum of particles comes in two basic kinds. Orbital angular momentum is a result of the angular motion of particles, while spin is "built-in" angular momentum of the particles.

Orbital angular momentum is usually indicated by $\widehat{\vec{L}}$ and spin angular momentum by $\widehat{\vec{S}}$. A system of particles will normally involve both orbital and spin angular momentum. The combined angular momentum is typically indicated by

$$
\widehat{\vec{J}}=\widehat{\vec{L}}+\widehat{\vec{S}}
$$

However, this chapter will use $\widehat{\vec{J}}$ as a generic name for any angular momentum. So in this chapter $\widehat{\vec{J}}$ can indicate orbital angular momentum, spin angular momentum, or any combination of the two.

### 12.1 Introduction

The standard eigenfunctions of orbital angular momentum are the so called "spherical harmonics" of chapter 4.2. They show that the square orbital angular momentum has the possible values

$$
L^{2} \equiv L_{x}^{2}+L_{y}^{2}+L_{z}^{2}=l(l+1) \hbar^{2} \quad \text { where } l \text { is one of } 0,1,2,3, \ldots
$$

The nonnegative integer $l$ is called the azimuthal quantum number.
Further, the orbital angular momentum in any arbitrarily chosen direction, taken as the $z$-direction from now on, comes in multiples $m$ of Planck's constant $\hbar$ :

$$
L_{z}=m_{l} \hbar \quad \text { where } m_{l} \text { is one of }-l,-l+1,-l+2, \ldots, l-1, l \text {. }
$$

The integer $m_{l}$ is called the magnetic quantum number.
The possible values of the square spin angular momentum can be written as

$$
S^{2} \equiv S_{x}^{2}+S_{y}^{2}+S_{z}^{2}=s(s+1) \hbar^{2} \quad \text { where } s \text { is one of } 0,1 / 2,1,3 / 2, \ldots
$$

The "spin azimuthal quantum number" $s$ is usually called the "spin" for short. Note that while the orbital azimuthal quantum number $l$ had to be an integer, the spin can be half integer. But one important conclusion of this chapter will be that the spin cannot be anything more. A particle with, say, spin $\frac{1}{3}$ cannot not exist according to the theory.

For the spin angular momentum in the $z$-direction

$$
S_{z}=m_{s} \hbar \quad \text { where } m_{s} \text { is one of }-s,-s+1,-s+2, \ldots, s-1, s
$$

Note that if the spin $s$ is half integer, then so are all the spin magnetic quantum numbers $m_{s}$. If the nature of the angular momentum is self-evident, the subscript $l$ or $s$ of the magnetic quantum numbers $m$ will be omitted.

Particles with half-integer spin are called fermions. That includes electrons, as well as protons and neutrons and their constituent quarks. All of these critically important particles have spin $1 / 2$. (Excited proton and neutron states can have spin $3 / 2$.) Particles with integer spin are bosons. That includes the particles that act as carriers of fundamental forces; the photons, intermediate vector bosons, gluons, and gravitons. All of these have spin 1, except the graviton which supposedly has spin 2 .

### 12.2 The fundamental commutation relations

Analyzing nonorbital angular momentum is a challenge. How can you say anything sensible about angular momentum, the dynamic motion of masses around a given point, without a mass moving around a point? For, while a particle like an electron has spin angular momentum, trying to explain it as angular motion of the electron about some internal axis leads to gross contradictions such as the electron exceeding the speed of light [25, p. 172]. Spin is definitely part of the law of conservation of angular momentum, but it does not seem to be associated with any familiar idea of some mass moving around some axis as far as is known.

There goes the Newtonian analogy, then. Something else than classical physics is needed to analyze spin.

Now, the complex discoveries of mathematics are routinely deduced from apparently self-evident simple axioms, such as that a straight line will cross each of a pair of parallel lines under the same angle. Actually, such axioms are not as obvious as they seem, and mathematicians have deduced very different answers from changing the axioms into different ones. Such answers may be just
as good or better than others depending on circumstances, and you can invent imaginary universes in which they are the norm.

Physics has no such latitude to invent its own universes; its mission is to describe ours as well as it can. But the idea of mathematics is still a good one: try to guess the simplest possible basic "law" that nature really seems to obey, and then reconstruct as much of the complexity of nature from it as you can. The more you can deduce from the law, the more ways you have to check it against a variety of facts, and the more confident you can become in it.

Physicist have found that the needed equations for angular momentum are given by the following "fundamental commutation relations:"

$$
\begin{equation*}
\left[\widehat{J}_{x}, \widehat{J}_{y}\right]=\mathrm{i} \hbar \widehat{J}_{z} \quad\left[\widehat{J}_{y}, \widehat{J}_{z}\right]=\mathrm{i} \hbar \widehat{J}_{x} \quad\left[\widehat{J}_{z}, \widehat{J}_{x}\right]=\mathrm{i} \hbar \widehat{J}_{y} \tag{12.1}
\end{equation*}
$$

They can be derived for orbital angular momentum (see chapter 4.5.4), but must be postulated to also apply to spin angular momentum $\{\mathrm{N} .26\}$.

At first glance, these commutation relations do not look like a promising starting point for much analysis. All they say on their face is that the angular momentum operators $\widehat{J}_{x}, \widehat{J}_{y}$, and $\widehat{J}_{z}$ do not commute, so that they cannot have a full set of eigenstates in common. That is hardly impressive.

But if you read the following sections, you will be astonished by what knowledge can be teased out of them. For starters, one thing that immediately follows is that the only eigenstates that $\widehat{J}_{x}, \widehat{J}_{y}$, and $\widehat{J}_{z}$ have in common are states $|00\rangle$ of no angular momentum at all $\{\mathrm{D} .63\}$. No other common eigenstates exist.

One assumption will be implicit in the use of the fundamental commutation relations, namely that they can be taken at face value. It is certainly possible to imagine that say $\widehat{J}_{x}$ would turn an eigenfunction of say $\widehat{J}_{z}$ into some singular object for which angular momentum would be ill-defined. That would of course make application of the fundamental commutation relations improper. It will be assumed that the operators are free of such pathological nastiness.

### 12.3 Ladders

This section starts the quest to figure out everything that the fundamental commutation relations mean for angular momentum. It will first be verified that any angular momentum can always be described using $|j m\rangle$ eigenstates with definite values of square angular momentum $J^{2}$ and $z$ angular momentum $J_{z}$. Then it will be found that these angular momentum states occur in groups called "ladders".

To start with the first one, the mathematical condition for a complete set of eigenstates $|j m\rangle$ to exist is that the angular momentum operators $\widehat{J}^{2}$ and $\widehat{J}_{z}$ commute. They do; using the commutator manipulations of chapter 4.5.4), it is easily found that:

$$
\left[\widehat{J}^{2}, \widehat{J}_{x}\right]=\left[\widehat{J}^{2}, \widehat{J}_{y}\right]=\left[\widehat{J}^{2}, \widehat{J}_{z}\right]=0 \quad \text { where } \widehat{J}^{2}=\widehat{J}_{x}^{2}+\widehat{J}_{y}^{2}+\widehat{J}_{z}^{2}
$$

So mathematics says that eigenstates $|j m\rangle$ of $\widehat{J}_{z}$ and $\widehat{J}^{2}$ exist satisfying

$$
\begin{array}{ll}
\widehat{J}_{z}|j m\rangle=J_{z}|j m\rangle & \text { where by definition } J_{z}=m \hbar \\
\widehat{J}^{2}|j m\rangle=J^{2}|j m\rangle & \text { where by definition } J^{2}=j(j+1) \hbar^{2} \text { and } j \geqslant(\mathbb{D 2 . 3})
\end{array}
$$

and that are complete in the sense that any state can be described in terms of these $|j m\rangle$.

Unfortunately the eigenstates $|j m\rangle$, except for $|00\rangle$ states, do not satisfy relations like (12.2) for $\widehat{J}_{x}$ or $\widehat{J}_{y}$. The problem is that $\widehat{J}_{x}$ and $\widehat{J}_{y}$ do not commute with $\widehat{J}_{z}$. But $\widehat{J}_{x}$ and $\widehat{J}_{y}$ do commute with $\widehat{J}^{2}$, and you might wonder if that is still worth something. To find out, multiply, say, the zero commutator $\left[\widehat{J}^{2}, \widehat{J}_{x}\right]$ by $|j m\rangle$ :

$$
\left[\widehat{J}^{2}, \widehat{J}_{x}\right]|j m\rangle=\left(\widehat{J}^{2} \widehat{J}_{x}-\widehat{J}_{x} \widehat{J}^{2}\right)|j m\rangle=0
$$

Now take the second term to the right hand side of the equation, noting that $\widehat{J}^{2}|j m\rangle=J^{2}|j m\rangle$ with $J^{2}$ just a number that can be moved up-front, to get:

$$
\widehat{J}^{2}\left(\widehat{J}_{x}|j m\rangle\right)=J^{2}\left(\widehat{J}_{x}|j m\rangle\right)
$$

Looking a bit closer at this equation, it shows that the combination $\widehat{J}_{x}|j m\rangle$ satisfies the same eigenvalue problem for $\widehat{J}^{2}$ as $|j m\rangle$ itself. In other words, the multiplication by $\widehat{J}_{x}$ does not affect the square angular momentum $J^{2}$ at all.

To be picky, that is not quite true if $\widehat{J}_{x}|j m\rangle$ would be zero, because zero is not an eigenstate of anything. However, such a thing only happens if there is no angular momentum; (it would make $|j m\rangle$ an eigenstate of $\widehat{J}_{x}$ with eigenvalue zero in addition to an eigenstate of $\left.\widehat{J}_{z}\{\mathrm{D} .63\}\right)$. Except for that trivial case, $\widehat{J}_{x}$ does not affect square angular momentum. And neither does $\widehat{J}_{y}$ or any combination of the two.

Angular momentum in the $z$-direction is affected by $\widehat{J}_{x}$ and by $\widehat{J}_{y}$, since they do not commute with $\widehat{J}_{z}$ like they do with $\widehat{J}^{2}$. Nor is it possible to find any linear combination of $\widehat{J}_{x}$ and $\widehat{J}_{y}$ that does commute with $\widehat{J}_{z}$. What is the next best thing? Well, it is possible to find two combinations, to wit

$$
\begin{equation*}
\widehat{J}^{+} \equiv \widehat{J}_{x}+\mathrm{i} \widehat{J}_{y} \quad \text { and } \quad \widehat{J}^{-} \equiv \widehat{J}_{x}-\mathrm{i} \widehat{J}_{y} \tag{12.4}
\end{equation*}
$$

that satisfy the "commutator eigenvalue problems":

$$
\left[\widehat{J}_{z}, \widehat{J}^{+}\right]=\hbar \widehat{J}^{+} \quad \text { and } \quad\left[\widehat{J}_{z}, \widehat{J}^{-}\right]=-\hbar \widehat{J}^{-}
$$

These two turn out to be quite remarkable operators.
Like $\widehat{J}_{x}$ and $\widehat{J}_{y}$, their combinations $\widehat{J}^{+}$and $\widehat{J^{-}}$leave $J^{2}$ alone. To examine what the operator $\widehat{J}^{+}$does with the linear momentum in the $z$-direction, multiply its commutator relation above by an eigenstate $|j m\rangle$ :

$$
\left(\widehat{J}_{z} \widehat{J}^{+}-\widehat{J}^{+} \widehat{J}_{z}\right)|j m\rangle=\hbar \widehat{J}^{+}|j m\rangle
$$

Or, taking the second term to the right hand side of the equation and noting that by definition $\widehat{J}_{z}|j m\rangle=m \hbar|j m\rangle$,

$$
\widehat{J}_{z}\left(\widehat{J}^{+}|j m\rangle\right)=(m+1) \hbar\left(\widehat{J}^{+}|j m\rangle\right)
$$

That is a stunning result, as it shows that $\widehat{J}^{+}|j m\rangle$ is an eigenstate with $z$ angular momentum $J_{z}=(m+1) \hbar$ instead of $m \hbar$. In other words, $\widehat{J}^{+}$adds exactly one unit $\hbar$ to the $z$ angular momentum, turning an $|j m\rangle$ state into a $|j m+1\rangle$ one!

Figure 12.1: Example bosonic ladders.
If you apply $\widehat{J}^{+}$another time, you get a state of still higher $z$ angular momentum $|j m+2\rangle$, and so on, like the rungs on a ladder. This is graphically illustrated for some examples in figures 12.1 and 12.2. The process eventually comes to an halt at some top rung $m=m_{\max }$ where $\widehat{J}^{+}\left|j m_{\max }\right\rangle=0$. It has to, because the angular momentum in the $z$-direction cannot just keep growing forever: the square angular momentum in the $z$-direction only must stay less than the total square angular momentum in all three directions $\{\mathrm{N} .27\}$.

The second "ladder operator" $\widehat{J}^{-}$works in much the same way, but it goes down the ladder; its deducts one unit $\hbar$ from the angular momentum in the $z$ direction at each application. $\widehat{J}^{-}$provides the second stile to the ladders, and must terminate at some bottom rung $m_{\text {min }}$.

Figure 12.2: Example fermionic ladders.

### 12.4 Possible values of angular momentum

The fact that the angular momentum ladders of the previous section must have a top and a bottom rung restricts the possible values that angular momentum can take. This section will show that the azimuthal quantum number $j$ can either be a nonnegative whole number or half of one, but nothing else. And it will show that the magnetic quantum number $m$ must range from $-j$ to $+j$ in unit increments. In other words, the bosonic and fermionic example ladders in figures 12.1 and 12.2 are representative of all that is possible.

To start, in order for a ladder to end at a top rung $m_{\max }, \widehat{J}^{+}|l m\rangle$ has to be zero for $m=m_{\max }$. More specifically, its magnitude $\left.\left|\widehat{J}^{+}\right| j m\right\rangle \mid$ must be zero. The square magnitude is given by the inner product with itself:

$$
\left.\left.\left.\left|\widehat{J}^{+}\right| j m\right\rangle\left.\right|^{2}=\left\langle\widehat{J}^{+} \mid j m\right\rangle\left|\widehat{J}^{+}\right| j m\right\rangle\right\rangle=0
$$

Now because of the complex conjugate that is used in the left hand side of an inner product, (see chapter 2.3), $\widehat{J}^{+}=\widehat{J}_{x}+\mathrm{i} \widehat{J}_{y}$ goes to the other side of the product as $\widehat{J}^{-}=\widehat{J}_{x}-\mathrm{i} \widehat{J}_{y}$, and you must have

$$
\left.\left.\left.\left|\widehat{J}^{+}\right| j m\right\rangle\left.\right|^{2}=\langle\mid j m\rangle\left|\widehat{J}^{-} \widehat{J}^{+}\right| j m\right\rangle\right\rangle
$$

That operator product can be multiplied out:

$$
\widehat{J}^{-} \widehat{J}^{+} \equiv\left(\widehat{J}_{x}-\mathrm{i} \widehat{J}_{y}\right)\left(\widehat{J}_{x}+\mathrm{i} \widehat{J}_{y}\right)=\widehat{J}_{x}^{2}+\widehat{J}_{y}^{2}+\mathrm{i}\left(\widehat{J}_{x} \widehat{J}_{y}-\widehat{J}_{y} \widehat{J}_{x}\right)
$$

but $\widehat{J}_{x}^{2}+\widehat{J}_{y}^{2}$ is the square angular momentum $\widehat{J}^{2}$ except for $\widehat{J}_{z}^{2}$, and the term within the parentheses is the commutator $\left[\widehat{J}_{x}, \widehat{J}_{y}\right]$ which is according to the
fundamental commutation relations equal to $\mathrm{i} \hbar \widehat{J}_{z}$, so

$$
\begin{equation*}
\widehat{J}^{-} \widehat{J}^{+}=\widehat{J}^{2}-\widehat{J}_{z}^{2}-\hbar \widehat{J}_{z} \tag{12.5}
\end{equation*}
$$

The effect of each of the operators in the left hand side on a state $|j m\rangle$ is known and the inner product can be figured out:

$$
\begin{equation*}
\left.\left|\widehat{J}^{+}\right| j m\right\rangle\left.\right|^{2}=j(j+1) \hbar^{2}-m^{2} \hbar^{2}-m \hbar^{2} \tag{12.6}
\end{equation*}
$$

The question where angular momentum ladders end can now be answered:

$$
j(j+1) \hbar^{2}-m_{\max }^{2} \hbar^{2}-m_{\max } \hbar^{2}=0
$$

There are two possible solutions to this quadratic equation for $m_{\max }$, to wit $m_{\max }=j$ or $-m_{\max }=j+1$. The second solution is impossible since it already would have the square $z$ angular momentum exceed the total square angular momentum. So unavoidably,

$$
m_{\max }=j
$$

That is one of the things this section was supposed to show.
The lowest rung on the ladder goes the same way; you get

$$
\begin{equation*}
\widehat{J}^{+} \widehat{J}^{-}=\widehat{J}^{2}-\widehat{J}_{z}^{2}+\hbar \widehat{J}_{z} \tag{12.7}
\end{equation*}
$$

and then

$$
\begin{equation*}
\left.\left|\widehat{J}^{-}\right| j m\right\rangle\left.\right|^{2}=j(j+1) \hbar^{2}-m^{2} \hbar^{2}+m \hbar^{2} \tag{12.8}
\end{equation*}
$$

and the only acceptable solution for the lowest rung on the ladders is

$$
m_{\min }=-j
$$

It is nice and symmetric; ladders run from $m=-j$ up to $m=j$, as the examples in figures 12.1 and 12.2 already showed.

And in fact, it is more than that; it also limits what the quantum numbers $j$ and $m$ can be. For, since each step on a ladder increases the magnetic quantum number $m$ by one unit, you have for the total number of steps up from bottom to top:

$$
\text { total number of steps }=m_{\max }-m_{\min }=2 j
$$

But the number of steps is a whole number, and so the azimuthal quantum $j$ must either be a nonnegative integer, such as $0,1,2, \ldots$, or half of one, such as $\frac{1}{2}, \frac{3}{2}, \ldots$

Integer $j$ values occur, for example, for the spherical harmonics of orbital angular momentum and for the spin of bosons like photons. Half-integer values occur, for example, for the spin of fermions such as electrons, protons, neutrons, and $\Delta$ particles.

Note that if $j$ is a half-integer, then so are the corresponding values of $m$, since $m$ starts from $-j$ and increases in unit steps. See again figures 12.1 and 12.2 for some examples. Also note that ladders terminate just before $z$ momentum would exceed total momentum.

It may also be noted that ladders are distinct. It is not possible to go up one ladder, like the first $Y_{3}^{m}$ one in figure 12.1 with $\widehat{J}^{+}$and then come down the second one using $\widehat{J}^{-}$. The reason is that the states $|j m\rangle$ are eigenstates of the operators $\widehat{J}^{-} \widehat{J}^{+},(12.5)$, and $\widehat{J}^{+} \widehat{J}^{-},(12.7)$, so going up with $\widehat{J}^{+}$and then down again with $\widehat{J^{-}}$, or vice-versa, returns to the same state. For similar reasons, if the tops of two ladders are orthonormal, then so is the rest of their rungs.

### 12.5 A warning about angular momentum

Normally, eigenstates are indeterminate by a complex number of magnitude one. If you so desire, you can multiply any normalized eigenstate by a number of unit magnitude of your own choosing, and it is still a normalized eigenstate. It is important to remember that in analytical expressions involving angular momentum, you are not allowed to do this.

As an example, consider a pair of spin $1 / 2$ particles, call them $a$ and $b$, in the "singlet state", in which their spins cancel and there is no net angular momentum. It was noted in chapter 5.5.6 that this state takes the form

$$
|00\rangle_{a b}=\frac{|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}-|1 / 2-1 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}}{\sqrt{2}}
$$

(This section will use kets rather than arrows for spin states.) But if you were allowed to arbitrarily change the definition of say the spin state $\left|1 / L_{2}-1 / 2\right\rangle_{a}$ by a minus sign, then the minus sign in the singlet state above would turn in a plus sign. The given expression for the singlet state, with its minus sign, is only correct if you use the right normalization factors for the individual states.

It all has to do with the ladder operators $\widehat{J}^{+}$and $\widehat{J}^{-}$. They are very convenient for analysis, but to make that easiest, you would like to know exactly what they do to the angular momentum states $|j m\rangle$. What you have seen so far is that $\widehat{J}^{+}|j m\rangle$ produces a state with the same square angular momentum, and with angular momentum in the $z$-direction equal to $(m+1) \hbar$. In other words, $\widehat{J}^{+}|j m\rangle$ is some multiple of a suitably normalized eigenstate $|j m+1\rangle$;

$$
\widehat{J}^{+}|j m\rangle=C|j m+1\rangle
$$

where the number $C$ is the multiple. What is that multiple? Well, from the magnitude of $\widehat{J}^{+}|j m\rangle$, derived earlier in (12.6) you know that its square magnitude is

$$
|C|^{2}=j(j+1) \hbar^{2}-m^{2} \hbar^{2}-m \hbar^{2}
$$

But that still leaves $C$ indeterminate by a factor of unit magnitude. Which would be very inconvenient in the analysis of angular momentum.

To resolve this conundrum, restrictions are put on the normalization factors of the angular momentum states $|j m\rangle$ in ladders. It is required that the normalization factors are chosen such that the ladder operator constants are positive real numbers. That really leaves only one normalization factor in an entire ladder freely selectable, say the one of the top rung.

Most of the time, this is not a big deal. Only when you start trying to get too clever with angular momentum normalization factors, then you want to remember that you cannot really choose them to your own liking.

The good news is that in this convention, you know precisely what the ladder operators do $\{\mathrm{D} .64\}$ :

$$
\begin{align*}
& \widehat{J}^{+}|j m\rangle=\hbar \sqrt{j(j+1)-m(1+m)}|j m+1\rangle  \tag{12.9}\\
& \widehat{J}^{-}|j m\rangle=\hbar \sqrt{j(j+1)+m(1-m)}|j m-1\rangle \tag{12.10}
\end{align*}
$$

### 12.6 Triplet and singlet states

With the ladder operators, you can determine how different angular momenta add up to net angular momentum. As an example, this section will examine what net spin values can be produced by two particles, each with spin $1 / 2$. They may be the proton and electron in a hydrogen atom, or the two electrons in the hydrogen molecule, or whatever. The actual result will be to rederive the triplet and singlet states described in chapter 5.5.6, but it will also be an example for how more complex angular momentum states can be combined.

The particles involved will be denoted as $a$ and $b$. Since each particle can have two different spin states $|1 / 21 / 2\rangle$ and $|1 / 2-1 / 2\rangle$, there are four different combined "product" states:

$$
|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b},|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b},|1 / 2-1 / 2\rangle_{a}|1 / 21 / 2\rangle_{b} \text {, and }|1 / 2-1 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b} \text {. }
$$

In these product states, each particle is in a single individual spin state. The question is, what is the combined angular momentum of these four product states? And what combination states have definite net values for square and $z$ angular momentum?

The angular momentum in the $z$-direction is simple; it is just the sum of those of the individual particles. For example, the $z$-momentum of the $\left|\frac{1}{2} \frac{1}{2}\right\rangle_{a}\left|\frac{1}{2} \frac{1}{2}\right\rangle_{b}$ state follows from

$$
\begin{aligned}
\left(\widehat{J}_{z a}+\widehat{J}_{z b}\right)|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b} & =1 / 2 \hbar|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}+|1 / 21 / 2\rangle_{a} 1 / 2 \hbar|1 / 21 / 2\rangle_{b} \\
& =h|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}
\end{aligned}
$$

which makes the net angular momentum in the $z$-direction $\hbar$, or $1 / 2 \hbar$ from each particle. Note that the $z$ angular momentum operators of the two particles simply add up and that $\widehat{J}_{z_{a}}$ only acts on particle $a$, and $\widehat{J}_{z b}$ only on particle $b$ $\{N .28\}$. In terms of quantum numbers, the magnetic quantum number $m_{a b}$ is the sum of the individual quantum numbers $m_{a}$ and $m_{b} ; m_{a b}=m_{a}+m_{b}=1$.

The net total angular momentum is not so obvious; you cannot just add total angular momenta. To figure out the total angular momentum of $|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}$ anyway, there is a trick: multiply it with the combined step-up operator

$$
\widehat{J}_{a b}^{+}=\widehat{J}_{a}^{+}+\widehat{J}_{b}^{+}
$$

Each part returns zero: $\widehat{J}_{a}^{+}$because particle $a$ is at the top of its ladder and $\widehat{J}_{b}^{+}$ because particle $b$ is. So the combined state $|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}$ must be at the top of the ladder too; there is no higher rung. That must mean $j_{a b}=m_{a b}=1$; the combined state must be a $|11\rangle$ state. It can be defined it as the combination $|11\rangle$ state:

$$
\begin{equation*}
|11\rangle_{a b} \equiv|1 / 21 / 2\rangle_{a}\left|1 / 2 \frac{1}{2}\right\rangle_{b} \tag{12.11}
\end{equation*}
$$

You could just as well have defined $|11\rangle_{a b}$ as $-|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}$ or $\mathrm{i}|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}$, say. But why drag along a minus sign or i if you do not have to? The first triplet state has been found.

Here is another trick: multiply $|11\rangle_{a b}=|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}$ by $\widehat{J}_{a b}^{-}$: that will go one step down the combined states ladder and produce a combination state $|10\rangle_{a b}$ :

$$
\begin{aligned}
\widehat{J}_{a b}^{-}|11\rangle_{a b} & =\hbar \sqrt{1(1+1)+1(1-1)}|10\rangle_{a b} \\
& =\widehat{J}_{a}^{-}|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}+\widehat{J}_{b}^{-}\left|1 / 2_{2} 1 / 2\right\rangle_{a}|1 / 21 / 2\rangle_{b}
\end{aligned}
$$

or

$$
\hbar \sqrt{2}|10\rangle_{a b}=\hbar|1 / 2-1 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}+\hbar|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}
$$

where the effects of the ladder-down operators were taken from (12.10). (Note that this requires that the individual particle spin states are normalized consistent with the ladder operators.) The second triplet state is therefore:

$$
\begin{equation*}
|10\rangle_{a b} \equiv \sqrt{1 / 2}|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}+\sqrt{1 / 2}|1 / 2-1 / 2\rangle_{a}|1 / 21 / 2\rangle_{b} \tag{12.12}
\end{equation*}
$$

But this gives only one $|j m\rangle$ combination state for the two product states $|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}$ and $|1 / 2-1 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}$ with zero net $z$-momentum. If you want to describe unequal combinations of them, like $|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}$ by itself, it cannot be just a multiple of $|10\rangle_{a b}$. This suggests that there may be another $|j 0\rangle_{a b}$ combination state involved here. How do you get this second state?

Well, you can reuse the first trick. If you construct a combination of the two product states that steps up to zero, it must be a state with zero $z$ angular momentum that is at the end of its ladder, a $|00\rangle_{a b}$ state. Consider an
arbitrary combination of the two product states with as yet unknown numerical coefficients $C_{1}$ and $C_{2}$ :

$$
\left.\left.\left.\left.\left.C_{1}\right|^{1} / 21 / 2\right\rangle\left._{a}\right|^{1 / 2}-1 / 2\right\rangle_{b}+\left.C_{2}\right|^{1} / 2-1 / 2\right\rangle\left._{a}\right|^{1 / 2} 1 / 2\right\rangle_{b}
$$

For this combination to step up to zero,

$$
\begin{aligned}
\left(\widehat{J}_{a}^{+}+\widehat{J}_{b}^{+}\right)\left(C_{1}|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}\right. & \left.\left.+\left.C_{2}\right|^{1} / 2-1 / 2\right\rangle_{a}|1 / 21 / 2\rangle_{b}\right) \\
= & \left.\left.\left.\left.\hbar C_{1}\right|^{1} / 21 / 2\right\rangle\left._{a}\right|^{1} / 21 / 2\right\rangle_{b}+\left.\hbar C_{2}\right|^{1} / 21 / 2\right\rangle_{a}|1 / 21 / 2\rangle_{b}
\end{aligned}
$$

must be zero, which requires $C_{2}=-C_{1}$, leaving $C_{1}$ undetermined. $C_{1}$ must be chosen such that the state is normalized, but that still leaves a constant of magnitude one undetermined. To fix it, $C_{1}$ is taken to be real and positive, and so the singlet state becomes

$$
\begin{equation*}
\left.|00\rangle_{a b}=\sqrt{1 / 2}|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}-\left.\sqrt{1 / 2}|1 / 2-1 / 2\rangle_{a}\right|^{1 / 2} 1_{2} / 2\right\rangle_{b} . \tag{12.13}
\end{equation*}
$$

To find the remaining triplet state, just apply $\widehat{J}_{a b}^{-}$once more, to $|10\rangle_{a b}$ above. It gives:

$$
\begin{equation*}
|1-1\rangle_{a b}=|1 / 2-1 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b} \tag{12.14}
\end{equation*}
$$

Of course, the normalization factor of this bottom state had to turn out to be one; all three step-down operators produce only positive real factors.

Figure 12.3: Triplet and singlet states in terms of ladders
Figure 12.3 shows the results graphically in terms of ladders. The two possible spin states of each of the two electrons produce 4 combined product states indicated using up and down arrows. These product states are then combined to produce triplet and singlet states that have definite values for both $z$ and total net angular momentum, and can be shown as rungs on ladders.

Note that a product state like $|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}$ cannot be shown as a rung on a ladder. In fact, from adding (12.12) and (12.13) it is seen that

$$
|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}=\sqrt{1 / 2}|10\rangle_{a b}+\sqrt{1 / 2}|00\rangle_{a b}
$$

which makes it a combination of the middle rungs of the triplet and singlet ladders, rather than a single rung.

### 12.7 Clebsch-Gordan coefficients

In classical physics, combining angular momentum from different sources is easy; the net components in the $x, y$, and $z$ directions are simply the sum of the individual components. In quantum mechanics, things are trickier, because if the component in the $z$-direction exists, those in the $x$ and $y$ directions do not. But the previous subsection showed how to the spin angular momenta of two spin $1 / 2$ particles could be combined. In similar ways, the angular momentum states of any two ladders, whatever their origin, can be combined into net angular momentum ladders. And then those ladders can in turn be combined with still other ladders, allowing net angular momentum states to be found for systems of arbitrary complexity.

The key is to be able to combine the angular momentum ladders from two different sources into net angular momentum ladders. To do so, the net angular momentum can in principle be described in terms of product states in which each source is on a single rung of its ladder. But as the example of the last section illustrated, such product states give incomplete information about the net angular momentum; they do not tell you what square net angular momentum is. You need to know what combinations of product states produce rungs on the ladders of the net angular momentum, like the ones illustrated in figure 12.3. In particular, you need to know the coefficients that multiply the product states in those combinations.

Figure 12.4: Clebsch-Gordan coefficients of two spin one half particles.
These coefficients are called "Clebsch-Gordan" coefficients. The ones corresponding to figure 12.3 are tabulated in Figure 12.4. Note that there are really
three tables of numbers; one for each rung level. The top, single number, "table" says that the $|11\rangle$ net momentum state is found in terms of product states as:

$$
|11\rangle_{a b}=1 \times|1 / 21 / 2\rangle_{a}|1 / 21 / 2\rangle_{b}
$$

The second table gives the states with zero net angular momentum in the $z$ direction. For example, the first column of the table says that the $|00\rangle$ singlet state is found as:

$$
\left.\left.\left.|00\rangle_{a b}=\left.\sqrt{1 / 2}\right|^{1 / 2} \frac{1}{2}\right\rangle\left._{a}\right|^{1 / 2}-1 / 2\right\rangle_{b}-\left.\sqrt{1 / 2}\right|^{1 / 2}-1 / 2\right\rangle_{a}|1 / 21 / 2\rangle_{b}
$$

Similarly the second column gives the middle rung $|10\rangle$ on the triplet ladder. The bottom "table" gives the bottom rung of the triplet ladder.

You can also read the tables horizontally $\{$ N.29\}. For example, the first row of the middle table says that the $|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}$ product state equals

$$
|1 / 21 / 2\rangle_{a}|1 / 2-1 / 2\rangle_{b}=\sqrt{1 / 2}|00\rangle_{a b}+\sqrt{1 / 2}|10\rangle_{a b}
$$

That in turn implies that if the net square angular momentum of this product state is measured, there is a $50 / 50$ chance of it turning out to be either zero, or the $j=1$ (i.e. $2 \hbar^{2}$ ) value. The $z$-momentum will always be zero.

Figure 12.5: Clebsch-Gordan coefficients when the second angular momentum contribution has azimuthal quantum number $j_{b}=\frac{1}{2}$.

How about the Clebsch-Gordan coefficients to combine other ladders than the spins of two spin $1 / 2$ particles? Well, the same procedures used in the previous section work just as well to combine the angular momenta of any two angular momentum ladders, whatever their size. Just the thing for a long winter night. Or, if you live in Florida, you just might want to write a little computer program that does it for you $\{\mathrm{D} .65\}$ and outputs the tables in human-readable form $\{\mathrm{N} .30\}$, like figures 12.5 and 12.6 .

From the figures you may note that when two states with total angular momentum quantum numbers $j_{a}$ and $j_{b}$ are combined, the combinations have total angular quantum numbers ranging from $j_{a}+j_{b}$ to $\left|j_{a}-j_{b}\right|$. This is similar to the fact that when in classical mechanics two angular momentum vectors are combined, the combined total angular momentum $J_{a b}$ is at most $J_{a}+J_{b}$ and at least $\left|J_{a}-J_{b}\right|$. (The so-called "triangle inequality" for combining vectors.) But of course, $j$ is not quite a proportional measure of $J$ unless $J$ is large; in fact, $J$ $=\sqrt{j(j+1)} \hbar\{\mathrm{D} .66\}$.

### 12.8 Some important results

This section gives some results that are used frequently in quantum analysis, but usually not explicitly stated.

First a note on notations. It is fairly common to use the letter $l$ for orbital angular momentum, $s$ for spin, and $j$ for combinations of orbital and angular momentum. This subsection will follow these conventions where appropriate.

1. If all possible angular momentum states are filled with a fermion, the resulting angular momentum is zero and the wave function is spherically symmetric. For example, consider the simplified case that there is one spinless fermion in each spherical harmonic at a given azimuthal quantum number $l$. Then it is easy to see from the form of the spherical harmonics that the combined wave function is independent of the angular position around the $z$-axis. And all spherical harmonics at that $l$ are filled whatever you take to be the $z$-axis. This makes noble gasses into the equivalent of billiard balls. More generally, if there is one fermion for every possible "direction" of the angular momentum, by symmetry the net angular momentum can only be zero.
2. If a spin $1 / 2$ fermion has orbital angular momentum quantum number $l$, net (orbital plus spin) angular momentum quantum number $j=$ $l+\frac{1}{2}$, and net momentum in the $z$-direction quantum number $m_{j}$, its net state is given in terms of the individual orbital and spin states as:

$$
j=l+\frac{1}{2}: \quad\left|j m_{j}\right\rangle=\sqrt{\frac{j+m_{j}}{2 j}} Y_{l}^{m_{j}-\frac{1}{2}} \uparrow+\sqrt{\frac{j-m_{j}}{2 j}} Y_{l}^{m_{j}+\frac{1}{2}} \downarrow
$$

Figure 12.6: Clebsch-Gordan coefficients when the second angular momentum contribution has azimuthal quantum number $j_{b}=1$.

If the net spin is $j=l-\frac{1}{2}$, assuming that $l>0$, that becomes

$$
j=l-\frac{1}{2}: \quad\left|j m_{j}\right\rangle=-\sqrt{\frac{j+1-m_{j}}{2 j+2}} Y_{l}^{m_{j}-\frac{1}{2}} \uparrow+\sqrt{\frac{j+1+m_{j}}{2 j+2}} Y_{l}^{m_{j}+\frac{1}{2}} \downarrow
$$

Note that if the net angular momentum is unambiguous, the orbital and spin magnetic quantum numbers $m$ and $m_{s}$ are in general uncertain.
3. For identical particles, an important question is how the ClebschGordan coefficients change under particle exchange:

$$
\left\langle j_{a b} m_{a b} \| j_{a} m_{a}\right\rangle\left|j_{b} m_{b}\right\rangle=(-1)^{j_{a}+j_{b}-j_{a b}}\left\langle j_{a b} m_{a b}\right|\left|j_{b} m_{b}\right\rangle\left|j_{a} m_{a}\right\rangle
$$

For $j_{a}=j_{b}=\frac{1}{2}$, this verifies that the triplet states $j_{a b}=1$ are symmetric, and the singlet state $j_{a b}=0$ is antisymmetric. More generally, states with the maximum net angular momentum $j_{a b}=$ $j_{a}+j_{b}$ and whole multiples of 2 less are symmetric under particle exchange. States that are odd amounts less than the maximum are antisymmetric under particle exchange.
4. When the net angular momentum state is swapped with one of the component states, the relation is

$$
\begin{aligned}
& \left\langle j_{a b} m_{a b} \| j_{a} m_{a}\right\rangle\left|j_{b} m_{b}\right\rangle= \\
& \quad(-1)^{j_{a}-j_{a b}+m_{b}} \sqrt{\frac{2 j_{a b}+1}{2 j_{a}+1}}\left\langle j_{a} m_{a} \| j_{a b} m_{a b}\right\rangle\left|j_{b}-m_{b}\right\rangle
\end{aligned}
$$

This is of interest in figuring out what states produce zero net angular momentum, $j_{a b}=m_{a b}=0$. In that case, the right hand side is zero unless $j_{b}=j_{a}$ and $m_{b}=-m_{a}$; and then $\left\langle j_{a} m_{a}\right||00\rangle\left|j_{a} m_{a}\right\rangle$ $=1$. You can only create zero angular momentum from a pair of particles that have the same square angular momentum; also, only product states with zero net angular momentum in the $z$-direction are involved.

Table 12.1: Possible combined angular momentum of identical fermions in shells of single-particle states that differ in magnetic quantum number. The top shows odd numbers of particles, the bottom even numbers.
states are antisymmetric with respect to exchange of the fermions, and therefore allowed? More specifically, what is their combined net angular momentum?

The answer is given in table 12.1, $\{\mathrm{D} .67\}$. In it, $I$ is the number of fermions in the shell. Further $j^{\mathrm{p}}$ is the net angular momentum of the single-particle states that make up the shell. (Or the azimuthal quantum number of that angular momentum really.) Similarly the values of $j$ indicate the possible net angular momentum quantum numbers of all $i$ fermions combined. The main body of the table lists the multiplicity of sets with the given angular momentum. Note that the table is split into odd and even numbers of particles. That simplifies the presentation, because odd numbers of particles produce only half-integer net angular momentum, and even numbers only integer net angular momentum.

For example, consider a single particle, $I=1$, in a set of single-particle states with angular momentum $j^{\mathrm{p}}=9 / 2$. For a single particle, the "combined" momentum $j$ is simply the single particle momentum $j^{\mathrm{p}}$, explaining the single 1 in the $9 / 2$ column. But note that the 1 stands for a set of states; the magnetic net quantum number $m^{\mathrm{p}}$ of the single particle could still be any one of $9 / 2,7 / 2$, $\ldots,-9 / 2$. All the ten states in this set have net angular momentum $j=j^{\mathrm{p}}=$ $9 / 2$.

Next assume that there are two particles in the same $j^{\mathrm{p}}=9 / 2$ single-particle states. Then if both particles would be in the $m^{\mathrm{p}}=9 / 2$ single-particle state, their combined angular momentum in the $z$-direction $m$ would be $2 \times 9 / 2=$ 9. Following the Clebsch-Gordan derivation shows that this state would have combined angular momentum $j=m=9$. But the two identical fermions cannot be both in the $m^{\mathrm{p}}=9 / 2$ state; that violates the Pauli exclusion principle. That is why there is no entry in the $j=9$ column. If the first particle is in the $m^{\mathrm{p}}$ $=9 / 2$ state, the second one can at most be in the $m^{\mathrm{p}}=7 / 2$ state, for a total of $m=8$. More precisely, the particles would have to be in the antisymmetric combination, or Slater determinant, of these two states. That antisymmetric combination can be seen to have combined angular momentum $j=8$. There are other combinations of states that also have $j=8$, but values of $m$ equal to $7,6, \ldots,-8$, for a total of 17 states. That set of 17 states is indicated by the 1 in the $j=8$ column.

It is also possible for the two $j^{\mathrm{p}}=9 / 2$ particles to combine their angular momentum into smaller even values of the total angular momentum $j$. In fact, it is possible for the particles to combine their angular momenta so that they exactly cancel one another; then the net angular momentum $j=0$. That is indicated by the 1 in the $j=0$ column. Classically you would say that the momentum vectors of the two particles are exactly opposite, producing a zero resultant. In quantum mechanics true angular momentum vectors do not exist due to uncertainty of the components, but complete cancelation is still possible.

The $j=0$ set consists of just one state, because $m$ can only be zero for a state with zero angular momentum. The entire table row for two $j^{\mathrm{p}}=9 / 2$ particles could in principle be derived by writing out the appropriate Clebsch-Gordan
coefficients. But that would be one very big table.
If there are five $j^{\mathrm{p}}=9 / 2$ particles. they can combine their angular momenta into quite a wide variety of net angular momentum values. For example, the 2 in the $j=5 / 2$ column indicates that there are two sets of states with combined angular momentum $j=5 / 2$. Each set has 6 members, because for each set $m$ can be any one of $5 / 2,3 / 2, \ldots,-5 / 2$. So there are a total of 12 independent combination states that have net angular momentum $j=5 / 2$.

Note that a shell has $2 j^{\mathrm{p}}+1$ different single-particle states, because the magnetic quantum number $m^{\mathrm{p}}$ can have the values $j^{\mathrm{p}}, j^{\mathrm{p}}-1, \ldots,-j^{\mathrm{p}}$. Therefore a shell can accommodate up to $2 j^{\mathrm{p}}+1$ fermions according to the exclusion principle. However, the table only lists combined angular momentum values for up to $j^{\mathrm{p}}+1 / 2$ particles. The reason is that any more is unnecessary. A given number of "holes" in an otherwise filled shell produces the same combined angular momentum values as the same number of particles in an otherwise empty shell. For example, two fermions in a $j^{\mathrm{p}}=1 / 2$ shell, (zero holes), have the same combined angular momentum as zero particles: zero. Indeed, those two fermions must be in the antisymmetric singlet state with spin zero. In general, a completely filled shell has zero angular momentum and is spherically symmetric.

The same situation for identical bosons is shown in table 12.2. For identical bosons there is no limit to the number of particles that can go into a shell. The table was arbitrarily cut off at 9 particles and a maximum spin of 18 .

### 12.10 Pauli spin matrices

This subsection returns to the simple two-rung spin ladder (doublet) of an electron, or any other spin $1 / 2$ particle for that matter, and tries to tease out some more information about the spin. While the analysis so far has made statements about the angular momentum in the arbitrarily chosen $z$-direction, you often also need information about the spin in the corresponding $x$ and $y$ directions. This subsection will find it.

But before getting at it, a matter of notations. It is customary to indicate angular momentum that is due to spin by a capital $S$. Similarly, the azimuthal quantum number of spin is indicated by $s$. This subsection will follow this convention.

Now, suppose you know that the particle is in the "spin-up" state with $S_{z}$ $=1 / 2 \hbar$ angular momentum in a chosen $z$ direction; in other words that it is in the $|1 / 21 / 2\rangle$, or $\uparrow$, state. You want the effect of the $\widehat{S}_{x}$ and $\widehat{S}_{y}$ operators on this state. In the absence of a physical model for the motion that gives rise to the spin, this may seem like a hard question indeed. But again the faithful ladder operators $\widehat{S}^{+}$and $\widehat{S}^{-}$clamber up and down to your rescue!

Assuming that the normalization factor of the $\downarrow$ state is chosen in terms of the one of the $\uparrow$ state consistent with the ladder relations (12.9) and (12.10),
you have:

$$
\widehat{S}^{+} \uparrow=\left(\widehat{S}_{x}+\mathrm{i} \widehat{S}_{y}\right) \uparrow=0 \quad \widehat{S}^{-} \uparrow=\left(\widehat{S}_{x}-\mathrm{i} \widehat{S}_{y}\right) \uparrow=\hbar \downarrow
$$

By adding or subtracting the two equations, you find the effects of $\widehat{S}_{x}$ and $\widehat{S}_{y}$ on the spin-up state:

$$
\widehat{S}_{x} \uparrow=\frac{1}{2} \hbar \downarrow \quad \widehat{S}_{y} \uparrow=\frac{1}{2} \mathrm{i} \hbar \downarrow
$$

It works the same way for the spin-down state $\downarrow=|1 / 2-1 / 2\rangle$ :

$$
\widehat{S}_{x \downarrow} \downarrow=\frac{1}{2} \hbar \uparrow \quad \widehat{S}_{y \downarrow} \downarrow=-\frac{1}{2} i \hbar \uparrow
$$

You now know the effect of the $x$ and $y$ angular momentum operators on the $z$ direction spin states. Chalk one up for the ladder operators.

Next, assume that you have some spin state that is an arbitrary combination of spin-up and spin-down:

$$
a \uparrow+b \downarrow
$$

Then, according to the expressions above, application of the $x$ spin operator $\widehat{S}_{x}$ will turn it into:

$$
\widehat{S}_{x}(a \uparrow+b \downarrow)=a\left(0 \uparrow+\frac{1}{2} \hbar \downarrow\right)+b\left(\frac{1}{2} \hbar \uparrow+0 \downarrow\right)
$$

while the operator $\widehat{S}_{y}$ turns it into

$$
\widehat{S}_{y}(a \uparrow+b \downarrow)=a\left(0 \uparrow+\frac{1}{2} \hbar \mathrm{i} \downarrow\right)+b\left(-\frac{1}{2} \hbar \mathrm{i} \uparrow+0 \downarrow\right)
$$

And of course, since $\uparrow$ and $\downarrow$ are the eigenstates of $\widehat{S}_{z}$,

$$
\widehat{S}_{z}(a \uparrow+b \downarrow)=a\left(\frac{1}{2} \hbar \uparrow+0 \downarrow\right)+b\left(0 \uparrow-\frac{1}{2} \hbar \downarrow\right)
$$

If you put the coefficients in the formula above, except for the common factor $\frac{1}{2} \hbar$, in little $2 \times 2$ tables, you get the so-called "Pauli spin matrices":

$$
\sigma_{x}=\left(\begin{array}{ll}
0 & 1  \tag{12.15}\\
1 & 0
\end{array}\right) \quad \sigma_{y}=\left(\begin{array}{rr}
0 & -\mathrm{i} \\
\mathrm{i} & 0
\end{array}\right) \quad \sigma_{z}=\left(\begin{array}{rr}
1 & 0 \\
0 & -1
\end{array}\right)
$$

where the convention is that $a$ multiplies the first column of the matrices and $b$ the second. Also, the top rows in the matrices produce the spin-up part of the result and the bottom rows the spin down part. In linear algebra, you also put the coefficients $a$ and $b$ together in a vector:

$$
a \uparrow+b \downarrow \equiv\binom{a}{b}
$$

You can now go further and find the eigenstates of the $\widehat{S}_{x}$ and $\widehat{S}_{y}$ operators in terms of the eigenstates $\uparrow$ and $\downarrow$ of the $\widehat{S}_{z}$ operator. You can use the techniques of linear algebra, or you can guess. For example, if you guess $a=b=1$,

$$
\widehat{S}_{x}\binom{1}{1}=\frac{1}{2} \hbar \sigma_{x}\binom{1}{1}=\frac{1}{2} \hbar\binom{0 \times 1+1 \times 1}{1 \times 1+0 \times 1}=\frac{1}{2} \hbar\binom{1}{1}
$$

so $a=b=1$ is an eigenstate of $\widehat{S}_{x}$ with eigenvalue $\frac{1}{2} \hbar$, call it a $\rightarrow$, "spin-right", state. To normalize the state, you still need to divide by $\sqrt{2}$ :

$$
\rightarrow=\frac{1}{\sqrt{2}} \uparrow+\frac{1}{\sqrt{2}} \downarrow
$$

Similarly, you can guess the other eigenstates, and come up with:

$$
\rightarrow=\frac{1}{\sqrt{2}} \uparrow+\frac{1}{\sqrt{2}} \downarrow \quad \leftarrow=-\frac{\mathrm{i}}{\sqrt{2}} \uparrow+\frac{\mathrm{i}}{\sqrt{2}} \downarrow \quad \otimes=\frac{1}{\sqrt{2}} \uparrow+\frac{\mathrm{i}}{\sqrt{2}} \downarrow \quad \odot=\frac{1}{\sqrt{2}} \uparrow-\frac{\mathrm{i}}{\sqrt{2}} \downarrow
$$

Note that the square magnitudes of the coefficients of the states are all one half, giving a $50 / 50$ chance of finding the $z$-momentum up or down. Since the choice of the axis system is arbitrary, this can be generalized to mean that if the spin in a given direction has an definite value, then there will be a $50 / 50$ chance of the spin in any orthogonal direction turning out to be $\frac{1}{2} \hbar$ or $-\frac{1}{2} \hbar$.

You might wonder about the choice of normalization factors in the spin states (12.16). For example, why not leave out the common factor i in the $\leftarrow$, (negative $x$ spin, or spin-left), state? The reason is to ensure that the $x$ direction ladder operator $\widehat{S}_{y} \pm \mathrm{i} \widehat{S}_{z}$ and the $y$-direction one $\widehat{S}_{z} \pm \mathrm{i} \widehat{S}_{x}$, as obtained by cyclic permutation of the ones for $z$, produce real, positive multiplication factors. This allows relations valid in the $z$-direction (like the expressions for triplet and singlet states) to also apply in the $x$ and $y$ directions. In addition, with this choice, if you do a simple change in the labeling of the axes, from $x y z$ to $y z x$ or $z x y$, the form of the Pauli spin matrices remains unchanged. The $\rightarrow$ and $\otimes$ states of positive $x$-, respectively $y$-momentum were chosen a different way: if you rotate the axis system $90^{\circ}$ around the $y$ or $x$ axis, these are the spin-up states along the new $z$-axis, the $x$-axis or $y$-axis in the system you are looking at now, $\{\mathrm{D} .68\}$.

### 12.11 General spin matrices

The arguments that produced the Pauli spin matrices for a system with spin $1 / 2$ work equally well for systems with larger square angular momentum.

In particular, from the definition of the ladder operators

$$
\widehat{J}^{+} \equiv \widehat{J}_{x}+\mathrm{i} \widehat{J}_{y} \quad \widehat{J}^{-} \equiv \widehat{J}_{x}-\mathrm{i} \widehat{J}_{y}
$$

it follows by taking the sum, respectively difference, that

$$
\begin{equation*}
\widehat{J}_{x}=\frac{1}{2} \widehat{J}^{+}+\frac{1}{2} \widehat{J}^{-} \quad \widehat{J}_{y}=-\mathrm{i} \frac{1}{2} \widehat{J}^{+}+\mathrm{i} \frac{1}{2} \widehat{J}^{-} \tag{12.17}
\end{equation*}
$$

Therefore, the effect of either $\widehat{J}_{x}$ or $\widehat{J}_{y}$ is to produce multiples of the states with the next higher and the next lower magnetic quantum number. The multiples can be determined using (12.9) and (12.10).

If you put these multiples again in matrices, after ordering the states by magnetic quantum number, you get Hermitian tridiagonal matrices with nonzero sub and superdiagonals and zero main diagonal, where $\widehat{J}_{x}$ is real symmetric while $\widehat{J}_{y}$ is purely imaginary, equal to i times a real skew-symmetric matrix. Be sure to tell all you friends that you heard it here first. Do watch out for the well-informed friend who may be aware that forming such matrices is bad news anyway since they are almost all zeros. If you want to use canned matrix software, at least use the kind for tridiagonal matrices.

### 12.12 The Relativistic Dirac Equation

Relativity threw up some road blocks when quantum mechanics was first formulated, especially for the particles physicist wanted to look at most, electrons. This section explains some of the ideas.

You will need a good understanding of linear algebra to really follow the reasoning. A summary of the Dirac equation that is less heavy on the linear algebra can be found in $\{\mathrm{A} .44\}$.

For zero spin particles, including relativity appears to be simple. The classical kinetic energy Hamiltonian for a particle in free space,

$$
H=\frac{1}{2 m} \sum_{i=1}^{3} \widehat{p}_{i}^{2} \quad \widehat{p}_{i}=\frac{\hbar}{\mathrm{i}} \frac{\partial}{\partial r_{i}}
$$

can be replaced by Einstein's relativistic expression

$$
H=\sqrt{\left(m c^{2}\right)^{2}+\sum_{i=1}^{3}\left(\widehat{p}_{i} c\right)^{2}}
$$

where $m$ is the rest mass of the particle and $m c^{2}$ is the energy this mass is equivalent to. You can again write $H \psi=E \psi$, or squaring the operators in both sides to get rid of the square root:

$$
\left[\left(m c^{2}\right)^{2}+\sum_{i=1}^{3}\left(\widehat{p}_{i} c\right)^{2}\right] \psi=E^{2} \psi
$$

This is the "Klein-Gordon" relativistic version of the Hamiltonian eigenvalue problem. With a bit of knowledge of partial differential equations, you can check that the unsteady version, chapter 7.1 , obeys the speed of light as the maximum propagation speed, as you would expect, chapter 8.6.

Unfortunately, throwing a dash of spin into this recipe simply does not seem to work in a convincing way. Apparently, that very problem led Schrödinger to limit himself to the nonrelativistic case. It is hard to formulate simple equations with an ugly square root in your way, and surely, you will agree, the relativistic equation for something so very fundamental as an electron in free space should be simple and beautiful like other fundamental equations in physics. (Can you be more concise than $\vec{F}=m \vec{a}$ or $E=m c^{2}$ ?).

So P.A.M. Dirac boldly proposed that for a particle like an electron, (and other spin $1 / 2$ elementary particles like quarks, it turned out,) the square root produces a simple linear combination of the individual square root terms:

$$
\begin{equation*}
\sqrt{\left(m c^{2}\right)^{2}+\sum_{i=1}^{3}\left(\widehat{p}_{i} c\right)^{2}}=\alpha_{0} m c^{2}+\sum_{i=1}^{3} \alpha_{i} \widehat{p}_{i} c \tag{12.18}
\end{equation*}
$$

for suitable coefficients $\alpha_{0}, \alpha_{1}, \alpha_{2}$ and $\alpha_{3}$. Now, if you know a little bit of algebra, you will quickly recognize that there is absolutely no way this can be true. The teacher will have told you that, say, a function like $\sqrt{x^{2}+y^{2}}$ is definitely not the same as the function $\sqrt{x^{2}}+\sqrt{y^{2}}=x+y$, otherwise the Pythagorean theorem would look a lot different, and adding coefficients as in $\alpha_{1} x+\alpha_{2} y$ does not do any good at all.

But here is the key: while this does not work for plain numbers, Dirac showed it is possible if you are dealing with matrices, tables of numbers. In particular, it works if the coefficients are given by

$$
\alpha_{0}=\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right) \quad \alpha_{1}=\left(\begin{array}{cc}
0 & \sigma_{x} \\
\sigma_{x} & 0
\end{array}\right) \quad \alpha_{2}=\left(\begin{array}{cc}
0 & \sigma_{y} \\
\sigma_{y} & 0
\end{array}\right) \quad \alpha_{3}=\left(\begin{array}{cc}
0 & \sigma_{z} \\
\sigma_{z} & 0
\end{array}\right)
$$

This looks like $2 \times 2$ size matrices, but actually they are $4 \times 4$ matrices since all elements are $2 \times 2$ matrices themselves: the ones stand for $2 \times 2$ unit matrices, the zeros for $2 \times 2$ zero matrices, and the $\sigma_{x}, \sigma_{y}$ and $\sigma_{z}$ are the so-called $2 \times 2$ Pauli spin matrices that also pop up in the theory of spin angular momentum, section 12.10. The square root cannot be eliminated with matrices smaller than $4 \times 4$ in actual size. (A derivation is in \{D.70\}. See also $\{$ A. 36$\}$ for alternate forms of the equation.)

Now if the Hamiltonian is a $4 \times 4$ matrix, the wave function at any point must have four components. As you might guess from the appearance of the spin matrices, half of the explanation of the wave function splitting into four is the two spin states of the electron. How about the other half? It turns out that the Dirac equation brings with it states of negative total energy, in particular negative rest mass energy.

That was of course a curious thing. Consider an electron in what otherwise is an empty vacuum. What prevents the electron from spontaneously transitioning to the negative rest mass state, releasing twice its rest mass in energy? Dirac concluded that what is called empty vacuum should in the mathematics of quantum mechanics be taken to be a state in which all negative energy states are already filled with electrons. Clearly, that requires the Pauli exclusion principle to be valid for electrons, otherwise the electron could still transition into such a state. According to this idea, nature really does not have a free choice in whether to apply the exclusion principle to electrons if it wants to create a universe as we know it.

But now consider the vacuum without the electron. What prevents you from adding a big chunk of energy and lifting an electron out of a negative rest-mass state into a positive one? Nothing, really. It will produce a normal electron and a place in the vacuum where an electron is missing, a "hole". And here finally Dirac's boldness appears to have deserted him; he shrank from proposing that this hole would physically show up as the exact antithesis of the electron, its anti-particle, the positively charged positron. Instead Dirac weakly pointed the finger at the proton as a possibility. "Pure cowardice," he called it later. The positron that his theory really predicted was subsequently discovered anyway. (It had already been observed earlier, but was not recognized.)

The reverse of the production of an electron/positron pair is pair annihilation, in which a positron and an electron eliminate each other, creating two gamma-ray photons. There must be two, because viewed from the combined center of mass, the net momentum of the pair is zero, and momentum conservation says it must still be zero after the collision. A single photon would have nonzero momentum, you need two photons coming out in opposite directions. However, pairs can be created from a single photon with enough energy if it happens in the vicinity of, say, a heavy nucleus: a heavy nucleus can absorb the momentum of the photon without picking up much velocity, so without absorbing too much of the photon's energy.

The Dirac equation also gives a very accurate prediction of the magnetic moment of the electron, section 13.4, though the quantum electromagnetic field affects the electron and introduces a correction of about a tenth of a percent. But the importance of the Dirac equation was much more than that: it was the clue to our understanding how quantum mechanics can be reconciled with relativity, where particles are no longer absolute, but can be created out of nothing or destroyed according to the mass-energy relation $E=m c^{2}$, chapter 1.1.2.

Dirac was a theoretical physicist at Cambridge University, but he moved to Florida in his later life to be closer to his elder daughter, and was a professor of physics at the Florida State University when I got there. So it gives me some pleasure to include the Dirac equation in my text as the corner stone of relativistic quantum mechanics.

## Chapter 13

## Electromagnetism

This chapter explains how quantum mechanics deals with electromagnetic effects.

Some more advanced topics will be left to introductory addenda. That includes how the solution for the hydrogen atom may be corrected for relativistic effects, $\{\mathrm{A} .39\}$, using perturbation theory, $\{$ A. 38$\}$. It also includes the quantization of the electromagnetic field, $\{\mathrm{A} .23\}$, using quantum field theory, $\{\mathrm{A} .15\}$.

Electromagnetics is closely tied to more advanced concepts in angular momentum and relativity. These have been discussed in chapters 1 and 12 .

### 13.1 The Electromagnetic Hamiltonian

This section describes very basically how electromagnetism fits into quantum mechanics. However, electromagnetism is fundamentally relativistic; its carrier, the photon, readily emerges or disappears. To describe electromagnetic effects fully requires quantum electrodynamics, and that is far beyond the scope of this text. (However, see addenda $\{$ A. 15$\}$ and $\{$ A. 23$\}$ for some of the ideas.)

In classical electromagnetics, the force on a particle with charge $q$ in a field with electric strength $\overrightarrow{\mathcal{E}}$ and magnetic strength $\overrightarrow{\mathcal{B}}$ is given by the Lorentz force law

$$
\begin{equation*}
m \frac{\mathrm{~d} \vec{v}}{\mathrm{~d} t}=q(\overrightarrow{\mathcal{E}}+\vec{v} \times \overrightarrow{\mathcal{B}}) \tag{13.1}
\end{equation*}
$$

where $\vec{v}$ is the velocity of the particle and for an electron, the charge is $q=-e$
Unfortunately, quantum mechanics uses neither forces nor velocities. In fact, the earlier analysis of atoms and molecules in this book used the fact that the electric field is described by the corresponding potential energy $V$, see for example the Hamiltonian of the hydrogen atom. The magnetic field must appear differently in the Hamiltonian; as the Lorentz force law shows, it couples with velocity. You would expect that still the Hamiltonian would be relatively simple, and the simplest idea is then that any potential corresponding to the
magnetic field moves in together with momentum. Since the momentum is a vector quantity, then so must be the magnetic potential. So, your simplest guess would be that the Hamiltonian takes the form

$$
\begin{equation*}
H=\frac{1}{2 m}(\widehat{\vec{p}}-q \vec{A})^{2}+q \varphi \tag{13.2}
\end{equation*}
$$

where $\varphi=V / q$ is the "electric potential" and $\vec{A}$ is the "magnetic vector potential." And this simplest guess is in fact right

The relationship between the vector potential $\vec{A}$ and the magnetic field strength $\overrightarrow{\mathcal{B}}$ will now be found from requiring that the classical Lorentz force law is obtained in the classical limit that the quantum uncertainties in position and momentum are small. In that case, expectation values can be used to describe position and velocity, and the field strengths $\overrightarrow{\mathcal{E}}$ and $\overrightarrow{\mathcal{B}}$ will be constant on the small quantum scales. That means that the derivatives of $\varphi$ will be constant, (since $\overrightarrow{\mathcal{E}}$ is the negative gradient of $\varphi$ ), and presumably the same for the derivatives of $\vec{A}$.

Now according to chapter 7.2, the evolution of the expectation value of position is found as

$$
\frac{\mathrm{d}\langle\widehat{\vec{r}}\rangle}{\mathrm{d} t}=\left\langle\frac{\mathrm{i}}{\hbar}[H, \vec{r}]\right\rangle
$$

Working out the commutator with the Hamiltonian above, $\{$ D.71\}, you get,

$$
\frac{\mathrm{d}\langle\widehat{\vec{r}}\rangle}{\mathrm{d} t}=\frac{1}{m}\langle\widehat{\vec{p}}-q \vec{A}\rangle
$$

This is unexpected; it shows that $\widehat{\vec{p}}$, i.e. $\hbar \nabla / \mathrm{i}$, is no longer the operator of the normal momentum $m \vec{v}$ when there is a magnetic field; $\overrightarrow{\vec{p}}-q \vec{A}$ gives the normal momentum. The momentum represented by $\widehat{\vec{p}}$ by itself is called "canonical" momentum to distinguish it from normal momentum:

The canonical momentum $\hbar \nabla / \mathrm{i}$ only corresponds to normal momentum if there is no magnetic field involved.
(Actually, it was not that unexpected to physicists, since the same happens in the classical description of electromagnetics using the so-called Lagrangian approach, chapter 1.3.2.)

Next, Newton's second law says that the time derivative of the linear momentum $m \vec{v}$ is the force. Since according to the above, the linear momentum operator is $\widehat{\vec{p}}-q \vec{A}$, then

$$
m \frac{\mathrm{~d}\langle\vec{v}\rangle}{\mathrm{d} t}=\frac{\mathrm{d}\langle\widehat{\vec{p}}-q \vec{A}\rangle}{\mathrm{d} t}=\left\langle\frac{\mathrm{i}}{\hbar}[H, \widehat{\vec{p}}-q \vec{A}]\right\rangle-q\left\langle\frac{\partial \vec{A}}{\partial t}\right\rangle
$$

The objective is now to ensure that the right hand side is the correct Lorentz force (13.1) for the assumed Hamiltonian, by a suitable definition of $\overrightarrow{\mathcal{B}}$ in terms of $\vec{A}$.

After a lot of grinding down commutators, $\{$ D. 71$\}$, it turns out that indeed the Lorentz force is obtained,

$$
m \frac{\mathrm{~d}\langle\vec{v}\rangle}{\mathrm{d} t}=q(\overrightarrow{\mathcal{E}}+\langle\vec{v}\rangle \times \overrightarrow{\mathcal{B}})
$$

provided that:

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=-\nabla \varphi-\frac{\partial \vec{A}}{\partial t} \quad \overrightarrow{\mathcal{B}}=\nabla \times \vec{A} \tag{13.3}
\end{equation*}
$$

So the magnetic field is found as the curl of the vector potential $\vec{A}$. And the electric field is no longer just the negative gradient of the scalar potential $\varphi$ if the vector potential varies with time.

These results are not new. The electric scalar potential $\varphi$ and the magnetic vector potential $\vec{A}$ are the same in classical physics, though they are a lot less easy to guess than done here. Moreover, in classical physics they are just convenient mathematical quantities to simplify analysis. In quantum mechanics they appear as central to the formulation.

And it can make a difference. Suppose you do an experiment where you pass electron wave functions around both sides of a very thin magnet: you will get a wave interference pattern behind the magnet. The classical expectation is that this interference pattern will be independent of the magnet strength: the magnetic field $\overrightarrow{\mathcal{B}}$ outside a very thin and long ideal magnet is zero, so there is no force on the electron. But the magnetic vector potential $\vec{A}$ is not zero outside the magnet, and Aharonov and Bohm argued that the interference pattern would therefore change with magnet strength. So it turned out to be in experiments done subsequently. The conclusion is clear; nature really goes by the vector potential $\vec{A}$ and not the magnetic field $\overrightarrow{\mathcal{B}}$ in its actual workings.

### 13.2 Maxwell's Equations

Maxwell's equations are commonly not covered in a typical engineering program. While these laws are not directly related to quantum mechanics, they do tend to pop up in nanotechnology. This section intends to give you some of the ideas. The description is based on the divergence and curl spatial derivative operators, and the related Gauss and Stokes theorems commonly found in calculus courses (Calculus III in the US system.)

Skipping the first equation for now, the second of Maxwell's equations comes directly out of the quantum mechanical description of the previous section. Consider the expression for the magnetic field $\overrightarrow{\mathcal{B}}$ "derived" (guessed) there,
(13.3). If you take its divergence, (premultiply by $\nabla \cdot$ ), you get rid of the vector potential $\vec{A}$, since the divergence of any curl is always zero, so you get

$$
\begin{equation*}
\text { Maxwell's second equation: } \quad \nabla \cdot \overrightarrow{\mathcal{B}}=0 \tag{13.4}
\end{equation*}
$$

and that is the second of Maxwell's four beautifully concise equations. (The compact modern notation using divergence and curl is really due to Heaviside and Gibbs, though.)

The first of Maxwell's equations is a similar expression for the electric field $\overrightarrow{\mathcal{E}}$, but its divergence is not zero:

$$
\begin{equation*}
\text { Maxwell's first equation: } \quad \nabla \cdot \overrightarrow{\mathcal{E}}=\frac{\rho}{\epsilon_{0}} \tag{13.5}
\end{equation*}
$$

where $\rho$ is the electric charge per unit volume that is present and the constant $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is called the permittivity of space.

Figure 13.1: Relationship of Maxwell's first equation to Coulomb's law.
What does it all mean? Well, the first thing to verify is that Maxwell's first equation is just a very clever way to write Coulomb's law for the electric field of a point charge. Consider therefore an electric point charge of strength $q$, and imagine this charge surrounded by a translucent sphere of radius $r$, as shown in figure 13.1. By symmetry, the electric field at all points on the spherical surface is radial, and everywhere has the same magnitude $\mathcal{E}=|\overrightarrow{\mathcal{E}}|$; figure 13.1 shows it for eight selected points.

Now watch what happens if you integrate both sides of Maxwell's first equation (13.5) over the interior of this sphere. Starting with the right hand side, since the charge density is the charge per unit volume, by definition its integral over the volume is the charge $q$. So the right hand side integrates simply to $q / \epsilon_{0}$. How about the left hand side? Well, the Gauss, or divergence, theorem of calculus says that the divergence of any vector, $\overrightarrow{\mathcal{E}}$ in this case, integrated over
the volume of the sphere, equals the radial electric field $\mathcal{E}$ integrated over the surface of the sphere. Since $\mathcal{E}$ is constant on the surface, and the surface of a sphere is just $4 \pi r^{2}$, the right hand side integrates to $4 \pi r^{2} \mathcal{E}$. So in total, you get for the integrated first Maxwell's equation that $4 \pi r^{2} \mathcal{E}=q / \epsilon_{0}$. Take the $4 \pi r^{2}$ to the other side and there you have the Coulomb electric field of a point charge:

$$
\begin{equation*}
\text { Coulomb's law: } \quad \mathcal{E}=\frac{q}{4 \pi r^{2} \epsilon_{0}} \tag{13.6}
\end{equation*}
$$

Multiply by $-e$ and you have the electrostatic force on an electron in that field according to the Lorentz equation (13.1). Integrate with respect to $r$ and you have the potential energy $V=-q e / 4 \pi \epsilon_{0} r$ that has been used earlier to analyze atoms and molecules.

Of course, all this raises the question, why bother? If Maxwell's first equation is just a rewrite of Coulomb's law, why not simply stick with Coulomb's law in the first place? Well, to describe the electric field at a given point using Coulomb's law requires you to consider every charge everywhere else. In contrast, Maxwell's equation only involves local quantities at the given point, to wit, the derivatives of the local electric field and the local charge per unit volume. It so happens that in numerical or analytical work, most of the time it is much more convenient to deal with local quantities, even if those are derivatives, than with global ones.

Figure 13.2: Maxwell's first equation for a more arbitrary region. The figure to the right includes the field lines through the selected points.

Of course, you can also integrate Maxwell's first equation over more general regions than a sphere centered around a charge. For example figure 13.2 shows a sphere with an off-center charge. But the electric field strength is no longer constant over the surface, and divergence theorem now requires you to integrate the component of the electric field normal to the surface over the surface. Clearly, that does not have much intuitive meaning. However, if you are willing
to loosen up a bit on mathematical preciseness, there is a better way to look at it. It is in terms of the "electric field lines", the lines that everywhere trace the direction of the electric field. The left figure in figure 13.2 shows the field lines through the selected points; a single charge has radial field lines.

Figure 13.3: The net number of field lines leaving a region is a measure for the net charge inside that region.

Assume that you draw the field lines densely, more like figure 13.3 say, and moreover, that you make the number of field lines coming out of a charge proportional to the strength of that charge. In that case, the local density of field lines at a point becomes a measure of the strength of the electric field at that point, and in those terms, Maxwell's integrated first equation says that the net number of field lines leaving a region is proportional to the net charge inside that region. That remains true when you add more charges inside the region. In that case the field lines will no longer be straight, but the net number going out will still be a measure of the net charge inside.

Now consider the question why Maxwell's second equation says that the divergence of the magnetic field is zero. For the electric field you can shove, say, some electrons in the region to create a net negative charge, or you can shove in some ionized molecules to create a net positive charge. But the magnetic equivalents to such particles, called "magnetic monopoles", being separate magnetic north pole particles or magnetic south pole particles, simply do not exist, $\{\mathrm{N} .31\}$. It might appear that your bar magnet has a north pole and a south pole, but if you take it apart into little pieces, you do not end up with north pole pieces and south pole pieces. Each little piece by itself is still a little magnet, with equally strong north and south poles. The only reason the com-
bined magnet seems to have a north pole is that all the microscopic magnets of which it consists have their north poles preferentially pointed in that direction.

Figure 13.4: Since magnetic monopoles do not exist, the net number of magnetic field lines leaving a region is always zero.

If all microscopic magnets have equal strength north and south poles, then the same number of magnetic field lines that come out of the north poles go back into the south poles, as figure 13.4 illustrates. So the net magnetic field lines leaving a given region will be zero; whatever goes out comes back in. True, if you enclose the north pole of a long bar magnet by an imaginary sphere, you can get a pretty good magnetic approximation of the electrical case of figure 13.1. But even then, if you look inside the magnet where it sticks through the spherical surface, the field lines will be found to go in towards the north pole, instead of away from it. You see why Maxwell's second equation is also called "absence of magnetic monopoles." And why, say, electrons can have a net negative charge, but have zero magnetic pole strength; their spin and orbital angular momenta produce equally strong magnetic north and south poles, a magnetic "dipole" (di meaning two.)

You can get Maxwell's third equation from the electric field "derived" in the previous section. If you take its curl, (premultiply by $\nabla \times$ ), you get rid of the potential $\varphi$, since the curl of any gradient is always zero, and the curl of $\vec{A}$ is the magnetic field. So the third of Maxwell's equations is:

$$
\begin{equation*}
\nabla \times \overrightarrow{\mathcal{E}}=-\frac{\partial \overrightarrow{\mathcal{B}}}{\partial t} \tag{13.7}
\end{equation*}
$$

The "curl", $\nabla \times$, is also often indicated as "rot".

Figure 13.5: Electric power generation.

Now what does that one mean? Well, the first thing to verify in this case is that this is just a clever rewrite of Faraday's law of induction, governing electric power generation. Assume that you want to create a voltage to drive some load (a bulb or whatever, don't worry what the load is, just how to get the voltage for it.) Just take a piece of copper wire and bend it into a circle, as shown in figure 13.5. If you can create a voltage difference between the ends of the wire you are in business; just hook your bulb or whatever to the ends of the wire and it will light up. But to get such a voltage, you will need an electric field as shown in figure 13.5 because the voltage difference between the ends is the integral of the electric field strength along the length of the wire. Now Stokes' theorem of calculus says that the electric field strength along the wire integrated over the length of the wire equals the integral of the curl of the electric field strength integrated over the inside of the wire, in other words over the imaginary translucent circle in figure 13.5. So to get the voltage, you need a nonzero curl of the electric field on the translucent circle. And Maxwell's third equation above says that this means a time-varying magnetic field on the translucent circle. Moving the end of a strong magnet closer to the circle should do it, as suggested by figure 13.5. You better not make that a big bulb unless you you wrap the wire around a lot more times to form a spool, but anyway. \{N.32\}.

Maxwell's fourth and final equation is a similar expression for the curl of the magnetic field:

$$
\begin{equation*}
\text { Maxwell's fourth equation: } \quad c^{2} \nabla \times \overrightarrow{\mathcal{B}}=\frac{\vec{\jmath}}{\epsilon_{0}}+\frac{\partial \overrightarrow{\mathcal{E}}}{\partial t} \tag{13.8}
\end{equation*}
$$

where $\vec{\jmath}$ is the "electric current density," the charge flowing per unit cross sectional area, and $c$ is the speed of light. (It is possible to rescale $\overrightarrow{\mathcal{B}}$ by a factor $c$ to get the speed of light to show up equally in the equations for the curl of $\overrightarrow{\mathcal{E}}$ and the curl of $\overrightarrow{\mathcal{B}}$, but then the Lorentz force law must be adjusted too.)

Figure 13.6: Two ways to generate a magnetic field: using a current (left) or using a varying electric field (right).

The big difference from the third equation is the appearance of the current density $\vec{\jmath}$. So, there are two ways to create a circulatory magnetic field, as shown in figure 13.6: (1) pass a current through the enclosed circle (the current density integrates over the area of the circle into the current through the circle), and (2) by creating a varying electric field over the circle, much like was done for the electric field in figure 13.5.

The fact that a current creates a surrounding magnetic field was already known as Ampere's law when Maxwell did his analysis. Maxwell himself however added the time derivative of the electric field to the equation to have the mathematics make sense. The problem was that the divergence of any curl must be zero, and by itself, the divergence of the current density in the right hand side of the fourth equation is not zero. Just like the divergence of the electric field is the net field lines coming out of a region per unit volume, the divergence of the current density is the net current coming out. And it is perfectly OK for a net charge to flow out of a region: it simply reduces the charge remaining within the region by that amount. This is expressed by the "continuity equation:"

$$
\begin{equation*}
\text { Maxwell's continuity equation: } \quad \nabla \cdot \vec{\jmath}=-\frac{\partial \rho}{\partial t} \tag{13.9}
\end{equation*}
$$

So Maxwell's fourth equation without the time derivative of the electric field is mathematically impossible. But after he added it, if you take the divergence of the total right hand side then you do indeed get zero as you should. To check that, use the continuity equation above and the first equation.

In empty space, Maxwell's equations simplify: there are no charges so both the charge density $\rho$ and the current density $\vec{\jmath}$ will be zero. In that case, the solutions of Maxwell's equations are simply combinations of "traveling waves." A traveling wave takes the form

$$
\begin{equation*}
\overrightarrow{\mathcal{E}}=\hat{k} \mathcal{E}_{0} \cos (\omega(t-y / c)-\alpha) \quad \overrightarrow{\mathcal{B}}=\hat{\imath} \frac{1}{c} \mathcal{E}_{0} \cos (\omega(t-y / c)-\alpha) \tag{13.10}
\end{equation*}
$$

where for simplicity, the $y$-axis of the coordinate system has been aligned with the direction in which the wave travels, and the $z$-axis with the amplitude $\hat{k} \mathcal{E}_{0}$ of the electric field of the wave. Such a wave is called "linearly polarized" in the $z$-direction. The constant $\omega$ is the angular frequency of the wave, equal to $2 \pi$ times its frequency $\nu$ in cycles per second, and is related to its wave length $\lambda$ by $\omega \lambda / c=2 \pi$. The constant $\alpha$ is just a phase angle. For these simple waves, the magnetic and electric field must be normal to each other, as well as to the direction of wave propagation.

You can plug the above wave solution into Maxwell's equations and so verify that it satisfies them all. With more effort and knowledge of Fourier analysis, you can show that they are the most general possible solutions that take this traveling wave form, and that any arbitrary solution is a combination of these waves (if all directions of the propagation direction and of the electric field relative to it, are included.)

The point is that the waves travel with the speed $c$. When Maxwell wrote down his equations, $c$ was just a constant to him, but when the propagation speed of electromagnetic waves matched the experimentally measured speed of light, it was just too much of a coincidence and he correctly concluded that light must be traveling electromagnetic waves.

It was a great victory of mathematical analysis. Long ago, the Greeks had tried to use mathematics to make guesses about the physical world, and it was an abysmal failure. You do not want to hear about it. Only when the Renaissance started measuring how nature really works, the correct laws were discovered for people like Newton and others to put into mathematical form. But here, Maxwell successfully amends Ampere's measured law, just because the mathematics did not make sense. Moreover, by deriving how fast electromagnetic waves move, he discovers the very fundamental nature of the then mystifying physical phenomenon humans call light.

For those with a knowledge of partial differential equations, separate wave equations for the electric and magnetic fields and their potentials are derived in addendum $\{\mathrm{A} .37\}$.

An electromagnetic field obviously contains energy; that is how the sun transports heat to our planet. The electromagnetic energy within an otherwise empty volume $\mathcal{V}$ can be found as

$$
\begin{equation*}
E_{\mathcal{V}}=\frac{1}{2} \epsilon_{0} \int_{\mathcal{V}}\left(\overrightarrow{\mathcal{E}}^{2}+c^{2} \overrightarrow{\mathcal{B}}^{2}\right) \mathrm{d}^{3} \vec{r} \tag{13.11}
\end{equation*}
$$

This is typically derived by comparing the energy from discharging a condenser to the electric field that it initially holds, and from comparing the energy from discharging a coil to the magnetic field it initially holds. That is too much detail for this book.

But at least the result can be made plausible. First note that the time derivative of the energy above can be written as

$$
\frac{\mathrm{d} E_{\mathcal{V}}}{\mathrm{d} t}=-\int_{S} \epsilon_{0} c(\overrightarrow{\mathcal{E}} \times c \overrightarrow{\mathcal{B}}) \cdot \vec{n} \mathrm{~d} S
$$

Here $S$ is the surface of volume $\mathcal{V}$, and $\vec{n}$ is the unit vector normal to the surface element $\mathrm{d} S$. To verify this expression, bring the time derivative inside the integral in (13.11), then get rid of the time derivatives using Maxwell's third and fourth laws, use the standard vector identity [41, 20.40], and finally the divergence theorem.

Now suppose you have a finite amount of radiation in otherwise empty space. If the amount of radiation is finite, the field should disappear at infinity. So, taking the volume to be all of space, the integral in the right hand side above will be zero. So $E_{\mathcal{V}}$ will be constant. That indicates that $E_{\mathcal{V}}$ should be at least a multiple of the energy. After all, what other scalar quantity than energy would be constant? And the factor $\epsilon_{0}$ is needed because of units. That misses only the factor $\frac{1}{2}$ in the expression for the energy.

For an arbitrary volume $\mathcal{V}$, the surface integral must then be the energy outflow through the surface of the volume. That suggests that the energy flow rate per unit area is given by the so-called "Poynting vector"

$$
\begin{equation*}
\epsilon_{0} c \overrightarrow{\mathcal{E}} \times c \overrightarrow{\mathcal{B}} \tag{13.12}
\end{equation*}
$$

Unfortunately, this argument is flawed. You cannot deduce local values of the energy flow from its integral over an entire closed surface. In particular, you can find different vectors that describe the energy flow also without inconsistency. Just add an arbitrary solenoidal vector, a vector whose divergence is zero, to the Poynting vector. For example, adding a multiple of the magnetic field would do it. However, if you look at simple lightwaves like (13.10), the Poynting vector seems the intuitive choice. This paragraph was included because other books have Poynting vectors and you would be very disappointed if yours did not.

You will usually not find Maxwell's equations in the exact form described here. To explain what is going on inside materials, you would have to account
for the electric and magnetic fields of every electron and proton (and neutron!) of the material. That is just an impossible task, so physicists have developed ways to average away all those effects by messing with Maxwell's equations. But then the messed-up $\overrightarrow{\mathcal{E}}$ in one of Maxwell's equations is no longer the same as the messed-up $\overrightarrow{\mathcal{E}}$ in another, and the same for $\overrightarrow{\mathcal{B}}$. So physicists rename one messedup $\overrightarrow{\mathcal{E}}$ as, maybe, the "electric flux density" $\vec{D}$, and a messed up magnetic field as, maybe, "the auxiliary field". And they define many other symbols, and even refer to the auxiliary field as being the magnetic field, all to keep engineers out of nanotechnology. Don't let them! When you need to understand the messed-up Maxwell's equations, Wikipedia has a list of the countless definitions.

### 13.3 Example Static Electromagnetic Fields

In this section, some basic solutions of Maxwell's equations are described. They will be of interest in addendum \{A.39\} for understanding relativistic effects on the hydrogen atom (though certainly not essential). They are also of considerable practical importance for a lot of nonquantum applications.

It is assumed throughout this subsection that the electric and magnetic fields do not change with time. All solutions also assume that the ambient medium is vacuum.

For easy reference, Maxwell's equations and various results to be obtained in this section are collected together in tables 13.1 and 13.2. While the existence of magnetic monopoles is unverified, it is often convenient to compute as if they do exist. It allows you to apply ideas from the electric field to the magnetic field and vice-versa. So, the tables include magnetic monopoles with strength $q_{m}$, in addition to electric charges with strength $q$, and a magnetic current density $\vec{\jmath}_{m}$ in addition to an electric current density $\vec{\jmath}$. The table uses the permittivity of space $\epsilon_{0}$ and the speed of light $c$ as basic physical constants; the permeability of space $\mu_{0}=1 / \epsilon_{0} c^{2}$ is just an annoyance in quantum mechanics and is avoided. The table has been written in terms of $c \overrightarrow{\mathcal{B}}$ and $\vec{\jmath}_{m} / c$ because in terms of those combinations Maxwell's equations have a very pleasing symmetry. It allows you to easily convert between expressions for the electric and magnetic fields. You wish that physicists would have defined the magnetic field as $c \overrightarrow{\mathcal{B}}$ instead of $\overrightarrow{\mathcal{B}}$ in SI units, but no such luck.

### 13.3.1 Point charge at the origin

A point charge is a charge concentrated at a single point. It is a very good model for the electric field of the nucleus of an atom, since the nucleus is so small compared to the atom. A point charge of strength $q$ located at the origin has a charge density

$$
\begin{equation*}
\text { point charge at the origin: } \quad \rho(\vec{r})=q \delta^{3}(\vec{r}) \tag{13.13}
\end{equation*}
$$

Physical constants:
$\epsilon_{0}=8.854187817 \ldots 10^{-12} \mathrm{C}^{2} / \mathrm{Nm}^{2} \quad c=299792458 \mathrm{~m} / \mathrm{s} \approx 310^{8} \mathrm{~m} / \mathrm{s}$
Lorentz force law:

$$
\vec{F}=q\left(\overrightarrow{\mathcal{E}}+\frac{\vec{v}}{c} \times c \overrightarrow{\mathcal{B}}\right)+\frac{q_{m}}{c}\left(c \overrightarrow{\mathcal{B}}-\frac{\vec{v}}{c} \times \overrightarrow{\mathcal{E}}\right)
$$

Maxwell's equations:

$$
\begin{array}{cc}

Table 13.2: Electromagnetics II: Electromagnetostatic solutions.
where $\delta^{3}(\vec{r})$ is the three-dimensional delta function. A delta function is a spike at a single point that integrates to one, so the charge density above integrates to the total charge $q$.

The electric field lines of a point charge are radially outward from the charge; see for example figure 13.3 in the previous subsection. According to Coulomb's law, the electric field of a point charge is

$$
\begin{equation*}
\text { electric field of a point charge: } \overrightarrow{\mathcal{E}}=\frac{q}{4 \pi \epsilon_{0} r^{2}} \hat{\imath}_{r} \tag{13.14}
\end{equation*}
$$

where $r$ is the distance from the charge, $\hat{\imath}_{r}$ is the unit vector pointing straight away from the charge, and $\epsilon_{0}=8.8510^{-12} \mathrm{C}^{2} / \mathrm{J} \mathrm{m}$ is the permittivity of space. Now for static electric charges the electric field is minus the gradient of a potential $\varphi$,

$$
\overrightarrow{\mathcal{E}}=-\nabla \varphi \quad \nabla \equiv \hat{\imath} \frac{\partial}{\partial x}+\hat{\jmath} \frac{\partial}{\partial y}+\hat{k} \frac{\partial}{\partial z}
$$

In everyday terms the potential $\varphi$ is called the "voltage." It follows by integration of the electric field strength with respect to $r$ that the potential of a point charge is

$$
\begin{equation*}
\text { electric potential of a point charge: } \quad \varphi=\frac{q}{4 \pi \epsilon_{0} r} \tag{13.15}
\end{equation*}
$$

Multiply by $-e$ and you get the potential energy $V$ of an electron in the field of the point charge. That was used in writing the Hamiltonians of the hydrogen and heavier atoms.

Delta functions are often not that easy to work with analytically, since they are infinite and infinity is a tricky mathematical thing. It is often easier to do the mathematics by assuming that the charge is spread out over a small sphere of radius $\varepsilon$, rather than concentrated at a single point. If it is assumed that the charge distribution is uniform within the radius $\varepsilon$, then it is

$$
\text { spherical charge around the origin: } \quad \rho=\left\{\begin{array}{cl}
\frac{q}{\frac{4}{3} \pi \varepsilon^{3}} & \text { if } r \leqslant \varepsilon  \tag{13.16}\\
0 & \text { if } r>\varepsilon
\end{array}\right.
$$

Since the charge density is the charge per unit volume, the charge density times the volume $\frac{4}{3} \pi \varepsilon^{3}$ of the little sphere that holds it must be the total charge $q$. The expression above makes it so.

Figure 13.7 shows that outside the region with charge, the electric field and potential are exactly like those of a point charge with the same net charge $q$. But inside the region of charge distribution, the electric field varies linearly with radius, and becomes zero at the center. It is just like the gravity of earth: going above the surface of the earth out into space, gravity decreases like $1 / r^{2}$ if $r$ is the distance from the center of the earth. But if you go down below the

Figure 13.7: Electric field and potential of a charge that is distributed uniformly within a small sphere. The dotted lines indicate the values for a point charge.
surface of the earth, gravity decreases also and becomes zero at the center of the earth. If you want, you can derive the electric field of the spherical charge from Maxwell's first equation; it goes much in the same way that Coulomb's law was derived from it in the previous section.

If magnetic monopoles exist, they would create a magnetic field much like an electric charge creates an electric field. As table 13.1 shows, the only difference is the square of the speed of light $c$ popping up in the expressions. (And that is really just a matter of definitions, anyway.) In real life, these expressions give an approximation for the magnetic field near the north or south pole of a very long thin magnet as long as you do not look inside the magnet.

Figure 13.8: Electric field of a two-dimensional line charge.
A homogeneous distribution of charges along an infinite straight line is called a line charge. As shown in figure 13.8, it creates a two-dimensional field in the planes normal to the line. The line charge becomes a point charge within such a plane. The expression for the field of a line charge can be derived in much the
same way as Coulomb's law was derived for a three-dimensional point charge in the previous section. In particular, where that derivation surrounded the point charge by a spherical surface, surround the line charge by a cylinder. (Or by a circle, if you want to think of it in two dimensions.) The resulting expressions are given in table 13.1; they are in terms of the charge per unit length of the line $q^{\prime}$. Note that in this section a prime is used to indicate that a quantity is per unit length.

### 13.3.2 Dipoles

A point charge can describe a single charged particle like an atom nucleus or electron. But much of the time in physics, you are dealing with neutral atoms or molecules. For those, the net charge is zero. The simplest model for a system with zero net charge is called the "dipole." It is simply a combination of a positive point charge $q$ and a negative one $-q$, making the net charge zero.

Figure 13.9: Field lines of a vertical electric dipole.
Figure 13.9 shows an example of a dipole in which the positive charge is straight above the negative one. Note the distinctive egg shape of the biggest electric field lines. The "electric dipole moment" $\vec{\wp}$ is defined as the product of the charge strength $q$ times the connecting vector from negative to positive charge:

$$
\begin{equation*}
\text { electric dipole moment: } \vec{\wp}=q\left(\vec{r}_{\oplus}-\vec{r}_{\ominus}\right) \tag{13.17}
\end{equation*}
$$

where $\vec{r}_{\oplus}$ and $\vec{r}_{\ominus}$ are the positions of the positive and negative charges respectively.

The potential of a dipole is simply the sum of the potentials of the two charges:

$$
\begin{equation*}
\text { potential of an electric dipole: } \quad \varphi=\frac{q}{4 \pi \epsilon_{0}} \frac{1}{\left|\vec{r}-\vec{r}_{\oplus}\right|}-\frac{q}{4 \pi \epsilon_{0}} \frac{1}{\left|\vec{r}-\vec{r}_{\ominus}\right|} \tag{13.18}
\end{equation*}
$$

Note that to convert the expressions for a charge at the origin to one not at the origin, you need to use the position vector measured from the location of the charge.

The electric field of the dipole can be found from either taking minus the gradient of the potential above, or from adding the fields of the individual point charges, and is
field of an electric dipole: $\overrightarrow{\mathcal{E}}=\frac{q}{4 \pi \epsilon_{0}} \frac{\vec{r}-\vec{r}_{\oplus}}{\left|\vec{r}-\vec{r}_{\oplus}\right|^{3}}-\frac{q}{4 \pi \epsilon_{0}} \frac{\vec{r}-\vec{r}_{\ominus}}{\left|\vec{r}-\vec{r}_{\ominus}\right|^{3}}$
To obtain that result from taking the the gradient of the potential, remember the following important formula for the gradient of $\left|\vec{r}-\vec{r}_{0}\right|^{n}$ with $n$ an arbitrary power:

$$
\begin{equation*}
\frac{\partial\left|\vec{r}-\vec{r}_{0}\right|^{n}}{\partial r_{i}}=n\left|\vec{r}-\vec{r}_{0}\right|^{n-2}\left(r_{i}-r_{0, i}\right) \quad \nabla_{\vec{r}}\left|\vec{r}-\vec{r}_{0}\right|^{n}=n\left|\vec{r}-\vec{r}_{0}\right|^{n-2}\left(\vec{r}-\vec{r}_{0}\right) \tag{13.20}
\end{equation*}
$$

The first expression gives the gradient in index notation and the second gives it in vector form. The subscript on $\nabla$ merely indicates that the differentiation is with respect to $\vec{r}$, not $\vec{r}_{0}$. These formulae will be used routinely in this section. Using them, you can check that minus the gradient of the dipole potential does indeed give its electric field above.

Similar expressions apply for magnetic dipoles. The field outside a thin bar magnet can be approximated as a magnetic dipole, with the north and south poles of the magnet as the positive and negative magnetic point charges. The magnetic field lines are then just like the electric field lines in figure 13.9.

Figure 13.10: Electric field of a two-dimensional dipole.
Corresponding expressions can also be written down in two dimensions, for opposite charges distributed along parallel straight lines. Figure 13.10 gives
an example. In two dimensions, all field lines are circles passing through both charges.

A particle like an electron has an electric charge and no known size. It can therefore be described as an ideal point charge. But an electron also has a magnetic moment: it acts as a magnet of zero size. Such a magnet of zero size will be referred to as an "ideal magnetic dipole." More precisely, an ideal magnetic dipole is defined as the limit of a magnetic dipole when the two poles are brought vanishingly close together. Now if you just let the two poles approach each other without doing anything else, their opposite fields will begin to increasingly cancel each other, and there will be no field left when the poles are on top of each other. When you make the distance between the poles smaller, you also need to increase the strengths $q_{m}$ of the poles to ensure that the

$$
\begin{equation*}
\text { magnetic dipole moment: } \vec{\mu}=q_{m}\left(\vec{r}_{\oplus}-\vec{r}_{\ominus}\right) \tag{13.21}
\end{equation*}
$$

remains finite. So you can think of an ideal magnetic dipole as infinitely strong magnetic poles infinitely close together.

Figure 13.11: Field of an ideal magnetic dipole.
The field lines of a vertical ideal magnetic dipole are shown in figure 13.11 . Their egg shape is in spherical coordinates described by, $\{\mathrm{D} .72\}$,

$$
\begin{equation*}
r=r_{\max } \sin ^{2} \theta \quad \phi=\text { constant } \tag{13.22}
\end{equation*}
$$

To find the magnetic field itself, start with the magnetic potential of a nonideal dipole,

$$
\varphi_{m}=\frac{q_{m}}{4 \pi \epsilon_{0} c^{2}}\left[\frac{1}{\left|\vec{r}-\vec{r}_{\oplus}\right|}-\frac{1}{\left|\vec{r}-\vec{r}_{\ominus}\right|}\right]
$$

Now take the negative pole at the origin, and allow the positive pole to approach it vanishingly close. Then the potential above takes the generic form

$$
\varphi_{m}=f\left(\vec{r}-\vec{r}_{\oplus}\right)-f(\vec{r}) \quad f(\vec{r})=\frac{q_{m}}{4 \pi \epsilon_{0} c^{2}} \frac{1}{|\vec{r}|}
$$

Now according to the total differential of calculus, (or the multi-dimensional Taylor series theorem, or the definition of directional derivative), for small $\vec{r}_{\oplus}$ an expression of the form $f\left(\vec{r}-\vec{r}_{\oplus}\right)-f(\vec{r})$ can be approximated as

$$
f\left(\vec{r}-\vec{r}_{\oplus}\right)-f(\vec{r}) \sim-\vec{r}_{\oplus} \cdot \nabla f \quad \text { for } \quad \vec{r}_{\oplus} \rightarrow 0
$$

From this the magnetic potential of an ideal dipole at the origin can be found by using the expression (13.20) for the gradient of $1 /|\vec{r}|$ and then substituting the magnetic dipole strength $\vec{\mu}$ for $q_{m} \vec{r}_{\oplus}$. The result is

$$
\begin{equation*}
\text { potential of an ideal magnetic dipole: } \quad \varphi_{m}=\frac{1}{4 \pi \epsilon_{0} c^{2}} \frac{\vec{\mu} \cdot \vec{r}}{r^{3}} \tag{13.23}
\end{equation*}
$$

The corresponding magnetic field can be found as minus the gradient of the potential, using again (13.20) and the fact that the gradient of $\vec{\mu} \cdot \vec{r}$ is just $\vec{\mu}$ :

$$
\begin{equation*}
\overrightarrow{\mathcal{B}}=\frac{1}{4 \pi \epsilon_{0} c^{2}} \frac{3(\vec{\mu} \cdot \vec{r}) \vec{r}-\vec{\mu} r^{2}}{r^{5}} \tag{13.24}
\end{equation*}
$$

Similar expressions can be written down for ideal electric dipoles and in twodimensions. They are listed in tables 13.1 and 13.2. (The delta functions will be discussed in the next subsection.)

Figure 13.12: Electric field of an almost ideal two-dimensional dipole.

Figure 13.12 shows an almost ideal two-dimensional electric dipole. The spacing between the charges has been reduced significantly compared to that in figure 13.10, and the strength of the charges has been increased. For two-dimensional ideal dipoles, the field lines in a cross-plane are circles that all touch each other at the dipole.

### 13.3.3 Arbitrary charge distributions

Modeling electric systems like atoms and molecules and their ions as singular point charges or dipoles is not very accurate, except in a detailed quantum solution. In a classical description, it is more reasonable to assume that the charges are "smeared out" over space into a distribution. In that case, the charges are described by the charge per unit volume, called the charge density $\rho$. The integral of the charge density over volume then gives the net charge,

$$
\begin{equation*}
q_{\text {region }}=\int_{\text {region }} \rho(\underline{\vec{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}} \tag{13.25}
\end{equation*}
$$

As far as the potential is concerned, each little piece $\rho(\underline{\vec{r}}) \mathrm{d}^{3} \underline{\underline{r}}$ of the charge distribution acts like a point charge at the point $\underline{\vec{r}}$. The expression for the potential of such a point charge is like that of a point charge at the origin, but with $\vec{r}$ replaced by $\vec{r}-\underline{\vec{r}}$. The total potential results from integrating over all the point charges. So, for a charge distribution,

$$
\begin{equation*}
\varphi(\vec{r})=\frac{1}{4 \pi \epsilon_{0}} \int_{\text {all } \underline{\underline{r}}} \frac{1}{|\vec{r}-\underline{\vec{r}}|} \rho(\underline{\vec{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}} \tag{13.26}
\end{equation*}
$$

The electric field and similar expression for magnetic charge distributions and in two dimensions may be found in table 13.2

Note that when the integral expression for the potential is differentiated to find the electric field, as in table 13.2, the integrand becomes much more singular at the point of integration where $\overrightarrow{\underline{r}}=\vec{r}$. This may be of importance in numerical work, where the more singular integrand can lead to larger errors. It may then be a better idea not to differentiate under the integral, but instead put the derivative of the charge density in the integral, like in

$$
\mathcal{E}_{x}=-\frac{\partial \varphi}{\partial x}=-\frac{1}{4 \pi \epsilon_{0}} \int_{\text {all } \underline{\underline{r}}} \frac{1}{|\vec{r}-\underline{\vec{r}}|} \frac{\partial \rho(\underline{\vec{r}})}{\partial \underline{x}} \mathrm{~d}^{3} \underline{\underline{r}}
$$

and similar for the $y$ and $z$ components. That you can do that may be verified by noting that differentiating $\vec{r}-\overrightarrow{\vec{r}}$ with respect to $x$ is within a minus sign the same as differentiating with respect to $\underline{x}$, and then you can use integration by parts to move the derivative to $\rho$.

Now consider the case that the charge distribution is restricted to a very small region around the origin, or equivalently, that the charge distribution is viewed from a very large distance. For simplicity, assume the case that the charge distribution is restricted to a small region around the origin. In that case, $\underline{\vec{r}}$ is small wherever there is charge; the integrand can therefore be approximated by a Taylor series in terms of $\underset{\underline{r}}{ }$ to give:

$$
\varphi=\frac{1}{4 \pi \epsilon_{0}} \int_{\text {all } \vec{r}}\left[\frac{1}{|\vec{r}|}+\frac{\vec{r}}{|\vec{r}|^{3}} \cdot \underline{\vec{r}}+\ldots\right] \rho(\underline{\vec{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}}
$$

where (13.20) was used to evaluate the gradient of $1 /|\underline{\vec{r}}-\vec{r}|$ with respect to $\underline{\vec{r}}$.
Since the fractions no longer involve $\underline{\vec{r}}$, they can be taken out of the integrals and so the potential simplifies to

$$
\begin{equation*}
\varphi=\frac{q}{4 \pi \epsilon_{0}} \frac{1}{r}+\frac{1}{4 \pi \epsilon_{0}} \frac{\vec{\wp} \cdot \vec{r}}{r^{3}}+\ldots \quad q \equiv \int_{\text {all }} \rho(\overrightarrow{\underline{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}} \quad \vec{\wp} \equiv \int_{\text {all }} \underset{\underline{r}}{ } \vec{r}^{\underline{r}} \rho(\overrightarrow{\underline{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}} \tag{13.27}
\end{equation*}
$$

The leading term shows that a distributed charge distribution will normally look like a point charge located at the origin when seen from a sufficient distance. However, if the net charge $q$ is zero, like happens for a neutral atom or molecule, it will look like an ideal dipole, the second term, when seen from a sufficient distance.

The expansion (13.27) is called a "multipole expansion." It allows the effect of a complicated charge distribution to be described by a few simple terms, assuming that the distance from the charge distribution is sufficiently large that its small scale features can be ignored. If necessary, the accuracy of the expansion can be improved by using more terms in the Taylor series. Now recall from the previous section that one advantage of Maxwell's equations over Coulomb's law is that they allow you to describe the electric field at a point using purely local quantities, rather than having to consider the charges everywhere. But using a multipole expansion, you can simplify the effects of distant charge distributions. Then Coulomb's law can become competitive with Maxwell's equations, especially in cases where the charge distribution is restricted to a relatively limited fraction of the total space.

The previous subsection discussed how an ideal dipole could be created by decreasing the distance between two opposite charges with a compensating increase in their strength. The multipole expansion above shows that the same ideal dipole is obtained for a continuous charge distribution, provided that the net charge $q$ is zero.

The electric field of this ideal dipole can be found as minus the gradient of the potential. But caution is needed; the so-obtained electric field may not be sufficient for your needs. Consider the following ballpark estimates. Assume that the charge distribution has been contracted to a typical small size $\varepsilon$. Then the net positive and negative charges will have been increased by a corresponding factor $1 / \varepsilon$. The electric field within the contracted charge distribution will then have a typical magnitude $1 / \varepsilon|\underline{\vec{r}}-\vec{r}|^{2}$, and that means $1 / \varepsilon^{3}$, since the typical size of the region is $\varepsilon$. Now a quantity of order $1 / \varepsilon^{3}$ can integrate to a finite amount even if the volume of integration is small of order $\varepsilon^{3}$. In other words, there seems to be a possibility that the electric field may have a delta function hidden within the charge distribution when it is contracted to a point. And so it does. The correct delta function is derived in derivation \{D.72\} and shown in table 13.2. It is important in applications in quantum mechanics where you need some integral of the electric field; if you forget about the delta function,
you will get the wrong result.

### 13.3.4 Solution of the Poisson equation

The previous subsections stumbled onto the solution of an important mathematical problem, the Poisson equation. The Poisson equation is

$$
\begin{equation*}
\nabla^{2} \varphi=f \tag{13.28}
\end{equation*}
$$

where $f$ is a given function and $\varphi$ is the unknown one to be found. The Laplacian $\nabla^{2}$ is also often found written as $\Delta$.

The reason that the previous subsection stumbled on to the solution of this equation is that the electric potential $\varphi$ satisfies it. In particular, minus the gradient of $\varphi$ gives the electric field; also, the divergence of the electric field gives according to Maxwell's first equation the charge density $\rho$ divided by $\epsilon_{0}$. Put the two together and it says that $\nabla^{2} \varphi=-\rho / \epsilon_{0}$. So, identify the function $f$ in the Poisson equation with $-\rho / \epsilon_{0}$, and there you have the solution of the Poisson equation.

Because it is such an important problem, it is a good idea to write out the abstract mathematical solution without the "physical entourage" of (13.26):

$$
\begin{equation*}
\nabla^{2} \varphi=f \quad \Longrightarrow \quad \varphi(\vec{r})=\int_{\text {all } \underline{\underline{r}}} G(\vec{r}-\underline{\vec{r}}) f(\overrightarrow{\underline{r}}) \mathrm{d}^{3} \underline{\underline{r}} \quad G(\vec{r})=-\frac{1}{4 \pi|\vec{r}|} \tag{13.29}
\end{equation*}
$$

The function $G(\vec{r}-\underline{\vec{r}})$ is called the Green's function of the Laplacian. It is the solution for $\varphi$ if the function $f$ is a delta function at point $\underline{\vec{r}}$. The integral solution of the Poisson equation can therefore be understood as dividing function $f$ up into spikes $f(\underline{\vec{r}}) \mathrm{d}^{3} \underline{\vec{r}}$; for each of these spikes the contribution to $\varphi$ is given by corresponding Green's function.

It also follows that applying the Laplacian on the Green's function produces the three-dimensional delta function,

$$
\begin{equation*}
\nabla^{2} G(\vec{r})=\delta^{3}(\vec{r}) \quad G(\vec{r})=-\frac{1}{4 \pi|\vec{r}|} \tag{13.30}
\end{equation*}
$$

with $|\vec{r}|=r$ in spherical coordinates. That sometimes pops up in quantum mechanics, in particular in perturbation theory. You might object that the Green's function is infinite at $\vec{r}=0$, so that its Laplacian is undefined there, rather than a delta function spike. And you would be perfectly right; just saying that the Laplacian of the Green's function is the delta function is not really justified. However, if you slightly round the Green's function near $\vec{r}=0$, say like $\varphi$ was rounded in figure 13.7, its Laplacian does exist everywhere. The Laplacian of this rounded Green's function is a spike confined to the region of rounding, and it integrates to one. (You can see the latter from applying the divergence theorem on a sphere enclosing the region of rounding.) If you then
contract the region of rounding to zero, this spike becomes a delta function in the limit of no rounding. Understood in this way, the Laplacian of the Green's function is indeed a delta function.

The multipole expansion for a charge distribution can also be converted to purely mathematical terms:

$$
\begin{equation*}
\varphi=-\frac{1}{4 \pi r} \int_{\text {all }} f(\overrightarrow{\underline{r}}) \mathrm{d}^{3} \underline{\vec{r}}-\frac{\vec{r}}{4 \pi r^{3}} \cdot \int_{\operatorname{all} \underline{\underline{r}}} \underline{\vec{r}} f(\underline{\vec{r}}) \mathrm{d}^{3} \overrightarrow{\underline{r}}+\ldots \tag{13.31}
\end{equation*}
$$

(Of course, delta functions are infinite objects, and you might wonder at the mathematical rigor of the various arguments above. However, there are solid arguments based on "Green's second integral identity" that avoid the infinities and produce the same final results.)

### 13.3.5 Currents

Streams of moving electric charges are called currents. The current strength $I$ through an electric wire is defined as the amount of charge flowing through a cross section per unit time. It equals the amount of charge $q^{\prime}$ per unit length times its velocity $v$;

$$
\begin{equation*}
I \equiv q^{\prime} v \tag{13.32}
\end{equation*}
$$

The current density $\vec{\jmath}$ is defined as the current per unit volume, and equals the charge density times the charge velocity. Integrating the current density over the cross section of a wire gives its current.

Figure 13.13: Magnetic field lines around an infinite straight electric wire.
As shown in figure 13.13, electric wires are encircled by magnetic field lines. The strength of this magnetic field may be computed from Maxwell's fourth equation. To do so, take an arbitrary field line circle. The field strength is
constant on the line by symmetry. So the integral of the field strength along the line is just $2 \pi r \mathcal{B}$; the perimeter of the field line times its magnetic strength. Now the Stokes' theorem of calculus says that this integral is equal to the curl of the magnetic field integrated over the interior of the field line circle. And Maxwell's fourth equation says that that is $1 / \epsilon_{0} c^{2}$ times the current density integrated over the circle. And the current density integrated over the circle is just the current through the wire. Put it all together to get

$$
\begin{equation*}
\text { magnetic field of an infinite straight wire: } \quad \mathcal{B}=\frac{I}{2 \pi \epsilon_{0} c^{2} r} \tag{13.33}
\end{equation*}
$$

Figure 13.14: An electromagnet consisting of a single wire loop. The generated magnetic field lines are in blue.

An infinite straight wire is of course not a practical way to create a magnetic field. In a typical electromagnet, the wire is spooled around an iron bar. Figure 13.14 shows the field produced by a single wire loop, in vacuum. To find the fields produced by curved wires, use the so-called "Biot-Savart law" listed in table 13.2 and derived in $\{$ D. 72$\}$. You need it when you end up writing a book on quantum mechanics and have to plot the field.

Of course, while figure 13.14 does not show it, you will also need a lead from your battery to the electromagnet and a second lead back to the other pole of the battery. These two leads form a two-dimensional "current dipole," as shown in figure 13.15, and they produce a magnetic field too. However, the currents in the two leads are opposite; one coming from the battery and other returning to it, so the magnetic fields that they create are opposite. Therefore, if you strand the wires very closely together, their magnetic fields will cancel each other, and not mess up that of your electromagnet.

It may be noted that if you bring the wires close together, whatever is left of the field has circular field lines that touch at the dipole. In other words, a horizontal ideal current dipole produces the same field as a two-dimensional

Figure 13.15: A current dipole.
vertical ideal charge dipole. Similarly, the horizontal wire loop, if small enough, produces the same field lines as a three-dimensional vertical ideal charge dipole. (However, the delta functions are different, \{D.72\}.)

### 13.3.6 Principle of the electric motor

The previous section discussed how Maxwell's third equation allows electric power generation using mechanical means. The converse is also possible; electric power allows mechanical power to be generated; that is the principle of the electric motor.

It is possible because of the Lorentz force law, which says that a charge $q$ moving with velocity $\vec{v}$ in a magnetic field $\overrightarrow{\mathcal{B}}$ experiences a force pushing it sideways equal to

$$
\vec{F}=q \vec{v} \times \overrightarrow{\mathcal{B}}
$$

Consider the wire loop in an external magnetic field sketched in figure 13.16. The sideways forces on the current carriers in the wire produce a net moment $\vec{M}$ on the wire loop that allows it to perform useful work.

To be more precise, the forces caused by the component of the magnetic field normal to the wire loop are radial and produce no net force nor moment. However, the forces caused by the component of the magnetic field parallel to the loop produce forces normal to the plane of the loop that do generate a net moment. Using spherical coordinates aligned with the wire loop as in figure 13.17, the component of the magnetic field parallel to the loop equals $\mathcal{B}_{\text {ext }} \sin \theta$. It causes a sideways force on each element $r \mathrm{~d} \phi$ of the wire equal to

$$
\mathrm{d} F=\underbrace{q^{\prime} r \mathrm{~d} \phi}_{\mathrm{d} q} \underbrace{v \mathcal{B}_{\text {ext }} \sin \theta \sin \phi}_{\vec{v} \times \overrightarrow{\mathcal{B}}_{\text {parallel }}}
$$

Figure 13.16: Electric motor using a single wire loop. The Lorentz forces (black vectors) exerted by the external magnetic field on the electric current carriers in the wire produce a net moment $M$ on the loop. The self-induced magnetic field of the wire and the corresponding radial forces are not shown.

Figure 13.17: Variables for the computation of the moment on a wire loop in a magnetic field.
where $q^{\prime}$ is the net charge of current carriers per unit length and $v$ their velocity. The corresponding net force integrates to zero. However the moment does not; integrating

$$
\mathrm{d} M=\underbrace{r \sin \phi}_{\text {arm }} \underbrace{q^{\prime} r \mathrm{~d} \phi v \mathcal{B}_{\text {ext }} \sin \theta \sin \phi}_{\text {force }}
$$

produces

$$
M=\pi r^{2} q^{\prime} v \mathcal{B}_{\mathrm{ext}} \sin \theta
$$

If the work $M \mathrm{~d} \theta$ done by this moment is formulated as a change in energy of the loop in the magnetic field, that energy is

$$
E_{\mathrm{ext}}=-\pi r^{2} q^{\prime} v \mathcal{B}_{\mathrm{ext}} \cos \theta
$$

The magnetic dipole moment $\vec{\mu}$ is defined as the factor that only depends on the wire loop, independent of the magnetic field. In particular $\mu=\pi r^{2} q^{\prime} v$ and it is taken to be in the axial direction. So the moment and energy can be written more concisely as

$$
\vec{M}=\vec{\mu} \times \overrightarrow{\mathcal{B}}_{\mathrm{ext}} \quad E_{\mathrm{ext}}=-\vec{\mu} \cdot \overrightarrow{\mathcal{B}}_{\mathrm{ext}}
$$

Yes, $\vec{\mu}$ also governs how the magnetic field looks at large distances; feel free to approximate the Biot-Savart integral for large distances to check.

A book on electromagnetics would typically identify $q^{\prime} v$ with the current through the wire $I$ and $\pi r^{2}$ with the area of the loop, so that the magnetic dipole moment is just $I A$. This is then valid for a flat wire loop of any shape, not just a circular one.

But this is a book on quantum mechanics, and for electrons in orbits about nuclei, currents and areas are not very useful. In quantum mechanics the more meaningful quantity is angular momentum. So identify $2 \pi r q^{\prime}$ as the total electric charge going around in the wire loop, and multiply that with the ratio $m_{\mathrm{c}} / q_{\mathrm{c}}$ of mass of the current carrier to its charge to get the total mass going around. Then multiply with $r v$ to get the angular momentum $L$. In those terms, the magnetic dipole moment is

$$
\begin{equation*}
\vec{\mu}=\frac{q_{\mathrm{c}}}{2 m_{\mathrm{c}}} \vec{L} \tag{13.34}
\end{equation*}
$$

Usually the current carrier is an electron, so $q_{\mathrm{c}}=-e$ and $m_{\mathrm{c}}=m_{\mathrm{e}}$.
These results apply to any arbitrary current distribution, not just a circular wire loop. Formulae are in table 13.2 and general derivations in \{D.72\}.

### 13.4 Particles in Magnetic Fields

Maxwell's equations are fun, but back to real quantum mechanics. The serious question in this section is how a magnetic field $\overrightarrow{\mathcal{B}}$ affects a quantum system, like say an electron in an hydrogen atom.

Well, if the Hamiltonian (13.2) for a charged particle is written out and cleaned up, $\{$ D. 73$\}$, it is seen that a constant magnetic field adds two terms. The most important of the two is

$$
\begin{equation*}
H_{\mathcal{B} L}=-\frac{q}{2 m} \overrightarrow{\mathcal{B}} \cdot \hat{\vec{L}} \tag{13.35}
\end{equation*}
$$

where $q$ is the charge of the particle, $m$ its mass, $\overrightarrow{\mathcal{B}}$ the external magnetic field, assumed to be constant on the scale of the atom, and $\widehat{\vec{L}}$ is the orbital angular momentum of the particle.

In terms of classical physics, this can be understood as follows: a particle with angular momentum $\vec{L}$ can be pictured to be circling around the axis through $\vec{L}$. Now according to Maxwell's equations, a charged particle going around in a circle acts as a little electromagnet. Think of a version of figure 13.6 using a circular path. And a little magnet wants to align itself with an ambient magnetic field, just like a magnetic compass needle aligns itself with the magnetic field of earth.

In electromagnetics, the effective magnetic strength of a circling charged particle is described by the so called orbital "magnetic dipole moment" $\vec{\mu}_{L}$, defined as

$$
\begin{equation*}
\vec{\mu}_{L} \equiv \frac{q}{2 m} \vec{L} \tag{13.36}
\end{equation*}
$$

In terms of this magnetic dipole moment, the energy is

$$
\begin{equation*}
H_{\mathcal{B} L}=-\vec{\mu}_{L} \cdot \overrightarrow{\mathcal{B}} \tag{13.37}
\end{equation*}
$$

which is the lowest when the magnetic dipole moment is in the same direction as the magnetic field.

The scalar part of the magnetic dipole moment, to wit,

$$
\begin{equation*}
\gamma_{L}=\frac{q}{2 m} \tag{13.38}
\end{equation*}
$$

is called the "gyromagnetic ratio." But since in quantum mechanics the orbital angular momentum comes in chunks of size $\hbar$, and the particle is usually an electron with charge $q=-e$, much of the time you will find instead the "Bohr magneton"

$$
\begin{equation*}
\mu_{\mathrm{B}}=\frac{e \hbar}{2 m_{\mathrm{e}}} \approx 9.27410^{-24} \mathrm{~J} / \mathrm{T} \tag{13.39}
\end{equation*}
$$

used. Here T stands for Tesla, the $\mathrm{kg} / \mathrm{C}-\mathrm{s}$ unit of magnetic field strength.
Please, all of this is serious; this is not a story made up by this book to put physicists in a bad light. Note that the original formula had four variables in it: $q, m, \overrightarrow{\mathcal{B}}$, and $\widehat{\vec{L}}$, and the three new names they want you to remember are less than that.

The big question now is: since electrons have spin, build-in angular momentum, do they still act like little magnets even if not going around in a circle? The answer is yes; there is an additional term in the Hamiltonian due to spin. Astonishingly, the energy involved pops out of Dirac's relativistic description of the electron, $\{\mathrm{D} .74\}$. The energy that an electron picks up in a magnetic field due to its inherent spin is:

$$
\begin{equation*}
H_{\mathcal{B S}}=-g_{e} \frac{q}{2 m_{\mathrm{e}}} \overrightarrow{\mathcal{B}} \cdot \hat{\vec{S}} \quad g_{e} \approx 2 \quad q=-e \tag{13.40}
\end{equation*}
$$

(This section uses again $S$ to indicate spin angular momentum.) The constant $g$ is called the " $g$-factor". Since its value is 2 , electron spin produces twice the magnetic dipole strength as the same amount of orbital angular momentum would. That is called the "magnetic spin anomaly," [52, p. 222].

It should be noted that really the $g$-factor of an electron is about $0.1 \%$ larger than 2 because of the quantization of the electromagnetic field ignored in the Dirac equation. The quantized electromagnetic field, whose particle is the photon, has quantum uncertainty. You can think of it qualitatively as virtual photons popping up and disappearing continuously according to the energy-time uncertainty $\Delta E \Delta t \approx \hbar$, allowing particles with energy $\Delta E$ to appear as long as they don't stay around longer than a very brief time $\Delta t$. "Quantum electrodynamics" says that to a better approximation $g \approx 2+\alpha / \pi$ where $\alpha=e^{2} / 4 \pi \epsilon_{0} \hbar c$ $\approx 1 / 137$ is called the fine structure constant. This correction to $g$, due to the possible interaction of the electron with a virtual photon, [19, p. 116], is called the "anomalous magnetic moment," [25, p. 273]. (The fact that physicists have not yet defined potential deviations from the quantum electrodynamics value to be "magnetic spin anomaly anomalous magnetic moment anomalies" is an anomaly.) The prediction of the $g$-factor of the electron is a test for the accuracy of quantum electrodynamics, and so this $g$-factor has been measured to exquisite precision. At the time of writing, (2008), the experimental value is 2.002319304362 , to that many correct digits. Quantum electrodynamics has managed to get things right to more than ten digits by including more and more, increasingly complex interactions with virtual photons and virtual electron/positron pairs, [19], one of the greatest achievements of twentieth century physics.

You might think that the above formula for the energy of an electron in a magnetic field should also apply to protons and neutrons, since they too are spin $1 / 2$ particles. However, this turns out to be untrue. Protons and neutrons are not elementary particles, but consist of three "quarks." Still, for both electron and proton spin the gyromagnetic ratio can be written as

$$
\begin{equation*}
\gamma_{S}=g \frac{q}{2 m} \tag{13.41}
\end{equation*}
$$

but while the $g$-factor of the electron is 2 , the measured one for the proton is 5.59.

Do note that due to the much larger mass of the proton, its actual magnetic dipole moment is much less than that of an electron despite its larger $g$-factor. Still, under the right circumstances, like in nuclear magnetic resonance, the magnetic dipole moment of the proton is crucial despite its relative small size.

For the neutron, the charge is zero, but the magnetic moment is not, which would make its $g$-factor infinite! The problem is that the quarks that make up the neutron do have charge, and so the neutron can interact with a magnetic field even though its net charge is zero. When the proton mass and charge are arbitrarily used in the formula, the neutron's $g$-factor is -3.83 . More generally, nuclear magnetic moments are expressed in terms of the "nuclear magneton"

$$
\begin{equation*}
\mu_{\mathrm{N}}=\frac{e \hbar}{2 m_{\mathrm{p}}} \approx 5.0507810^{-27} \mathrm{~J} / \mathrm{T} \tag{13.42}
\end{equation*}
$$

that is based on proton charge and mass. Therefore nuclear $g$-factors are simply twice the nuclear magnetic moment in magnetons. (Needless to say, some authors leave out the factor 2 for that additional touch of confusion.)

At the start of this subsection, it was noted that the Hamiltonian for a charged particle has another term. So, how about it? It is called the "diamagnetic contribution," and it is given by

$$
\begin{equation*}
H_{\mathcal{B} D}=\frac{q^{2}}{8 m}(\overrightarrow{\mathcal{B}} \times \widehat{\vec{r}})^{2} \tag{13.43}
\end{equation*}
$$

Note that a system, like an atom, minimizes this contribution by staying away from magnetic fields: it is positive and proportional to $\mathcal{B}^{2}$.

The diamagnetic contribution can usually be ignored if there is net orbital or spin angular momentum. To see why, consider the following numerical values:

$$
\mu_{\mathrm{B}}=\frac{e \hbar}{2 m_{\mathrm{e}}} \approx 5.78810^{-5} \mathrm{eV} / \mathrm{T} \quad \frac{e^{2} a_{0}^{2}}{8 m_{\mathrm{e}}}=6.156510^{-11} \mathrm{eV} / \mathrm{T}^{2}
$$

The first number gives the magnetic dipole energy, for a quantum of angular momentum, per Tesla, while the second number gives the diamagnetic energy, for a Bohr-radius spread around the magnetic axis, per square Tesla.

It follows that it takes about a million Tesla for the diamagnetic energy to become comparable to the dipole one. Now at the time of this writing, (2008), the world record magnet that can operate continuously is right here at the Florida State University. It produces a field of 45 Tesla, taking in 33 MW of electricity and 4000 gallons of cooling water per minute. The world record magnet that can produce even stronger brief magnetic pulses is also here, and it produces 90 Tesla, going on 100. (Still stronger magnetic fields are possible if you allow the magnet to blow itself to smithereens during the fraction of a second that it operates, but that is so messy.) Obviously, these numbers are way below a million Tesla. Also note that since atom energies are in electron volts or more, none of these fields are going to blow an atom apart.

### 13.5 Stern-Gerlach Apparatus

A constant magnetic field will exert a torque, but no net force on a magnetic dipole like an electron; if you think of the dipole as a magnetic north pole and south pole close together, the magnetic forces on north pole and south pole will be opposite and produce no net force on the dipole. However, if the magnetic field strength varies with location, the two forces will be different and a net force will result.

The Stern-Gerlach apparatus exploits this process by sending a beam of atoms through a magnetic field with spatial variation, causing the atoms to deflect upwards or downwards depending on their magnetic dipole strength. The magnetic dipole strengths of the atoms will be proportional to the relevant electron angular momenta, (the nucleus can be ignored because of the large mass in its gyromagnetic ratio), and that will be quantized. So the incoming beam will split into distinct beams corresponding to the quantized values of the electron angular momentum.

The experiment was a great step forward in the development of quantum mechanics, because there is really no way that classical mechanics can explain the splitting into separate beams; classical mechanics just has to predict a smearedout beam. Angular momentum in classical mechanics can have any value, not just the values $m \hbar$ of quantum mechanics. Moreover, by capturing one of the split beams, you have a source of particles all in the same state without uncertainty, to use for other experiments or practical applications such as masers.

Stern and Gerlach used a beam of silver atoms in their experiment, and the separated beams deposited this silver on a plate. Initially, Gerlach had difficulty seeing any deposited silver on those plates because the layer was extremely thin. But fortunately for quantum mechanics, Stern was puffing his usual cheap cigars when he had a look, and the large amount of sulphur in the smoke was enough to turn some of the silver into jet-black silver sulfide, making it show clearly.

An irony is that that Stern and Gerlach assumed that that they had verified Bohr's orbital momentum. But actually, they had discovered spin. The net magnetic moment of silver's inner electrons is zero, and the lone valence electron is in a 5 s orbit with zero orbital angular momentum. It was the spin of the valence electron that caused the splitting. While spin has half the strength of orbital angular momentum, its magnetic moment is about the same due to its $g$-factor being two rather than one.

To use the Stern Gerlach procedure with charged particles such as lone electrons, a transverse electric field must be provided to counteract the large Lorentz force that the magnet imparts on the moving electrons.

### 13.6 Nuclear Magnetic Resonance

Nuclear magnetic resonance, or NMR, is a valuable tool for examining nuclei, for probing the structure of molecules, in particular organic ones, and for medical diagnosis, as MRI. This section will give a basic quantum description of the idea. Linear algebra will be used.

### 13.6.1 Description of the method

First demonstrated independently by Bloch and Purcell in 1946, NMR probes nuclei with net spin, in particular hydrogen nuclei or other nuclei with spin $1 / 2$. Various common nuclei, like carbon and oxygen do not have net spin; this can be a blessing since they cannot mess up the signals from the hydrogen nuclei, or a limitation, depending on how you want to look at it. In any case, if necessary isotopes such as carbon 13 can be used which do have net spin.

It is not actually the spin, but the associated magnetic dipole moment of the nucleus that is relevant, for that allows the nuclei to be manipulated by magnetic fields. First the sample is placed in an extremely strong steady magnetic field. Typical fields are in terms of Tesla. (A Tesla is about 20000 times the strength of the magnetic field of the earth.) In the field, the nucleus has two possible energy states; a ground state in which the spin component in the direction of the magnetic field is aligned with it, and an elevated energy state in which the spin is opposite $\{\mathrm{N} .33\}$. (Despite the large field strength, the energy difference between the two states is extremely small compared to the thermal kinetic energy at room temperature. The number of nuclei in the ground state may only exceed those in the elevated energy state by say one in 100000 , but that is still a large absolute number of nuclei in a sample.)

Now perturb the nuclei with a second, much smaller and radio frequency, magnetic field. If the radio frequency is just right, the excess ground state nuclei can be lifted out of the lowest energy state, absorbing energy that can be observed. The "resonance" frequency at which this happens then gives information about the nuclei. In order to observe the resonance frequency very accurately, the perturbing rf field must be very weak compared to the primary steady magnetic field.

In Continuous Wave NMR, the perturbing frequency is varied and the absorption examined to find the resonance. (Alternatively, the strength of the primary magnetic field can be varied, that works out to the same thing using the appropriate formula.)

In Fourier Transform NMR, the perturbation is applied in a brief pulse just long enough to fully lift the excess nuclei out of the ground state. Then the decay back towards the original state is observed. An experienced operator can then learn a great deal about the environment of the nuclei. For example, a nucleus in a molecule will be shielded a bit from the primary magnetic field by
the rest of the molecule, and that leads to an observable frequency shift. The amount of the shift gives a clue about the molecular structure at the nucleus, so information about the molecule. Additionally, neighboring nuclei can cause resonance frequencies to split into several through their magnetic fields. For example, a single neighboring perturbing nucleus will cause a resonance frequency to split into two, one for spin up of the neighboring nucleus and one for spin down. It is another clue about the molecular structure. The time for the decay back to the original state to occur is another important clue about the local conditions the nuclei are in, especially in MRI. The details are beyond this author's knowledge; the purpose here is only to look at the basic quantum mechanics behind NMR.

### 13.6.2 The Hamiltonian

The magnetic fields will be assumed to be of the form

$$
\begin{equation*}
\overrightarrow{\mathcal{B}}=\mathcal{B}_{0} \hat{k}+\mathcal{B}_{1}(\hat{\imath} \cos \omega t-\hat{\jmath} \sin \omega t) \tag{13.44}
\end{equation*}
$$

where $\mathcal{B}_{0}$ is the Tesla-strength primary magnetic field, $\mathcal{B}_{1}$ the very weak perturbing field strength, and $\omega$ is the frequency of the perturbation.

The component of the magnetic field in the $x y$-plane, $\mathcal{B}_{1}$, rotates around the $z$-axis at angular velocity $\omega$. Such a rotating magnetic field can be achieved using a pair of properly phased coils placed along the $x$ and $y$ axes. (In Fourier Transform NMR, a single perturbation pulse actually contains a range of different frequencies $\omega$, and Fourier transforms are used to take them apart.) Since the apparatus and the wave length of a radio frequency field is very large on the scale of a nucleus, spatial variations in the magnetic field can be ignored.

Now suppose you place a spin $1 / 2$ nucleus in the center of this magnetic field. As discussed in section 13.4, a particle with spin will act as a little compass needle, and its energy will be lowest if it is aligned with the direction of the ambient magnetic field. In particular, the energy is given by

$$
H=-\vec{\mu} \cdot \overrightarrow{\mathcal{B}}
$$

where $\vec{\mu}$ is called the magnetic dipole strength of the nucleus. This dipole strength is proportional to its spin angular momentum $\widehat{\vec{S}}$ :

$$
\vec{\mu}=\gamma \widehat{\vec{S}}
$$

where the constant of proportionality $\gamma$ is called the gyromagnetic ratio. The numerical value of the gyromagnetic ratio can be found as

$$
\gamma=\frac{g q}{2 m}
$$

In case of a hydrogen nucleus, a proton, the mass $m_{\mathrm{p}}$ and charge $q_{p}=e$ can be found in the notations section, and the proton's experimentally found $g$-factor is $g_{p}=5.59$.

The bottom line is that you can write the Hamiltonian of the interaction of the nucleus with the magnetic field in terms of a numerical gyromagnetic ratio value, spin, and the magnetic field:

$$
\begin{equation*}
H=-\gamma \widehat{\vec{S}} \cdot \overrightarrow{\mathcal{B}} \tag{13.45}
\end{equation*}
$$

Now turning to the wave function of the nucleus, it can be written as a combination of the spin-up and spin-down states,

$$
\Psi=a \uparrow+b \downarrow
$$

where $\uparrow$ has spin $\frac{1}{2} \hbar$ in the $z$-direction, along the primary magnetic field, and $\downarrow$ has $-\frac{1}{2} \hbar$. Normally, $a$ and $b$ would describe the spatial variations, but spatial variations are not relevant to the analysis, and $a$ and $b$ can be considered to be simple numbers.

You can use the concise notations of linear algebra by combining $a$ and $b$ in a two-component column vector (more precisely, a spinor),

$$
\Psi=\binom{a}{b}
$$

In those terms, the spin operators become matrices, the so-called Pauli spin matrices of section 12.10,

$$
\widehat{S}_{x}=\frac{\hbar}{2}\left(\begin{array}{ll}
0 & 1  \tag{13.46}\\
1 & 0
\end{array}\right) \quad \widehat{S}_{y}=\frac{\hbar}{2}\left(\begin{array}{rr}
0 & -\mathrm{i} \\
\mathrm{i} & 0
\end{array}\right) \quad \widehat{S}_{z}=\frac{\hbar}{2}\left(\begin{array}{rr}
1 & 0 \\
0 & -1
\end{array}\right)
$$

Substitution of these expressions for the spin, and (13.44) for the magnetic field into (13.45) gives after cleaning up the final Hamiltonian:

$$
H=-\frac{\hbar}{2}\left(\begin{array}{cc}
\omega_{0} & \omega_{1} e^{\mathrm{i} \omega t}  \tag{13.47}\\
\omega_{1} e^{-\mathrm{i} \omega t} & -\omega_{0}
\end{array}\right) \quad \omega_{0}=\gamma \mathcal{B}_{0} \quad \omega_{1}=\gamma \mathcal{B}_{1}
$$

The constants $\omega_{0}$ and $\omega_{1}$ have the dimensions of a frequency; $\omega_{0}$ is called the "Larmor frequency." As far as $\omega_{1}$ is concerned, the important thing to remember is that it is much smaller than the Larmor frequency $\omega_{0}$ because the perturbation magnetic field is small compared to the primary one.

### 13.6.3 The unperturbed system

Before looking at the perturbed case, it helps to first look at the unperturbed solution. If there is just the primary magnetic field affecting the nucleus, with
no radio-frequency perturbation $\omega_{1}$, the Hamiltonian derived in the previous subsection simplifies to

$$
H=-\frac{\hbar}{2}\left(\begin{array}{cc}
\omega_{0} & 0 \\
0 & -\omega_{0}
\end{array}\right)
$$

The energy eigenstates are the spin-up state, with energy $-\frac{1}{2} \hbar \omega_{0}$, and the spindown state, with energy $\frac{1}{2} \hbar \omega_{0}$.

The difference in energy is in relativistic terms exactly equal to a photon with the Larmor frequency $\omega_{0}$. While the treatment of the electromagnetic field in this discussion will be classical, rather than relativistic, it seems clear that the Larmor frequency must play more than a superficial role.

The unsteady Schrödinger equation tells you that the wave function evolves in time like $\mathrm{i} \hbar \dot{\Psi}=H \Psi$, so if $\Psi=a \uparrow+b \downarrow$,

$$
\mathrm{i} \hbar\binom{\dot{a}}{\dot{b}}=-\frac{\hbar}{2}\left(\begin{array}{cc}
\omega_{0} & 0 \\
0 & -\omega_{0}
\end{array}\right)\binom{a}{b}
$$

The solution for the coefficients $a$ and $b$ of the spin-up and -down states is:

$$
a=a_{0} e^{\mathrm{i} \omega_{0} t / 2} \quad b=b_{0} e^{-\mathrm{i} \omega_{0} t / 2}
$$

if $a_{0}$ and $b_{0}$ are the values of these coefficients at time zero.
Since $|a|^{2}=\left|a_{0}\right|^{2}$ and $|b|^{2}=\left|b_{0}\right|^{2}$ at all times, the probabilities of measuring spin-up or spin-down do not change with time. This was to be expected, since spin-up and spin-down are energy states for the steady system. To get more interesting physics, you really need the unsteady perturbation.

But first, to understand the quantum processes better in terms of the ideas of nonquantum physics, it will be helpful to write the unsteady quantum evolution in terms of the expectation values of the angular momentum components. The expectation value of the $z$-component of angular momentum is

$$
\left\langle S_{z}\right\rangle=|a|^{2} \frac{\hbar}{2}-|b|^{2} \frac{\hbar}{2}
$$

To more clearly indicate that the value must be in between $-\hbar / 2$ and $\hbar / 2$, you can write the magnitude of the coefficients in terms of an angle $\alpha$, the "precession angle",

$$
|a|=\left|a_{0}\right| \equiv \cos (\alpha / 2) \quad|b|=\left|b_{0}\right| \equiv \sin (\alpha / 2)
$$

In terms of the so-defined $\alpha$, you simply have, using the half-angle trig formulae,

$$
\left\langle S_{z}\right\rangle=\frac{\hbar}{2} \cos \alpha
$$

The expectation values of the angular momenta in the $x$ and $y$ directions can by found as the inner products $\left\langle\Psi \mid \widehat{S}_{x} \Psi\right\rangle$ and $\left\langle\Psi \mid \widehat{S}_{y} \Psi\right\rangle$, chapter 4.4.3. Substituting the representation in terms of spinors and Pauli spin matrices, and
cleaning up using the Euler formula (2.5), you get

$$
\left\langle S_{x}\right\rangle=\frac{\hbar}{2} \sin \alpha \cos \left(\omega_{0} t+\alpha\right) \quad\left\langle S_{y}\right\rangle=-\frac{\hbar}{2} \sin \alpha \sin \left(\omega_{0} t+\alpha\right)
$$

where $\alpha$ is some constant phase angle that is further unimportant.
The first thing that can be seen from these results is that the length of the expectation angular momentum vector is $\hbar / 2$. Next, the component with the $z$ axis, the direction of the primary magnetic field, is at all times $\frac{1}{2} \hbar \cos \alpha$. That implies that the expectation angular momentum vector is under a constant angle $\alpha$ with the primary magnetic field.

Figure 13.18: Larmor precession of the expectation spin (or magnetic moment) vector around the magnetic field.

The component in the $x y$-plane is $\frac{1}{2} \hbar \sin \alpha$, and this component rotates around the $z$-axis, as shown in figure 13.18 , causing the end point of the expectation angular momentum vector to sweep out a circular path around the magnetic field $\overrightarrow{\mathcal{B}}$. This rotation around the $z$-axis is called "Larmor precession." Since the magnetic dipole moment is proportional to the spin, it traces out the same conical path.

Caution should be used against attaching too much importance to this classical picture of a precessing magnet. The expectation angular momentum vector is not a physically measurable quantity. One glaring inconsistency in the expectation angular momentum vector versus the true angular momentum is that the square magnitude of the expectation angular momentum vector is $\hbar^{2} / 4$, three times smaller than the true square magnitude of angular momentum.

### 13.6.4 Effect of the perturbation

In the presence of the perturbing magnetic field, the unsteady Schrödinger equation $\mathrm{i} \hbar \dot{\Psi}=H \Psi$ becomes

$$
\mathrm{i} \hbar\binom{\dot{a}}{\dot{b}}=-\frac{\hbar}{2}\left(\begin{array}{cc}
\omega_{0} & \omega_{1} e^{\mathrm{i} \omega t}  \tag{13.48}\\
\omega_{1} e^{-\mathrm{i} \omega t} & -\omega_{0}
\end{array}\right)\binom{a}{b}
$$

where $\omega_{0}$ is the Larmor frequency, $\omega$ is the frequency of the perturbation, and $\omega_{1}$ is a measure of the strength of the perturbation and small compared to $\omega_{0}$.

The above equations can be solved exactly using standard linear algebra procedures, though the the algebra is fairly stifling \{D.75\}. The analysis brings in an additional quantity that will be called the "resonance factor"

$$
\begin{equation*}
f=\sqrt{\frac{\omega_{1}^{2}}{\left(\omega-\omega_{0}\right)^{2}+\omega_{1}^{2}}} \tag{13.49}
\end{equation*}
$$

Note that $f$ has its maximum value, one, at "resonance," i.e. when the perturbation frequency $\omega$ equals the Larmor frequency $\omega_{0}$.

The analysis finds the coefficients of the spin-up and spin-down states to be:

$$
\begin{align*}
& a=\left[a_{0}\left(\cos \left(\frac{\omega_{1} t}{2 f}\right)-\mathrm{i} f \frac{\omega-\omega_{0}}{\omega_{1}} \sin \left(\frac{\omega_{1} t}{2 f}\right)\right)+b_{0} \mathrm{i} f \sin \left(\frac{\omega_{1} t}{2 f}\right)\right] e^{\mathrm{i} \omega t / 2}(13.50)  \tag{13.50}\\
& b=\left[b_{0}\left(\cos \left(\frac{\omega_{1} t}{2 f}\right)+\mathrm{i} f \frac{\omega-\omega_{0}}{\omega_{1}} \sin \left(\frac{\omega_{1} t}{2 f}\right)\right)+a_{0} \mathrm{i} f \sin \left(\frac{\omega_{1} t}{2 f}\right)\right] e^{-\mathrm{i} \omega t / 2}(13.51)
\end{align*}
$$

where $a_{0}$ and $b_{0}$ are the initial coefficients of the spin-up and spin-down states.
This solution looks pretty forbidding, but it is not that bad in application. The primary interest is in nuclei that start out in the spin-up ground state, so you can set $\left|a_{0}\right|=1$ and $b_{0}=0$. Also, the primary interest is in the probability that the nuclei may be found at the elevated energy level, which is

$$
\begin{equation*}
|b|^{2}=f^{2} \sin ^{2}\left(\frac{\omega_{1} t}{2 f}\right) \tag{13.52}
\end{equation*}
$$

That is a pretty simple result. When you start out, the nuclei you look at are in the ground state, so $|b|^{2}$ is zero, but with time the rf perturbation field increases the probability of finding the nuclei in the elevated energy state eventually to a maximum of $f^{2}$ when the sine becomes one.

Continuing the perturbation beyond that time is bad news; it decreases the probability of elevated states again. As figure 13.19 shows, over extended times, there is a flip-flop between the nuclei being with certainty in the ground state, and having a probability of being in the elevated state. The frequency at which the probability oscillates is called the "Rabi flopping frequency". The author's

Figure 13.19: Probability of being able to find the nuclei at elevated energy versus time for a given perturbation frequency $\omega$.

Figure 13.20: Maximum probability of finding the nuclei at elevated energy.
sources differ about the precise definition of this frequency, but the one that seems to be most logical is $\omega_{1} / f$.

Anyway, by keeping up the perturbation for the right time you can raise the probability of elevated energy to a maximum of $f^{2}$. A plot of $f^{2}$ against the perturbing frequency $\omega$ is called the "resonance curve," shown in figure 13.20. For the perturbation to have maximum effect, its frequency $\omega$ must equal the nuclei's Larmor frequency $\omega_{0}$. Also, for this frequency to be very accurately observable, the "spike" in figure 13.20 must be narrow, and since its width is proportional to $\omega_{1}=\gamma \mathcal{B}_{1}$, that means the perturbing magnetic field must be very weak compared to the primary magnetic field.

There are two qualitative ways to understand the need for the frequency of the perturbation to equal the Larmor frequency. One is geometrical and classical: as noted in the previous subsection, the expectation magnetic moment precesses around the primary magnetic field with the Larmor frequency. In order for the small perturbation field to exert a long-term downward "torque" on this precessing magnetic moment as in figure 13.21, it must rotate along with it. If it rotates at any other frequency, the torque will quickly reverse direction compared to the magnetic moment, and the vector will start going up again. The other way to look at it is from a relativistic quantum perspective: if the magnetic field frequency equals the Larmor frequency, its photons have exactly the energy required to lift the nuclei from the ground state to the excited state.

At the Larmor frequency, it would naively seem that the optimum time to maintain the perturbation is until the expectation spin vector is vertically down; then the nucleus is in the exited energy state with certainty. If you then allow nature the time to probe its state, every nucleus will be found to be in the excited state, and will emit a photon. (If not messed up by some

Figure 13.21: A perturbing magnetic field, rotating at precisely the Larmor frequency, causes the expectation spin vector to come cascading down out of the ground state.
collision or whatever, little in life is ideal, is it?) However, according to actual descriptions of NMR devices, it is better to stop the perturbation earlier, when the expectation spin vector has become horizontal, rather than fully down. In that case, nature will only find half the nuclei in the excited energy state after the perturbation, presumably decreasing the radiation yield by a factor 2 . The classical explanation that is given is that when the (expectation) spin vector is precessing at the Larmor frequency in the horizontal plane, the radiation is most easily detected by the coils located in that same plane. And that closes this discussion.

## Chapter 14

## Nuclei [Unfinished Draft]

This chapter has not been finished. Since I think some parts of it are already of interest, like the figures, I am posting it as is. The reader beware, much of it has been poorly proofread, if at all. The figures should be fine.

So far, the focus in this book has been mostly on electrons. That is normal because electrons are important like nothing else for the physical properties of matter. Atomic nuclei appear in the story only as massive anchors for the electrons, holding onto the electrons with their positive electric charge. But then there is nuclear energy. Here the nuclei call the shots. Nuclei are discussed in this chapter.

The theory of nuclear structure is much less advanced than that of the electronic structure of atoms. Unlike the electromagnetic forces, the nuclear forces are very poorly understood. Examining them with well-understood electromagnetic probes is limited since nuclear forces are extremely strong, resisting manipulation. Accurate direct measurement of quantities of interest is usually not possible.

Nuclear physicists responded to that with a tidal wave of ingenious experiments, usually leveraging one accepted fact to deduce the next one (and at the same time check the old one). Much of this data is presented in this chapter in the form of overview figures. This is intended to allow you to understand the big picture.

Some important approximate quantum models have been developed by nuclear physicists to explain all that data. This chapter also tries to explain these models in relatively simple terms.

The first few sections of the chapter give an overview of key concepts important for understanding nuclei. It is highly recommended that you read these before reading any later sections in this chapter.

But first one word of caution about the figures. Most of their data has been carefully machine-read from standard nuclear data bases. However, the used data bases date from around the year 2003. So check any data you get from the figures for any more recent updates that may be available. Also note that various
figures that depend on relatively delicate mathematical analysis were machine produced too. Typically this was done using reasonable simplifications and/or a priori assumptions. Use such figures to understand the big picture, but do not pick individual data from them without checking it. A simple automated procedure processing about 3000 different nuclei from some key data using an approximate model cannot compete with a nuclear specialist analyzing a single nucleus based on all the extensive knowledge that is available for that one nucleus.

### 14.1 Fundamental Concepts

This section describes the most basic facts about nuclei. These facts will be taken for granted in the rest of this chapter.

Nuclei consist of protons and neutrons. Protons and neutrons are therefore called "nucleons." Neutrons are electrically neutral, but protons are positively charged. In particular, the electric charge of a proton has the same magnitude as the charge of an electron, but has opposite sign. Since opposite charges attract, the protons in a nucleus attract electrons. Despite that, the electrons do not end up inside the nucleus. They have much larger quantum mechanical uncertainty in position than the much heavier nucleons. So the electrons form a "cloud" around the tiny nucleus, producing an atom.

Since charges of the same sign repel, protons mutually repel each other. That is due to the same electric "Coulomb" force that allows them to attract electrons. By itself, the Coulomb force between the protons in a nucleus would cause the nucleus to fly apart immediately. But nucleons, both protons and neutrons, also attract each other through another force, the "nuclear force." It is this force that keeps a nucleus together.

The nuclear force is very strong, which allows it to dominate electromagnetic forces like the repulsive Coulomb force in stable nuclei. But the nuclear force is also very short range, extending over no more than a few femtometers. (A femtometer, or fm , equals $10^{-15} \mathrm{~m}$. It is sometimes called a fermi after famous nuclear physicist Enrico Fermi. While not approved by SI, Fermi was one of the good guys, so we should make allowances.) In big nuclei, nucleons are only held together to other nucleons in their immediate neighborhood by the nuclear force. But the protons are repulsed by other protons everywhere in the nucleus. If the nucleus gets too big, this repulsion becomes so big that the nucleus can no longer be stable. Lead, with 82 protons, is the heaviest element that can be stable, and then only if it contains a suitable number of neutrons to keep the protons somewhat apart.

The strength of the nuclear force is about the same regardless of the type of nucleons involved, protons or neutrons. That is called "charge independence."

More restrictively, but even more accurately, the nuclear force is the same if you swap the nucleon types. In other words, the nuclear force is the same if you replace all protons by neutrons and vice-versa. That is called "charge symmetry." For example, if you swap the nucleon type of a pair of protons, you get a pair of neutrons. Therefore the nuclear force between a pair of protons is very accurately the same as the one between a pair of neutrons, all else being equal. (The already mentioned Coulomb repulsion between the protons is additional and not the same.) But if you swap the nucleon type of a pair of protons, or of a pair of neutrons, you do not get a proton and a neutron. So the nuclear force between a proton and a neutron is less accurately the same as that between two protons or two neutrons.

The nuclear force is not a fundamental one. It is just an effect of the "color force" or "strong force" between the "quarks" of which protons and neutrons consist. That is why the nuclear force is also often called the "residual strong force." It is much like how the Van der Waals force between molecules is not a fundamental one; that force is a residual of the electromagnetic force between the electrons and nuclei of which molecules exist, $\{\mathrm{A} .33\}$.

However, the theory of the color force, "quantum chromedynamics," is well beyond the scope of this book. It is also not really important for nanotechnology. In fact, it is not all that important for nuclear engineering either because the details of the theory are uncertain, and numerical solution is intractable, [19].

Despite the fact that the nuclear force is poorly understood, physicists can say some things with confidence. First of all,

## Nuclei are normally in the ground state.

The "ground state" is the quantum state of lowest energy $E$. Nuclei can also be in "excited" states of higher energy. However, a bit of thermal energy is not going to excite a nucleus. Differences between nuclear energy levels are extremely large on a microscopic scale. That is why nuclear bombs and nuclear reactors can create so much energy. Still, nuclear reactions will typically leave nuclei in excited states. Usually such states decay back to the ground state very quickly. (In special cases, it may take forever.)

It should be noted that if a nuclear state is not stable, it implies that it has a very slight uncertainty in energy, compare chapter 7.4.1. This uncertainty in energy is commonly called the "width" $\Gamma$ of the state. The discussion here will almost always ignore the uncertainty in energy.

A second general property of nuclei is:
Nuclear states have definite nuclear mass $m_{\mathrm{N}}$.
You may be surprised by this statement. It seems trivial. You would expect that the nuclear mass is simply the sum of the masses of the protons and neutrons that make up the nucleus. But Einstein's famous relation $E=m c^{2}$ relates
energy and mass. The nuclear mass is slightly less than the combined mass of the protons and neutrons from which it is made. The difference is the binding energy that keeps the nucleus together, expressed in mass units. (In other words, divided by the square speed of light $c^{2}$.) Sure, even for nuclear energies the changes in nuclear mass due to binding energy are tiny. But physicists can measure nuclear masses to very great accuracy. Different nuclear states have different binding energies. So they have slightly different nuclear masses.
(Similarly, a hydrogen atom has less mass than a free proton and a free electron. But here the difference, a few eV, is far too small to note. Since nuclear binding energies are millions of times bigger, in nuclei the effect is much more important.)

It may be noted that binding energies are almost never expressed in mass units in nuclear physics. Instead masses are expressed in energy units! And not in Joule either. The energy units used are almost invariably "electron volts" (eV). Never use an SI unit when talking to nuclear physicists. They will immediately know that you are one of those despised nonexperts. Just call it a "blah." In the unlikely case that they ask, tell them "That is what Fermi called it."

Next,

## Nuclear states have definite nuclear spin $j_{\mathrm{N}}$.

Here the "nuclear spin" $j_{N}$ is the quantum number of the net nuclear angular momentum. The magnitude of the net nuclear angular momentum itself is

$$
J=\sqrt{j_{\mathrm{N}}\left(j_{\mathrm{N}}+1\right)} \hbar
$$

Nuclei in excited energy states usually have different angular momentum than in the ground state.

The name nuclear "spin" may seem inappropriate since net nuclear angular momentum includes not just the spin of the nucleons but also their orbital angular momentum. But since nuclear energies are so large, in many cases nuclei act much like elementary particles do. Externally applied electromagnetic fields are not by far strong enough to break up the internal nuclear structure. And the angular momentum of an elementary particle is appropriately called spin. However, the fact that "nuclear spin" is two words and "azimuthal quantum number of the net nuclear angular momentum" is nine might conceivably also have something to do with the terminology.

According to quantum mechanics, $j_{\mathrm{N}}$ must be integer or half-integer. In particular, $j_{\mathrm{N}}$ must be an integer if the number of nucleons is even $\left(j_{\mathrm{N}}=0\right.$ or 1 or 2 or $\ldots$ ). If the number of nucleons is odd, $j_{\mathrm{N}}$ must be half an odd integer $\left(j_{\mathrm{N}}=1 / 2\right.$ or $3 / 2$ or $5 / 2$ or $\ldots$ ).

The fact that nuclei have definite angular momentum does not depend on the details of the nuclear force. It is a consequence of the very fundamental
observation that empty space has no "build-in" preferred direction. That issue was explored in more detail in chapter 7.3.
(Many references use the symbol $J$ also for $j_{\mathrm{N}}$ for that spicy extra bit of confusion. So one reference tells you that the eigenvalue [singular] of $J^{2}$ is $J(J+1)$, leaving the $\hbar^{2}$ away from conciseness. No kidding. One popular book uses $I$ instead of $j_{\mathrm{N}}$ and reserves $J$ for electronic angular momentum. At least this reference uses a bold face $I$ to indicate the angular momentum itself, as a vector.)

Consider also the component $J_{z}$ of the nuclear angular momentum in a selected $z$ direction. According to quantum mechanics, this component can have the measurable values $-j_{\mathrm{N}},-j_{\mathrm{N}}+1,-j_{\mathrm{N}}+2, \ldots, j_{\mathrm{N}}-1$, or $j_{\mathrm{N}}$. Note also that if $J_{z}$ has a definite value for nonzero $j_{\mathrm{N}}$, then the components in orthogonal directions have uncertain values and are therefore not that interesting for analysis.

Finally,

## Nuclear states have definite parity.

Here "parity" is what happens to the wave function when the nucleus is mirrored and then rotated $180^{\circ}$ around the axis normal to the mirror, chapter 7.3. (Mathematically, this corresponds to inverting every $\vec{r}$ position vector measured from the center of gravity into $-\vec{r}$. Since the rotation is already covered by angular momentum, the important step is the mirroring.) The wave function can either stay the same, (called parity 1 or even parity), or it can change sign, (called parity -1 or odd parity). The fact that nuclei have definite parity too does not depend on the details of the nuclear force. It is a consequence of the fact that the forces of nature behave the same way when seen in the mirror.

Or actually, there is one force of nature, the still unmentioned so-called "weak force" that does not behave the same way when seen in the mirror. But the weak force is, like it says, weak. On nuclear scales, it is many orders of magnitude smaller than the nuclear and electromagnetic forces. So, while the weak force introduces some quantum-mechanical uncertainty in the parity of nuclei, this uncertainty is usually negligibly small. The chances of finding a nucleus in a given energy state with the "wrong" parity can be ballparked at $10^{-14}$, [31, pp. 313ff]. That is almost always negligible. Only if, say, a nuclear process is strictly impossible solely because of parity, then the uncertainty in parity might give it a very slight possibility of occurring anyway.

Parity is commonly indicated by $\pi$ because $\pi$ is the Greek letter " $p$ " and is not used for anything else in science. And physicists usually list the spin and parity of a nucleus together in the form $J^{\pi}$. If you have two quantities like spin and parity that have nothing to do with one another, what is better than show one as a superscript of the other? But do not start raising $J$ to the power $\pi$ ! You should be translating this into common sense as follows:

$$
J^{\pi} \quad \Rightarrow \quad j_{\mathrm{N}}^{ \pm} \quad \Rightarrow \quad j_{\mathrm{N}} \text { and } \pm
$$

As a numerical example, $3^{-}$means a nucleus with spin 3 and odd parity. It does not mean a nucleus with spin $1 / 3$, (which is not even possible; spins can only be integer or half-integer.)

## Key Points

$0-$ Nuclei form the centers of atoms.
$0-$ Nuclei consist of protons and neutrons. Therefore protons and neutrons are called nucleons.
$0-$ Protons and neutrons themselves consist of quarks. But for practical purposes, you may as well forget about that.
$0-$ Neutrons are electrically neutral. Protons are positively charged.
$0-$ Nucleons are held together by the so-called nuclear force.
0- The nuclear force is approximately independent of whether the nucleons are protons or neutrons. That is called charge independence. Charge symmetry is a more accurate, but also more limited version of charge independence.
$0-$ Nuclear states, including the ground state, have definite nuclear energy $E$. The differences in energy between nuclear states are so large that they produce small but measurable differences in the nuclear mass $m_{\mathrm{N}}$.
$0 \simeq$ Nuclear states also have definite nuclear spin $j_{\mathrm{N}}$. Nuclear spin is the azimuthal quantum number of the net angular momentum of the nucleus. Many references indicate it by $J$ or $I$.
$0-$ Nuclear states have definite parity $\pi$. At least they do if the so-called weak force is ignored.
$0 \simeq$ Never use an SI unit when talking to a nuclear physicist.

### 14.2 Draft: The Simplest Nuclei

This subsection introduces the simplest nuclei and their properties.

### 14.2.1 Draft: The proton

The simplest nucleus is the hydrogen one, just a single proton. It is trivial. Or at least it is if you ignore the fact that that proton really consists of a conglomerate of three quarks held together by gluons. A proton has an electric charge $e$ that is the same as that of an electron but opposite in sign (positive). It has the same spin $s$ as an electron, $1 / 2$. Spin is the quantum number of inherent angular
momentum, chapter 5.4. Also like an electron, a proton has a magnetic dipole moment $\mu$. In other words, it acts as a little electromagnet.

However, the proton is roughly 2000 times heavier than the electron. On the other hand the magnetic dipole moment of a proton is roughly 700 times smaller than that of an electron. The differences in mass and magnetic dipole moment are related, chapter 13.4. In terms of classical physics, a lighter particle circles around a lot faster for given angular momentum.

Actually, the proton has quite a large magnetic moment for its mass. The proton has the same spin and charge as the electron but is roughly 2000 times heavier. So logically speaking the proton magnetic moment should be roughly 2000 times smaller than the one of the electron, not 700 times. The explanation is that the electron is an elementary particle, but the proton is not. The proton consists of two up quarks, each with charge $\frac{2}{3} e$, and one down quark, with charge $-\frac{1}{3} e$. All three quarks have spin $1 / 2$. Since the quarks have significantly lower effective mass than the proton, they have correspondingly higher magnetic moments. Even though the spins of the quarks are not all aligned in the same direction, the resulting net magnetic moment is still unusually large for the proton net charge, mass, and spin.

## Key Points

$0-$ The proton is the nucleus of a normal hydrogen atom.
$0-$ It really consists of three quarks, but ignore that.
$0-$ It has the opposite charge of an electron, positive.
$0-$ It has spin $1 / 2$.
$0-$ It is roughly 2000 times heavier than an electron.
$0-$ It has a magnetic dipole moment. But this moment is roughly 700 times smaller than that of an electron.

### 14.2.2 Draft: The neutron

It is hard to call a lone neutron a nucleus, as it has no net charge to hold onto any electrons. In any case, it is somewhat academic, since a lone neutron disintegrates in on average about 10 minutes. The neutron emits an electron and an antineutrino and turns into a proton. That is an example of what is called "beta decay." Neutrons in nuclei can be stable.

A neutron is slightly heavier than a proton. It too has spin $1 / 2$. And despite the zero net charge, it has a magnetic dipole moment. The magnetic dipole moment of a neutron is about two thirds of that of a proton. It is in the direction opposite to the spin rather than parallel to it like for the proton.

The reason that the neutron has a dipole moment is that the three quarks that make up a neutron do have charge. A neutron contains one up quark with
a charge of $\frac{2}{3} e$ and two down quarks with a charge of $-\frac{1}{3} e$ each. That makes the net charge zero, but the magnetic dipole moment can be and is nonzero.

## Key Points

$0-$ The neutron is slightly heavier than the proton.
$0-$ It too has spin $\frac{1}{2}$.
$0-$ It has no charge.
$0-$ Despite that, it does have a comparable magnetic dipole moment.
$0-$ Lone neutrons are unstable. They suffer beta decay.

### 14.2.3 Draft: The deuteron

The smallest nontrivial nucleus consists of one proton and one neutron. This nucleus is called the deuteron. (An atom with such a nucleus is called deuterium). Just like the proton-electron hydrogen atom has been critical for deducing the structure of atoms, so the proton-neutron deuteron has been very important in deducing knowledge about the internal structure of nuclei.

However, the deuteron is not by far as simple a two-particle system as the hydrogen atom. It is also much harder to analyze. For the hydrogen atom, spectroscopic analysis of its excited quantum states provided a gold mine of information. Unfortunately, it turns out that the deuteron is so weakly bound that it has no excited quantum states. If you try to excite it by adding energy, it falls apart.

The experimental binding energy of the deuteron is only about 2.22 MeV . Here a MeV is the energy that an electron would pick up in a one-million voltage difference. For an electron, that would be a gigantic energy. But for a nucleus it is ho-hum indeed. A typical stable nucleus has a binding energy on the order of 8 MeV per nucleon.

In any case, it is lucky that that 2.22 MeV of binding energy is there at all. If the deuteron would not bind, life as we know it would not exist. The formation of nuclei heavier than hydrogen, including the carbon of life, begins with the deuteron.

The lack of excited states makes it hard to understand the deuteron. In addition, spin has a major effect on the force between the proton and neutron. In the hydrogen atom, that effect exists but it is extremely small. In particular, in the true hydrogen atom ground state the electron and proton align their spins in opposite directions. That produces the so-called singlet state of zero net spin, chapter 5.5.6. However, the electron and proton can also align their spins in the same direction, at least as far as angular momentum uncertainty allows. That produces the so-called triplet state of unit net spin. For the hydrogen atom, it
turns out that the triplet state has very slightly higher energy than the singlet state, $\{\mathrm{A} .39\}$.

In case of the deuteron, however, the triplet state has the lowest energy. And the singlet state has so much more energy that it is not even bound. Almost bound maybe, but definitely not bound. For the proton and neutron to bind together at all, they must align their spins into the triplet state.

As a result, a nucleus consisting of two protons (the diproton) or of two neutrons (the dineutron) does not exist. That is despite the fact that two protons or two neutrons attract each other almost the same as the proton and neutron in the deuteron. The problem is the antisymmetrization requirement that two identical nucleons must satisfy, chapter 5.6. A spatial ground state should be symmetric. (See addendum $\{$ A. 40$\}$ for more on that.) To satisfy the antisymmetrization requirement, the spin state of a diproton or dineutron must then be the antisymmetric singlet state. But only the triplet state is bound.
(You might guess that the diproton would also not exist because of the Coulomb repulsion between the two protons. But if you ballpark the Coulomb repulsion using the models of $\{\mathrm{A} .41\}$, it is less than a third of the already small 2.22 MeV binding energy. In general, the Coulomb force is quite small for light nuclei.)

There is another qualitative difference between the hydrogen atom and the deuteron. The hydrogen atom has zero orbital angular momentum in its ground state. In particular, the quantum number of orbital angular momentum $l$ equals zero. That makes the spatial structure of the atom spherically symmetric.

But orbital angular momentum is not conserved in the deuteron. In terms of classical physics, the forces between the proton and neutron are not exactly along the line connecting them. They deviate from the line based on the directions of the nucleon spins.

In terms of quantum mechanics, this gets phrased a bit differently. The potential does not commute with the orbital angular momentum operators. Therefore the ground state is not a state of definite orbital angular momentum. The angular momentum is still limited by the experimental observations that the deuteron has spin 1 and even parity. That restricts the orbital angular momentum quantum number $l$ to the possible values 0 or 2 , \{A.40\}. Various evidence shows that there is a quantum probability of about $95 \%$ that $l=0$ and $5 \%$ that $l=2$.

One consequence of the nonzero orbital angular momentum is that the magnetic dipole strength of the deuteron is not exactly what would be expected based on the dipole strengths of proton and neutron. Since the charged proton has orbital angular momentum, its acts like a little electromagnet not just because of its spin, but also because of its orbital motion.

Another consequence of the nonzero orbital angular momentum is that the charge distribution of the deuteron is not exactly spherically symmetric. This asymmetric charge distribution allows the deuteron to interact with gradients
in an external electric field. It is said that the deuteron has a nonzero "electric quadrupole moment."

Roughly speaking, you may think of the charge distribution of the deuteron as elongated in the direction of its spin. That is not quite right, quantummechanically speaking, since angular momentum has uncertainty in direction. Therefore, instead consider the quantum state in which the deuteron spin has its maximum component, $\hbar$, in the chosen $z$-direction. In that state, the charge distribution is elongated in the $z$-direction.

The nonzero orbital momentum also shows up in experiments where various particles are scattered off deuterons.

To be sure, the precise probability of the $l=2$ state has never been established. However, assume that the deuteron is modeled as composed of a proton and a neutron. (Although in reality it is a system of 6 quarks.) And assume that the proton and neutron have the same properties as they have in free space. (That is almost certainly not a good assumption; compare the next section.) For such a model the $l=2$ state needs to have about $4 \%$ probability to get the magnetic moment right. Similar values can be deduced from the quadrupole moment and scattering experiments, [31].

## Key Points

$0-$ The deuteron consists of a proton and a neutron.
$0-$ The deuteron is the simplest nontrivial nucleus. The diproton and the dineutron do not exist.
$0-$ The deuteron has spin 1 and even parity. The binding energy is 2.225 MeV .
0- There are no excited states. The ground state of lowest energy is all there is.
$0-$ The deuteron has a nonzero magnetic dipole moment.
$0-$ It also has a nonzero electric quadrupole moment.

### 14.2.4 Draft: Property summary

Table 14.1 gives a summary of the properties of the three simplest nuclei. The electron is also included for comparison.

The first data column gives the mass. Note that nuclei are thousands of times heavier than electrons. As far as the units are concerned, what is really listed is the energy equivalent of the masses. That means that the mass is multiplied by the square speed of light following the Einstein mass-energy relation. The resulting energies in Joules are then converted to MeV . An MeV is the energy that an electron picks up in a 1 million voltage difference. Yes it is crazy, but

\end{gathered}
$$

Table 14.1: Properties of the electron and of the simplest nuclei.
that is how you will almost always find masses listed in nuclear references. So you may as well get used to it.

It can be verified from the given numbers that the deuteron mass is indeed smaller than the sum of proton and neutron masses by the 2.225 MeV of binding energy. It is a tenth of a percent, but it is very accurately measurable.

The second column gives the charge. Note that all these charges are whole multiples of the proton charge $e$. However, that is not a fundamental requirement of physics. In particular, "up" quarks have charge $\frac{2}{3} e$ while "down" quarks have charge $-\frac{1}{3} e$. The proton contains two up quarks and a down one, producing net charge $e$. The neutron contains one up quark and two down ones, producing zero net charge.

The third column gives the charge radius. That is a measure of the spatial extent of the charge distribution. The electron is, as far as is known, a point particle with no internal structure. For the neutron, with no net charge, it is not really clear what to define as charge radius.

The fourth column shows the quantum number of net angular momentum. For the first three particles, that is simply their spin. For the deuteron, it is the nuclear spin. That includes both the spins and the orbital angular momenta of the proton and neutron that make up the deuteron.

The fifth column is parity. It is even in all cases. More complicated nuclei can have negative parity.

The sixth column is the magnetic dipole moment. It is expressed in terms of the so-called nuclear magneton $\mu_{\mathrm{N}}$. A proton circling around with one quantum unit of orbital angular momentum has one nuclear magneton of magnetic moment due to its motion. (Which would be in addition to the intrinsic magnetic moment listed in the table. Note that magnetic moments are vectors like
angular momenta; they may cancel each other when summed.)
As the table shows, nuclei have much smaller magnetic moments than electrons. That is due to their much larger masses. However, using a magnetic field of just the right frequency, nuclear magnetic moments can be observed. That is how nuclear magnetic resonance works, chapter 13.6. Therefore nuclear magnetic moments are important for many applications, including medical ones like MRI.

The last column lists the electric quadrupole strength. That is a measure for the deviation of the nuclear charge distribution from a spherically symmetric shape. It is a complicating factor in nuclear magnetic resonance. Or an additional source of information, depending on your view point. Nuclei with spin less than 1 do not have electric quadrupole moments. (That is an implied consequence of the relation between angular momentum and symmetry in quantum mechanics.)

Note that the SI length unit of femtometer works very nicely for nuclei. So, since physicists hate perfection, they define a new non-SI unit called the barn b. A barn is $100 \mathrm{fm}^{2}$. So you will likely find the quadrupole moment of the deuteron listed as 0.00286 eb . Note the additional leading zeros. Some physicists do not like them, for good reason, and then use millibarn, giving 2.86 emb. However, the quadrupole moments for many heavy nuclei are quite large in terms of millibarn. For example, einsteinium- 253 has around 6700 emb . Anytime now, physicists are bound to figure out that centibarn works even better than millibarn. When that happens, let's all agree that we will not tell them that a centibarn is the same as that hated $\mathrm{fm}^{2}$. The charge $e$ is commonly left away from the definition of the quadrupole moment, giving it units of area.

## Key Points

$0-$ The properties of the simplest nuclei are summarized in table 14.1.

### 14.3 Draft: Overview of Nuclei

This section introduces basic terminology and concepts of nuclei. It also gives an overview of the ways that they can decay.

The number of protons in a nucleus is called its "atomic number" $Z$. Since each proton has an electric charge $e$, equal to $1.6021810^{-19} \mathrm{C}$, the total nuclear charge is $Z e$. While protons attract nearby protons and neutrons in the nucleus with the short-range nuclear force, they also repel other protons by the longrange Coulomb force. This force too is very strong at nuclear distances. It makes nuclei with more than 82 protons unstable, because for such large nuclei the longer range of the Coulomb forces becomes a major factor.

The number of neutrons in a nucleus is its neutron number $N$. Neutrons have no charge, so they do not produce Coulomb repulsions. Therefore, the right amount of neutrons has a stabilizing effect on nuclei. However, too many neutrons is not stable either, because neutrons by themselves are unstable particles that fall apart in about 10 minutes. Combined with protons in a nucleus, neutrons can be stable.

Since neutrons have no charge, they also do not attract the electrons in the atom or molecule that the nucleus is in. Therefore only the atomic number $Z$ is of much relevance for the chemical properties of an atom. It determines the position in the periodic table of chemistry, chapter 5.9. Nuclei with the same atomic number $Z$, so with the same place in the periodic table, are called "isotopes." (In Greek, "iso" means equal and "topos" place.)

However, the number of neutrons does have a secondary effect on the chemical properties, because it changes the mass of the nucleus. And the number of neutrons is of critical importance for the nuclear properties. Nuclei with the same number of neutrons are called "isotones." How clever, to replace the p in isotopes with an $n$.

The name of a nucleus indicates its number of protons $Z$; for example, "hydrogen" means $Z=1$, "helium" $Z=2$. To also indicate the number of neutrons, the convention is to follow the name by the "mass number, or "nucleon number" $A=N+Z$. It gives the total number of nucleons in the nucleus.

For example, the normal hydrogen nucleus, which consists of a lone proton, is hydrogen-1. The deuterium nucleus, which contains both a proton and a neutron, is hydrogen-2, indicating that it contains two nucleons total. Because it has the same charge as the normal hydrogen nucleus, a deuterium atom behaves chemically almost the same as a normal hydrogen atom. For example, you can create water with deuterium and oxygen just like you can with normal hydrogen and oxygen. Such water is called "heavy water." Don't drink it, however; the difference in chemical properties is still sufficient to upset biological systems. Trace amounts are harmless, as can be appreciated from the fact that deuterium occurs naturally. About 1 in 6500 hydrogen nuclei in water on earth are deuterium ones.

The normal helium nucleus contains two protons plus two neutrons, so it is called helium-4. There is a stable isotope, helium-3, that has only one neutron. In the atmosphere, one in a million helium atoms has a helium-3 nucleus. While normally, there is no big difference between the two isotopes, at very low cryogenic temperatures they do behave very differently. The reason is that both protons and neutrons have spin $1 / 2$, as do electrons, so a difference of one neutron switches the net atomic spin between half-integer (helium-3) and integer (helium-4). That makes the helium-3 atom a fermion but the helium-4 one a boson. At extremely low temperatures it makes a big difference in behavior, chapter 11.

In terms of symbols, it is conventional to precede the element symbol by
the mass number as a superscript and the atomic number as a subscript. So normal hydrogen-1 is indicated by ${ }_{1}^{1} \mathrm{H}$, hydrogen- 2 by ${ }_{1}^{2} \mathrm{H}$, helium- 3 by ${ }_{2}^{3} \mathrm{He}$, and helium- 4 by ${ }_{2}^{4} \mathrm{He}$.

Nuclei with the same mass number $A$ are called "isobars." Yes, this conflicts with the established usage of the word isobar for lines of constant pressure in meteorology, but in this case physicists have blown it. There is not likely to be any resulting confusion unless there is a nuclear winter.

Sometimes the element symbol is also followed by the number of neutrons as a subscript. However, that then raises the question whether $\mathrm{H}_{2}$ stands for hydrogen-3 or a hydrogen molecule. The neutron number can readily by found by subtracting the atomic number from the mass number,

$$
\begin{equation*}
N=A-Z \tag{14.1}
\end{equation*}
$$

so this book will leave it out.
It may also be noted that the atomic number is technically redundant, since the chemical symbol already implies the number of protons. It is often left away, because that confuses people who do not remember the atomic number of every chemical symbol in the periodic table. To create further confusion, deuterium is often indicated by chemical symbol D instead of H . It is hilarious to see people who have forgotten this search through a periodic table for element "D." For additional fun, the unstable hydrogen-3 nucleus, with one proton and two neutrons, is also called the "tritium" nucleus, or "triton," and indicated by T instead of ${ }_{1}^{3} \mathrm{H}$. The helium-3 nucleus is also called the "helion." Fortunately for us all, helion starts with an h .

The nuclei mentioned above are just a tiny sample of the total of 256 nuclei that are stable and a much greater number still that are observed but unstable. It is conventional to represent both the stable and unstable nuclei in a "Chart Of the Nuclides," (CON), like the one shown in figure 14.1. In the CON, the tiny green squares are the stable nuclei. Squares of colors other than green represent unstable nuclei. The horizontal position of each square gives the number of neutrons $N$ (selected "magic" values are listed along the horizontal axis). The vertical position gives the number of protons $Z$, (the crucial number that determines what chemical properties an atom with that nucleus has). Note that $Z=82$ is lead, the last element with at least one stable nucleus. In fact, lead has four stable isotopes and naturally occuring lead atoms have a fair chance of having any one of the four as nucleus. The fact that lead is so unusually stable has a lot to do with the fact that lead is right on top of the $Z=82$ magic line, and close to the $N=126$ magic line. But more on that later.

Before continuing the discussion of the CON, a graphical problem must be addressed. While you cannot argue about taste, $99.9 \%$ of readers would surely agree that 14.1 is (a) ugly as hell, and (b) requires a magnifying glass to read. The "Chart Of the Nuclides" is well suited for printing out on two yards of paper and hanging on the wall of your office in its full glory. But in a book, it really

Figure 14.1: Chart of the nuclides.
does not work. It could be made slightly bigger if printed out sideways, but rotating a monitor with coffee cups on it and cables attached is a bit awkward. And a crick in your neck is not that great either.

Based on these considerations, from now on, this book will no longer plot the neutron number $N$ along the horizontal axis, but the "neutron excess" $N-Z$. The neutron excess is how many more neutrons there are than protons. That is an important number, maybe even more important than the absolute number of neutrons. The corresponding modified chart of the nuclides is in figure 14.2. It will be called the RECON (Revised Chart of the Nuclei). It gives you something you can view in comfort.

But admittedly there are some disadvantages. In the RECON the isotones (the lines connecting nuclei with the same number of neutrons) are no longer vertical; now they slope down by $45^{\circ}$. That cannot be helped. Similarly the isobars, the lines connecting nuclei with the same total number of nucleons, no longer slope down by $45^{\circ}$ like in the CON. In the RECON they slope down with the smaller slope $1 / 2$ : going down one square to the previous chemical element now requires that you go two squares to the right to stay on the same isobar.

So be it. The good news is that the neutron excess is a lot more relevant to nuclear stability than the absolute number of nucleons. For example, at low values of $Z$, the green band in RECON figure 14.2 is vertical, demonstrating very clearly that indeed for light nuclei, the number of neutrons must be about

Figure 14.2: Nuclear decay modes. [pdf][con]
equal to the number of protons. Also for heavier nuclei, the RECON shows much more clearly exactly how much the relative number of neutrons goes up to mitigate the effect of the Coulomb repulsions between protons.

There is an other advantage to the RECON. It has to do with the fact that those nuclei in which both the number of protons and the number of neutrons is even, the "even-even" nuclei, are found to have enhanced stability. On the other hand those nuclei in which both the number of protons and the number of neutrons is odd, the "odd-odd" nuclei, are found to have reduced stability. Simply put, protons like to pair up, and so do neutrons.

It works out that in the RECON, the even-even and odd-odd nuclei end up on the same vertical lines. (These vertical lines alternate with vertical lines of even-odd and odd-even nuclei.) So wherever in figure 14.2 you see a vertical line with alternating green and non-green squares, well, the stable green squares are the even-even nuclei and the non-green ones in between the odd-odd ones. The pattern very convincingly demonstrates that indeed even-even nuclei are a lot more stable than odd-odd ones. (In the CON, the equivalent lines slant by $45^{\circ}$ and are not by far as striking.)

In the intermediate vertical lines in the RECON, where you do not see such a periodic variation of stability, you find the even-odd and odd-even nuclei. Note that on these lines, the vertical extent of green squares is much less than on the adjacent lines with even-even nuclei. This demonstrates graphically that even-even nuclei are not just a lot more stable than odd-odd ones; they are also a lot more stable than even-odd and odd-even ones.

All this also makes it easy to figure out whether a given nucleus is is eveneven or odd-odd in the RECON. Look whether the vertical line it is on has a series of alternating green and non-green squares; if so, then that is a line of even-even and odd-odd nuclei. The adjacent two lines then contain evenodd and odd-even nuclei. (In the region of heaviest nuclei, you can typically look at the yellow "alpha-decay" nuclei as a substitute for the green nuclei.) Alternatively, if you see two green squares immediately above each other in the RECON above $Z=8$, then that vertical line consists of even-odd and oddeven nuclei; there are no stable odd-odd nuclei above $Z=7$. (Conversely, the RECON illustrates that quite clearly too.)

Note also that the mass number $A$ is odd on the even-odd, odd-even vertical lines. And $A$ is even on the even-even, odd-odd vertical lines. While the mass number by iself does not have that much physical meaning, nuclear physicists often use "odd mass number nuclei" as a shorthand for "even-odd and odd-even nuclei."

If you are really a CON man or woman, there is nothing wrong with that. You can always click on the [con] link provided in the legend of the figure to load the figure in CON format as a separate pdf file. Conversely, if you really like the RECON format and you want to print it and hang it on your wall, click on the [pdf] link instead for a printable version. And either type of pdf can be
readily magnified to see details more clearly. [On linux I have to set preferences in buggy Adobe Acrobat reader to always open links before it works.]

Let's look at some of the details of RECON figure 14.2. The leftmost green square in the bottom row $(Z=1)$ is the hydrogen- 1 nucleus, and the green square immediately to the right of it is hydrogen-2, deuterium. The green squares on the second-lowest row $(Z=2)$ are helium- 3 and helium- 4 respectively.

Like in the CON, isotopes are found on the same horizontal line in the RECON. As mentioned, the horizontal position of each square in RECON figure 14.2 indicates the neutron excess. For example, hydrogen- 2 and helium -4 both have equal numbers of protons and neutrons. So they are at the same horizontal position, zero, in the figure. Similarly, hydrogen-1 and helium-3 both have a neutron excess of minus one. The figure shows that stable light nuclei have about the same number of neutrons as protons. However, for the heaviest nuclei, there are about $50 \%$ more neutrons than protons. For heavy nuclei, too many closely packed protons would mean too much Coulomb repulsion.

Many isotopes are unstable and decay spontaneously, liberating energy. For example, consider the blue square to the right of ${ }_{1}^{2} \mathrm{H}$ in figure 14.2. That is ${ }_{1}^{3} \mathrm{H}$, hydrogen-3 or tritium. It is unstable. After on average about twelve years, it will turn into helium-3. In particular, one of the two neutrons turns into a positively charged proton. So there are still three nucleons, the mass number has stayed the same, but the atomic number has increased one unit. In terms of RECON figure 14.2, the nucleus has changed into one that is one place up and two places to the left.

Since charge is conserved, the creation of the positive charge can only happen if the neutron emits a compensating negative charge; the neutron does so by emitting an electron. For historical reasons, a decay process of this type is called "beta decay" ( $\beta$-decay) instead of "electron emission;" initially it was not recognized that the observed radiation was merely high energy electrons. And the name could not be changed later, because that would add clarity. (An antineutrino is also emitted, but it is almost impossible to detect: solar neutrinos will readily travel all the way through the earth with only a miniscule chance of being captured.)

Nuclei with too many neutrons tend to use beta decay to turn the excess into protons in order to become stable. Figure 14.2 shows nuclei that suffer beta decay in blue. Since in the decay process they move towards the left, they move towards the stable green area. Although not shown in the figure, a lone neutron also suffers beta decay after about 10 minutes and so turns into a proton.

If nuclei have too many protons rather than too many neutrons, they can turn their excess protons into neutrons by emitting a positron. The positron, the anti-particle of the electron, carries away one unit of positive charge, turning a positively charged proton into a neutral neutron.

However, a nucleus has a much easier way to get rid of one unit of net
positive charge: it can swipe a negatively charged electron from the atom it is in. This is called "electron capture" (EC). An electron neutrino is emitted in this process.

Electron capture is also called K-capture of L-capture, depending on the electron shell from which the electron is swiped. It is also referred to as "inverse beta decay," especially within the context of "neutron stars." These stars are so massive that their atoms collapse under gravity and the electrons and protons combine into neutrons. These stars then emit enormous amounts of high-energy neutrinos, taking along a large amount of the available energy of the star.

Of course, "inverse beta decay" is not really inverse beta decay, because in beta decay the emitted electron does not go into an empty atomic orbit, and in beta decay no neutrino is absorbed; instead an antineutrino is emitted.

Positron emission is also often called "beta-plus decay" ( $\beta^{+}$-decay). After all, if you do have obsolete terminology, it is fun to use it to the fullest. Note that NUBASE 2003 uses the term beta-plus decay to indicate either positron emission or electron capture. In analogy with the beta-plus terminology, electron emission is also commonly called beta-minus decay or negatron emission. Some physicists leave the "r" away to save trees and talk about positons and negatons.

The nuclei that suffer beta-plus decay or electron capture are shown as red squares in figure 14.2. In the decay, a proton turns into a neutron, so the nucleus moves one place down and two places towards the right. That means that these nuclei too move towards the stable green area.

There are a variety of other ways in which nuclei may decay. If the number of protons or neutrons is really excessive, the nucleus may just kick out one of the bums instead of convert it. Nuclei that do that are marked with "P," respectively " N " in figure 14.2 ,

Similarly, heavy nuclei that are weakened by Coulomb repulsions tend to just throw some nucleons out. Commonly, a ${ }_{2}^{4} \mathrm{He}$ helium- 4 nucleus is emitted, as this is a very stable nucleus that does not require much energy to create. Such an emission is called "alpha decay" ( $\alpha$-decay) because helium- 4 emission would be easily understandable. Alpha decay reduces the mass number $A$ by 4 and the atomic number $Z$ by 2 . The nucleus moves two places straight down in RECON figure 14.2.

If nuclei are really oversized, they may just fall apart completely; that is called spontaneous fission.

Another process, "gamma decay," is not shown in figure 14.2. In gamma decay, an excited nucleus transitions to a lower energy state and emits the released energy as very energetic electromagnetic radiation. This is much like the spontaneous decay of excited electron levels in atoms, which too releases electromagnetic radiation. However, the electromagnetic radiation emitted in gamma decay is much more powerful than that emitted by atomic electrons, as nuclear energies are so much higher than those of atomic electrons. Unlike
the decays shown in figure 14.2, in gamma decay the type of nucleus does not change; there is no change in the number of protons nor neutrons.

Unlike gamma decay, the nuclear decays shown in figure 14.2 are from their their non-excited "ground state." But the shown decays are commonly associated with additional gamma radiation, since the decay tends to leave the changed nucleus in an excited state.

Gamma decay as a separate process, not directly caused by another process, is often referred to as an "isomeric transition" (IT) or "internal transition." In nuclear physics, an isomer is a long-lived excited state of a nucleus.

Besides gamma decay, a second way that an excited nucleus can get rid of excess energy is by throwing an electron from the atomic electron cloud surrounding the nucleus out of the atom. You or I would probably call that something like electron ejection. But what better name for throwing an electron, that is already outside the nucleus to start with, completely out of the atom than "internal conversion" (IC)? It can produce some of that hilarious confusion with the similar sounding term "internal transition." Internal conversion is usually included in the term "isomeric transition."

Figure 14.2 mixes colors if more than one decay mode occurs for a nucleus. The dominant decay is often immediately followed by another decay process. The subsequent decay is not shown. Data are from NUBASE 2003, without any later updates. The blank square right at the stable region is silver-106, and has a half-life of 24 minutes. Other sources list it as decaying through the expected electron capture or positron emission. But NUBASE 2003 lists that contribution as unknown and only mentions that beta-minus decay is negligible.

Since so many outsiders know what nuclear symbols mean, physicists prefer to use obsolete names to confuse them. Table 14.2 has a list of names used. The abbreviations refer to historical names for decay products of radium (radium emanation, radium A, etc.)

## Key Points

$0-$ Nuclei consist of protons and neutrons held together by the nuclear force.
$0-$ Protons and neutrons are collectively referred to as nucleons.
$0-$ Protons also repel each other by the Coulomb force.

0 The number of protons in a nucleus is the atomic number $Z$. The number of neutrons is the neutron number $N$. The total number of nucleons $Z+N$ is the mass number or nucleon number $A$.
$0-$ Nuclei with the same number of protons $Z$ correspond to atoms with the same place in the periodic table of chemistry. Therefore nuclei with the same atomic number are called isotopes.
$0-$ To promote confusion, nuclei with the same number of neutrons $N$ are called isotones, and nuclei with the same total number of nucleons $A$ are called isobars.
0- For an example nuclear symbol, consider ${ }_{2}^{4} \mathrm{He}$. It indicates a helium atom nucleus consisting of $A=4$ nucleons, the left superscript, of which $Z=2$ are protons, the left subscript. Since it would not be helium if it did not have 2 protons, that subscript is often left away. If you do not remember $Z$ for, say, ${ }^{146} \mathrm{Pm}$, you can look it up in a periodic table, like 5.8. But avoid doing so with "elements" $D$ and $T$.
$0-$ Since these rules are too simple, physicists often drag up obsolete symbols like "RE" and "RaF" from the dark history of nuclear physics. You can look these up in a table above.
$0-$ The name for the nucleus with symbol ${ }_{2}^{4} \mathrm{He}$ is helium-4, where the 4 is again the number of nucleons $A$.
0- An odd mass number $A$ corresponds to either an even-odd nucleus, a nucleus in which the number of protons is even and the number of nucleons odd, or to an odd-even nucleus, in which it is the other way around. An even mass number $A$ corresponds to either an even-even nucleus, which tends to have relatively high stability, or to an oddodd nucleus, which tends to have relatively low stability. The vertical columns in a RECON plot correspond alternatingly to odd and even mass numbers $A$. The two types of columns look very different.
$0-$ Nuclei can decay by various mechanisms. To promote confusion, emission of a helium-4 nucleus is called alpha decay or alpha decay. Emission of an electron is called beta decay, or $\beta$ decay, or beta-minus decay, or $\beta^{-}$decay, or negatron emission, or negaton emission, but never electron emission. To do the latter would be severely frowned upon by physicists. Emission of a positron (positon) may be called beta-plus decay, or $\beta^{+}$decay, but either term might be used to also indicate electron capture (EC), depending on who uses the term. Electron capture may also be called K-capture or L-capture or even inverse beta decay, though it is not. More extreme decay mechanisms are proton or neutron emission, and spontaneous fission. Kicking an electron in the electron cloud outside the nucleus completely free of the atom is called internal conversion. Mere emission of electromagnetic radiation is called gamma decay or $\gamma$ decay.
$0 \simeq$ No, this is not a story made up by this book to put physicists in a bad light.

### 14.4 Draft: Magic numbers

In nuclear physics, there are certain special values for the number of protons or the number of neutrons that keep popping up. Those are the values shown by horizontal and diagonal lines in the decay plot figure 14.2:

$$
\begin{equation*}
\text { magic numbers: } \quad 2,8,20,28,50,82,126, \ldots \tag{14.2}
\end{equation*}
$$

These "magic" numbers were historically found to be associated with unusual stability properties. For example, the magic number of 82 neutrons occurs in 7 stable nuclei, more stable nuclei than for any other number of neutrons. The runners-up are 20 and 50 neutrons, also both magic numbers, that each occur in 5 stable nuclei.

Nuclei that have a magic number of protons also tend to have unusual stability. For example, the element with the most stable isotopes is tin, with 10 of them. Tin has $Z=50$ protons, a magic number. To be sure, the runner up, Xenon with nine stable isotopes, has $Z=54$, not a magic number, but the heaviest of these nine stable isotopes has a magic number of neutrons.

The last element to have any stable isotopes at all is lead, and its number of protons $Z=82$ is magic. The lead isotope ${ }_{82}^{208} \mathrm{~Pb}$, with 82 protons and 126 neutrons, is doubly magic, and it shows. It holds the triple records of being the heaviest nucleus that is stable, the heaviest element that is stable, and the highest number of neutrons that is stable.

The doubly magic ${ }_{2}^{4} \mathrm{He}_{2}$ nucleus, the alpha particle, is stable enough to be emitted in alpha decays of other nuclei.

Nuclei with magic numbers also have unusually great isotopic presence on earth as well as cosmic abundance. The reason for the magic numbers will eventually be explained through a simple quantum model for nuclei called the "shell model." Their importance will further be apparent throughout the figures in this chapter.

### 14.5 Draft: Radioactivity

Nuclear decay is governed by chance. It is impossible to tell exactly when any specific nucleus will decay. Therefore, the decay is phrased in terms of statistical quantities like specific decay rate, lifetime and half-life. This section explains how these are defined.

### 14.5.1 Draft: Half-life and decay rate

As a generic example of an unstable nucleus, consider tritium, an isotope of hydrogen. The ${ }_{1}^{3} \mathrm{H}$ tritium nucleus, the triton, consists of one proton and two neutrons. The triton suffers beta decay. Eventually it will eject an electron and an antineutrino. This turns one of the two neutrons into a proton. So the decay turns the triton into the ${ }_{2}^{3} \mathrm{He}$ helium nucleus isotope called the "helion." The original triton is lost.

Unlike the "normal" ${ }_{2}^{4} \mathrm{He}$ helium nucleus, the helion contains only one neutron. However, it is stable; there will not be any further spontaneous decays.
(Note that the triton decays even though it has two neutrons, a magic number. But the helion it decays to has two protons, also magic. And just like a lone neutron decays into a less heavy proton, two neutrons in the tiny triton is just too much of a neutron excess compared to the negligible additional Coulomb repulsion in the helion.)

The big question in this section is, when will an unstable nucleus like the triton decay? Unfortunately, there is no complete anwer to that question. A given triton might last for 10 years, or it might last for 20 years or whatever. It could last less than a year, though that is not very likely. It could last for 100 years, even though that is much less likely still. But there is no way to tell for sure.

However, suppose you take a very large number of tritons and record for each how long the triton lives. Then you can average all these times and you get a number that is called the "lifetime" $\tau$ of the triton. The correct term would be expected or average lifetime, but this is physics, remember. Correct terms are not allowed. (To be fair, some physicists do use the proper term "mean lifetime" instead of just lifetime.)

If you average over enough tritons, you will find this mean lifetime of tritons to be almost 18 years. But not a single triton will decay after exactly 18 years. It is much like the expected lifetime of a newborn baby in the USA is, say, 80 years. Despite that, almost no one dies on their 80th birthday. Some die at birth or as kids.

Still, there is one big difference between people and nuclei. If you have a person who is 80 years old, surely you do not expect them to live until they become 160 years old. But if you have a bunch of tritons, on average this bunch of tritons will last for another 18 years. That is regardless of how long these tritons have survived already when you start observing them. Nuclear decay is a completely random process that occurs "out of the blue;" it does not depend on any previous history of the nucleus.

There is another issue. Unless you are an accountant by calling, why would you want to sit down, measure lifetimes of nuclei, and average them? What is the use?

A physically much more relevant scenario is that you have managed to create
a large number of tritons, and you would like to know how long they will last for doing experiments. In particular, you might want to know how long it takes before half of the tritons you created with blood, tears, and tax-payer money, are gone. This physically more meaningful time period is called the "half-life" $\tau_{1 / 2}$. It is related to the mean lifetime by a simple factor $\ln 2$ :

$$
\begin{equation*}
\tau_{1 / 2}=\tau \ln 2 \tag{14.3}
\end{equation*}
$$

Note that $\ln 2$ is less than one. Half-life is somewhat shorter than mean lifetime.
The half-life of the triton is 12.32 years. So if you initially have a large collection of tritium nuclei, after 12.32 years only half will be left. After 24.64 years, only a quarter will remain, and after a century only $0.4 \%$. After a millennium only $410^{-23} \%$ will remain. (Since a gram of tritium contains about $210^{23}$ atoms, after a millenium, not a single atom would be left of a gram of tritium, if you managed to create that many of them!)

Now the earth is over 4 million millenia old. So you will appreciate that almost none of the tritium ever present on earth still exists. Some new tritium is continuously being created in the atmosphere by high-energy cosmic rays, but because of the geologically short half-life, there is no measurable accumulation. The total amount of tritium present on earth is virtually zero.

As in an earlier section, figure 14.3 shows again the decay processes of the nuclei. But unlike in the earlier figure 14.2, this time the square size of each nucleus has been adjusted to illustrate its half-life.

For the full size squares in the figure, the half-life is $10^{18}$ seconds or longer. Now $10^{18}$ seconds is about twice the estimated age of the universe since the Big Bang. So for nuclei that really have full size squares in figure 14.3, most of these nuclei that the universe ever created is likely to be still around.

On the other hand, if the square size of a nucleus is even slightly smaller than full size, then most of these nuclei that the universe ever created will have decayed. You may note that the square size of the ${ }_{1}^{3} \mathrm{H}$ triton is noticably smaller than full size.

On the other hand, all stable green nuclei have full size squares. You might also note bismuth-209, ${ }_{83}^{209} \mathrm{Bi}$. While not actually stable, for all practical puposes it is. Its half-life of $610^{26}$ seconds exceeds the age of the unverse by a factor of over a billion. In fact, it took physicists until 2003 to observe that bismuth-209 did actually suffer alpha decay; until then it was believed stable. (Note that bismuth 209 has 126 neutrons, a magic number.) The various double-beta-decay light green nuclei live even longer, on the order of $10^{30}$ seconds.

Based on various arguments, it was decided to take the minimum half-life shown in figure 14.3 to be one nanosecond. Clearly the figure needs some lower limit. And a nanosecond is really fast for alpha decay, and much faster than any beta decay. (Note that you do not see any really small red or blue squares in figure 14.3, and only a few yellow ones.) And for gamma decay, a nanosecond is often used as a cut-off between "prompt" and "isomeric" decay.

Figure 14.3: Nuclear half-lifes. [pdf][con]

Still, some nuclear decay processes are much quicker than a nanosecond. For example, you might note that the light nuclei that decay though proton or neutron emission in figure 14.2 have disappeared in figure 14.3. Such a decay process may have a half life on the order of 100 ys , (i.e. $10010^{-24}$ seconds). That is much faster than the normal decays. In fact, in terms of quasi-classical physics, these decay times are comparable to the time for a nucleon with a speed of say a tenth of that of light to "move" just once through a nucleus with a size of the order of femtometers.

Another notable nucleus that has disappeared is ${ }_{4}^{8} \mathrm{Be}$, beryllium-8. Berylium8 falls apart in two ${ }_{2}^{4} \mathrm{He}$, helium-4, alpha particles. The half-life of that process is just 67 as (i.e. $6710^{-18}$ seconds). While it is technically called alpha-decay because an alpha particle is emitted, it is physically very different from the normal alpha decay of heavy nuclei. In the alpha decay of heavy nuclei, a heavy nucleus is left, not a second alpha particle. In particular, the berylium- 8 decay is many orders of magnitude faster than the normal alpha decays discussed in section 14.11.

Besides (mean) lifetime and half-life, there is one more related term that is commonly used in describing nuclear decays. It is called the "specific decay rate" $\lambda$. The specific decay rate is the relative amount of nuclei in a large sample that is lost per unit time. Mathematically, the specific decay rate is just the inverse of the mean lifetime $\tau$ :

$$
\begin{equation*}
\lambda \equiv \frac{1}{\tau} \tag{14.4}
\end{equation*}
$$

To better understand the various variables mathematically, it may be worthwhile to see how the mentioned relationships between them arise. First, according to the very definition of the decay rate $\lambda$ above, if the current number of nuclei is $I$, then the number of nuclei that are lost, call it $-\mathrm{d} I$, in an infinitesimally small time interval $\mathrm{d} t$ is given by

$$
\begin{equation*}
-\mathrm{d} I=\lambda I \mathrm{~d} t \tag{14.5}
\end{equation*}
$$

This can be integrated after moving the $I$ to the left-hand side. The result shows that if the amount of nuclei at time zero is $I_{0}$, then at an arbitrary later time $t$ the amount of remaining nuclei $I$ is

$$
\begin{equation*}
I=I_{0} e^{-\lambda t} \tag{14.6}
\end{equation*}
$$

(To check this expression, just differentiate it.) To find the half-life, you can set $I=\frac{1}{2} I_{0}$ and $t=\tau_{1 / 2}$; that shows that $\tau_{1 / 2}$ must be $\ln 2 / \lambda$. Also, from the expression above, you can compute the (average) lifetime as

$$
\tau=\int_{0}^{\infty} t \frac{-\mathrm{d} I}{\mathrm{~d} t} \mathrm{~d} t / \int_{0}^{\infty} \frac{-\mathrm{d} I}{\mathrm{~d} t} \mathrm{~d} t
$$

giving $\tau=1 / \lambda$. That then gives $\tau_{1 / 2}=\ln 2 \tau$.

### 14.5.2 Draft: More than one decay process

One very important point must be emphasized. Many nuclei undergo more than one decay process. In that case, each decay process has its own decay rate, independent of the other decay processes. In such cases,

Always add specific decay rates, never lifetimes or half-lifes.
The sum of the specific decay rates gives the total specific decay rate of the nucleus. The reciprocal of that total is the actual lifetime. Multiply by $\ln 2$ to get the actual half-life.

### 14.5.3 Draft: Other definitions

You probably think that having three different names, the specific decay rate $\lambda$, the lifetime $\tau$, and the half-life $\tau_{1 / 2}$, for essentially the same physical quantity, is no good. You want more! Physicists are only too happy to oblige. How about using the term "decay constant" instead of specific decay rate? Its redeeming feature is that "constant" is a much more vague term, maximizing confusion. Even better, how does "disintegration constant" sound? Especially since the nucleus clearly does not disintegrate in decays other than spontaneous fission? Why not call it "specific activity," come to think of it? Activity is another of these vague terms that the hated nonspecialists cannot make heads or tails of.

How about calling the product $\lambda I$ the "decay rate" or "disintegration rate" or simply the "activity?"

You probably want some units to go with that! What is more logical than to take the decay rate or activity to be in units of "curie," with symbol Ci and equal $3.710^{10}$ decays per second. (Of course you guessed that straight away. If you add 3 and 7 you get 10 , not?) There is also the "becquerel," Bq , equal to 1 decay per second, defined but almost never used. Why not "dpm," disintegrations per minute, come to think of it? Why not indeed. The minute is just the additional unit the SI system needs, and using an acronym is great for creating confusion.

Of course the "activity" only tells you the amount of decays, not how bad the generated radiation is for your health. The "exposure" is the ionization produced by the radiation in a given mass of air, in SI units of Coulomb per kg. Exposure is very important for all people made of air. Of course, a better unit than a blasted SI one is needed, so the "roentgen" or "röntgen" R is defined to $2.5810^{-4} \mathrm{C} / \mathrm{kg}$. Why not?

But health-wise you may be more interested in the "absorbed dose" or "total ionizing dose" or "TID." That is the radiation energy absorbed per unit mass. That would be in J/kg or "gray," Gy, in SI units, but people really use the "rad" which is one hundredth of a gray.

If an organ or tissue absorbs a given dose of radiation, it is likely to be a lot worse if all that radiation is concentrated near the surface than if it is spread
out. The "quality factor" $Q$ or the somewhat differently defined "radiation weighting factor" $w_{\mathrm{R}}$ is designed to correct for that fact. X-rays, beta rays, and gamma rays have radiation weighting factors (quality factors) of 1 , but energetic neutrons, alpha rays and heavier nuclei go up to 20 . Higher quality means worse for your health. Of course you already guessed that.

The bad effects of the radiation on your health are taken to be approximately given by the "equivalent dose," equal to the average absorbed dose of the organ or tissue times the radiation weighting factor. It is in SI units of $\mathrm{J} / \mathrm{kg}$, called the "sievert" Sv, but people really use the "rem," equal to one hundredth of a sievert. Note that the units of dose and equivalent dose are equal; the name is just a way to indicate what quantity you are talking about. It works if you can remember all these names.

To get the "effective dose" for your complete body, the equivalent doses for the organs and tissues must still be multiplied by "tissue weighting factors and summed. The weighting factors add up to one when summed over all the parts of your body. The ICRP defines "dose equivalent" different from equivalent dose. Dose equivalent is used on an operational basis. The personal dose equivalent is defined as the product of the dose at a point at an appropriate depth in tissue, (usually below the point where the dosimeter is worn), times the quality factor (not the radiation weighting factor).

### 14.6 Draft: Mass and energy

Nuclear masses are not what you would naively expect. For example, since the deuterium nucleus consists of one proton and one neutron, you might assume its mass is the sum of that of a proton and a neutron. It is not. It is less.

This weird effect is a consequence of Einstein's famous relation $E=m c^{2}$, in which $E$ is energy, $m$ mass, and $c$ the speed of light, chapter 1.1.2. When the proton and neutron combine in the deuterium nucleus, they lower their total energy by the binding energy that keeps the two together. According to Einstein's relation, that means that the mass goes down by the binding energy divided by $c^{2}$. In general, for a nucleus with $Z$ protons and $N$ neutrons,

$$
\begin{equation*}
m_{\text {nucleus }}=Z m_{\mathrm{p}}+N m_{\mathrm{n}}-\frac{E_{\mathrm{B}}}{c^{2}} \tag{14.7}
\end{equation*}
$$

where

$$
m_{\mathrm{p}}=1.67262110^{-27} \mathrm{~kg} \quad m_{\mathrm{n}}=1.67492710^{-27} \mathrm{~kg}
$$

are the mass of a lone proton respectively a lone neutron at rest, and $E_{\mathrm{B}}$ is the binding energy. This result is very important for nuclear physics, because mass is something that can readily be measured. Measure the mass accurately and you know the binding energy.

In fact, even a normal hydrogen atom has a mass lower than that of a proton and electron by the 12.6 eV (electron volt) binding energy between proton and electron. But scaled down by $c^{2}$, the associated change in mass is negligible.

In contrast, nuclear binding energies are on the scale of MeV instead of eV , a million times higher. It is the devastating difference between a nuclear bomb and a stick of dynamite. Or between the almost limitless power than can be obtained from peaceful nuclear reactors and the limited supply of fossil fuels.

At nuclear energy levels the changes in mass become noticeable. For example, deuterium has a binding energy of 2.2245 MeV . The proton has a rest mass that is equivalent to 938.272013 MeV in energy, and the neutron 939.565561 MeV . (You see how accurately physicists can measure masses.) Therefore the mass of the deuteron nucleus is lower than the combined mass of a proton and a neutron by about $0.1 \%$. It is not big, but observable. Physicists are able to measure masses of reasonably stable nuclei extremely accurately by ionizing the atoms and then sending them through a magnetic field in a mass spectrograph or mass spectrometer. And the masses of unstable isotopes can be inferred from the end products of nuclear reactions involving them.

As the above discussion illustrates, in nuclear physics masses are often expressed in terms of their equivalent energy in MeV instead of in kg. To add further confusion and need for conversion factors, still another unit is commonly used in nuclear physics and chemistry. That is the "unified atomic mass unit" (u), also called "Dalton," (Da) or "universal mass unit" to maximize confusion. The "atomic mass unit" (amu) is an older virtually identical unit, or rather two virtually identical units, since physicists and chemists used different versions of it in order to achieve that supreme perfection in confusion.

These units are chosen so that atomic or nuclear masses expressed in terms them are approximately equal to the number of nucleons, (within a percent or so.) The current official definition is that a carbon- $12,{ }_{6}^{12} \mathrm{C}$, atom has a mass of exactly 12 u . That makes 1 u equivalent 931.494028 MeV . That is somewhat less than the mass of a free proton or a neutron.

One final warning about nuclear masses is in order. Almost always, it is atomic mass that is reported instead of nuclear mass. To get the nuclear mass, the rest mass of the electrons must be subtracted, and a couple of additional correction terms applied to compensate for their binding energy, [37]:

$$
\begin{equation*}
m_{\text {nucleus }}=m_{\text {atom }}-Z m_{\mathrm{e}}+A_{e} Z^{2.39}+B_{e} Z^{5.35} \tag{14.8}
\end{equation*}
$$

$m_{\mathrm{e}}=0.51099891 \mathrm{MeV} \quad A_{e}=1.4438110^{-5} \mathrm{MeV} \quad B_{e}=1.5546810^{-12} \mathrm{MeV}$
The nuclear mass is taken to be in MeV . So it is really the rest mass energy, not the mass, but who is complaining? Just divide by $c^{2}$ to get the actual mass. The final two correction terms are really small, especially for light nuclei, and are often left away (but not in the data presented here).

### 14.7 Draft: Binding energy

The binding energy of a nucleus is the energy that would be needed to take it apart into its individual protons and neutrons. Binding energy explains the overall trends in nuclear reactions.

As explained in the previous section, the binding energy $E_{\mathrm{B}}$ can be found from the mass of the nucleus. The specific binding energy is defined as the binding energy per nucleon, $E_{\mathrm{B}} / A$. Figure 14.4 shows the specific binding energy of the nuclei with known masses. The highest specific binding energy is 8.8 MeV , and occurs for ${ }_{28}^{62} \mathrm{Ni}$ nickel. Nickel has 28 protons, a magic number. However, nonmagic ${ }_{26}^{58} \mathrm{Fe}$ and ${ }_{26}^{56} \mathrm{Fe}$ are right on its heels.

Nuclei can therefore lower their total energy by evolving towards the nickeliron region. Light nuclei can "fusion" together into heavier ones to do so. Heavy nuclei can emit alpha particles or fission, fall apart in smaller pieces.

Figure 14.4 also shows that the binding energy of most nuclei is roughly 8 MeV per nucleon. However, the very light nuclei are an exception; they tend to have a quite small binding energy per nucleon. In a light nucleus, each nucleon only experiences attraction from a small number of other nucleons. For example, deuterium only has a binding energy of 1.1 MeV per nucleon.

The big exception to the exception is the doubly magic ${ }_{2}^{4} \mathrm{He}$ nucleus, the alpha particle. It has a stunning 7.07 MeV binding energy per nucleon, exceeding its immediate neighbors by far.

The ${ }_{4}^{8}$ Be beryllium nucleus is not bad either, also with 7.07 MeV per nucleon, almost exactly as high as ${ }_{2}^{4} \mathrm{He}$, though admittedly that is achieved using eight nucleons instead of only four. But clearly, ${ }_{4}^{8} \mathrm{Be}$ is a lot more tightly bound than its immediate neighbors.

It is therefore ironic that while various of those neighbors are stable, the much more tightly bound ${ }_{4}^{8} \mathrm{Be}$ is not. It falls apart in about 67 as (i.e. $6710^{-18}$ s), a tragic consequence of being able to come neatly apart into two alpha particles that are just a tiny bit more tightly bound. It is the only alpha decay among the light nuclei. It is an exception to the rule that light nuclei prefer to fusion into heavier ones.

But despite its immeasurably short half-life, do not think that ${ }_{4}^{8} \mathrm{Be}$ is not important. Without it there would be no life on earth. Because of the absence of stable intermediaries, the Big Bang produced no elements heavier than beryllium, (and only trace amounts of that) including no carbon. As Hoyle pointed out, the carbon of life is formed in the interior of aging stars when ${ }_{4}^{8} \mathrm{Be}$ captures a third alpha particle, to produce ${ }_{6}^{12} \mathrm{C}$, which is stable. This is called the "triple alpha process." Under the extreme conditions in the interior of collapsing stars, given time this process produces significant amounts of carbon despite the extremely short half-life of ${ }_{4}^{8} \mathrm{Be}$. The process is far too slow to have occurred in the Big Bang, however.

For ${ }_{6}^{12} \mathrm{C}_{6}$ carbon, the superior number of nucleons has become big enough to

Figure 14.4: Binding energy per nucleon. [pdf][con]
overcome the doubly magic advantage of the three corresponding alpha particles. Carbon-12's binding energy is 7.68 MeV per nucleon, greater than that of alpha particles.

### 14.8 Draft: Nucleon separation energies

Nucleon separation energies are the equivalent of atomic ionization energies, but for nuclei. The proton separation energy is the minimum energy required to remove a proton from a nucleus. It is how much the rest mass energy of the nucleus is less than that of the nucleus with one less proton and a free proton.

Similarly, the neutron separation energy is the energy needed to remove a neutron. Figures 14.5 and 14.6 show proton and neutron separation energies as grey tones. Note that these energies are quite different from the average binding energy per nucleon given in the previous subsection. In particular, it takes a lot of energy to take another proton out of an already proton-deficient nucleus. And the same for taking a neutron out of an already neutron deficient nucleus.

In addition, the vertical striping in 14.5 shows that the proton separation energy is noticeably higher if the initial number of protons is even than if it is odd. Nucleons of the same kind like to pair up. If a proton is removed from a nucleus with an even number of protons, a pair must be broken up, and that requires additional energy. The neutron separation energy 14.6 shows diagonal striping for similar reasons; neutrons too pair up.

There is also a visible step down in overall grey level at the higher magic numbers. It is not dramatic, but real. It illustrates that the nucleon energy levels come in "shells" terminated by magic numbers. In fact, this step down in energy defines the magic numbers. That is discussed further in section 14.12.

Figures 14.7 and 14.8 show the energy to remove two protons, respectively two neutrons from even-even nuclei. This show up the higher magic numbers more clearly as the pairing energy effect is removed as a factor.

### 14.9 Draft: Modeling the Deuteron

This book largely limits itself to relatively simple, but effective, models for nuclei. However, the deuteron, the deuterium nucleus, is the most simple nontrivial nucleus, as it consists of only a single proton. So, to give a rough idea of what sort of more advanced nuclear theories there are out there, this one section will look at the deuteron in some more detail.

Addendum \{A.41\} explores some of the nuclear potentials that you can write down to model the deuteron. Simple potentials such as those described there give a lot of insight in the deuteron. They give ballpark values for the potential and kinetic energies. They also give an explanation for the observations that the deuteron is only weakly bound and that there is no second bound state.

Figure 14.5: Proton separation energy. [pdf][con]

Figure 14.6: Neutron separation energy. [pdf][con]

Figure 14.7: Proton pair separation energy. [pdf][con]

Figure 14.8: Neutron pair separation energy. [pdf][con]

They show the relatively large size of the deuteron: there is a good chance that the proton and neutron can be found way apart. Simple additions to the potential can describe the spin dependence and the violation of orbital angular momentum conservation.

However, there is a problem. These potentials describe a deuteron consisting of a proton and a neutron. But the proton and neutron are not elementary particles: each consists of three quarks.

This internal structure should not be a much of a concern when the proton and neutron are relatively far apart. But if the two get really close? Surely in that case the physics should be described in terms of six quarks that interact through gluons and the Pauli exclusion principle, [5, p. 95]? Eventually the proton and neutron must lose their identity. Then there is no longer any reasonable justification for a picture of a free-space proton interacting with a free-space neutron.

A rough idea of the scales involved may be obtained by looking at charge radii. The charge radius of a particle is a measure of the size of its charge distribution. Now the proton has a charge radius of about 0.88 fm . The deuteron has a charge radius of 2.14 fm . So at least the charge radius of a proton is not that much smaller than the size of the deuteron. And a quantum description of the deuteron needs to consider all possible nucleon spacings. Clearly for the smallest nucleon spacings, the two must intrude nontrivially into each other's space.

Consider another example of compound structures, noble gas atoms. When such atoms are relatively far apart, they can be modeled well as point particles forming an ideal gas. You might add some simple Van der Waals forces to that picture. However, when the atoms get pushed close together, the electromagnetic interactions between them become much more complex. And if you try to push the atoms even closer together, they resist that very strongly. The reason is the Pauli exclusion principle, chapter 5.10. More than two electrons cannot be pushed in the same spatial state.

The big difference is of course that the electromagnetic interactions of the electrons and nuclei that make up atoms are well understood. There is as yet no good way to describe the color force interactions between the quarks that make up nucleons. (Certainly not at the relatively low energies of importance for nuclear structure.)

Physicists have developed a model that is somewhere intermediate between that of interacting free-space nucleons and interacting quarks. In the model, the forces between nucleons are produced by the exchange of particles called "pions." That is much like how in relativistic quantum mechanics, electromagnetic forces are produced by the exchange of photons. Or how the forces between quarks are believed to be produced by the exchange of gluons. These exchanged particles are "virtual" ones.

Roughly speaking, relativistic mass-energy equivalence combined with quan-
tum uncertainty in energy allows some possibility for these particles to be found near the real particles. (See addendum \{A.42\} for a more quantitative description of these ideas.)

The picture is now that the proton and neutron are elementary particles but "dressed" in a coat of virtual pions. Pions consist of two quarks. More precisely, they consist of a quark and an antiquark. There are three pions; the positively charged $\pi^{+}$, the neutral $\pi^{0}$, and the negatively charged $\pi^{-}$. Pions have no spin. They have negative intrinsic parity. The charged pions have a mass of 140 MeV , while the uncharged one has a slightly smaller mass of 135 MeV .

When the neutron and proton exchange a pion, they also exchange its momentum. That produces a force between them.

There are a number of redeeming features to this model:

1. It explains the short range of the nuclear force. That is worked out in addendum $\{\mathrm{A} .42\}$.
However, the same result is often derived much quicker and easier in literature. That derivation does not require any Hamiltonians to be written down, or even any mathematics above the elementary school level. It uses the popular so-called "energy-time uncertainty equality," chapter 7.2.2,
any energy difference you want $\times$ any time difference you want $=\frac{1}{2} \hbar$
To apply it to pion exchange, replace "any energy difference you want" with the rest mass energy of the virtual pion that supposedly pops up, about 138 MeV on average. Replace "any time difference you want" with the time that the pion exists. (Model the pion here as a classical particle with definite values of position versus time.) From the time that the pion exists, you can compute how far it travels. That is because clearly it must travel with about half the speed of light: it cannot travel with a speed less than zero nor more than the speed of light. Put in the numbers, ignore the stupid factors $\frac{1}{2}$ because you do not need to be that accurate, and it shows that the pion would travel about 1.4 fm if it had a position to begin with. That range of the pion is consistent with the experimental data on the range of the nuclear force.
(OK, someone might object the pions do most decidedly not pop up and disappear again. The ground state of a nucleus is an energy eigenstate and those are stationary, chapter 7.1.4. But why worry about such minor details?)
2. It gives a reasonable explanation of the anomalous magnetic moments of the proton and neutron. The magnetic moment of the proton can be written as

$$
\mu_{\mathrm{p}}=g_{\mathrm{p}} \frac{1}{2} \mu_{\mathrm{N}} \quad g_{\mathrm{p}}=5.586 \quad \mu_{\mathrm{N}}=\frac{e \hbar}{2 m_{\mathrm{p}}} \approx 5.05110^{-27} \mathrm{~J} / \mathrm{T}
$$

Here $\mu_{\mathrm{N}}$ is called the nuclear magneton. It is formed with the charge and mass of the proton. Now, if the proton was an elementary particle with spin one-half, the factor $g_{\mathrm{p}}$ should be two, chapter 13.4. Or at least close to it. The electron is an elementary particle, and its similarly defined $g$-factor is 2.002 . (Of course that uses the electron mass instead of the proton one.)

The magnetic moment of the neutron can similarly be written

$$
\mu_{\mathrm{n}}=g_{\mathrm{n}} \frac{1}{2} \mu_{\mathrm{N}} \quad g_{\mathrm{n}}=-3.826 \quad \mu_{\mathrm{N}}=\frac{e \hbar}{2 m_{\mathrm{p}}} \approx 5.05110^{-27} \mathrm{~J} / \mathrm{T}
$$

Note that the proton charge and energy are used here. In fact, if you consider the neutron as an elementary particle with no charge, it should not have a magnetic moment in the first place.
Suppose however that the neutron occasionally briefly flips out a negatively charged virtual $\pi^{-}$. Because of charge conservation, that will leave the neutron as a positively charged proton. But the pion is much lighter than the proton. Lighter particles produce much greater magnetic moments, all else being the same, chapter 13.4. In terms of classical physics, lighter particles circle around a lot faster for the same angular momentum. To be sure, as a spinless particle the pion has no intrinsic magnetic moment. However, because of parity conservation, the pion should have at least one unit of orbital angular momentum to compensate for its intrinsic negative parity. So the neutral neutron acquires a big chunk of unexpected negative magnetic moment.
Similar ideas apply for the proton. The proton may temporarily flip out a positively charged $\pi^{+}$, leaving itself a neutron. Because of the mass difference, this can be expected to significantly increase the proton magnetic moment.
Apparently then, the virtual $\pi^{+}$pions increase the $g$-factor of the proton from 2 to 5.586 , an increase of 3.586 . So you would expect that the virtual $\pi^{-}$pions decrease the $g$-factor of the neutron from 0 to -3.586 . That is roughly right, the actual $g$-factor of the neutron is -3.826 .
The slightly larger value seems logical enough too. The fact that the proton turns occasionally into a neutron should decrease its total magnetic moment. Conversely, the neutron occasionally turns into a proton. Assume that the neutron has half a unit of spin in the positive chosen $z$-direction. That is consistent with one unit of orbital angular momentum for the $\pi^{-}$and minus half a unit of spin for the proton that is left behind. So the proton spins in the opposite direction of the neutron, which means that it increases the magnitude of the negative neutron magnetic moment. (The other possibility, that
the $\pi^{-1}$ has no $z$-momentum and the proton has half a positive unit, would decrease the magnitude. But this possibility has only half the probability, according to the Clebsch-Gordan coefficients figure 12.6.)
3. The same ideas also provide an explanation for a problem with the magnetic moments of heavier nuclei. These do not fit theoretical data that well, figure 14.42. A closer examination of these data suggests that the intrinsic magnetic moments of nucleons are smaller inside nuclei than they are in free space. That can reasonably be explained by assuming that the proximity of other nucleons affects the coats of virtual pions.
4. It explains a puzzling observation when high-energy neutrons are scattered off high-energy protons going the opposite way. Because of the high energies, you would expect that only a few protons and neutrons would be significantly deflected from their path. Those would be caused by the few collisions that happen to be almost head-on. And indeed relatively few are scattered to say about $90^{\circ}$ angles. But an unexpectedly large number seems to get scattered almost $180^{\circ}$, straight back to where they came from. That does not make much sense.
The more reasonable explanation is that the proton catches a virtual $\pi^{-}$from the neutron. Or the neutron catches a virtual $\pi^{+}$from the proton. Either process turns the proton into a neutron and viceversa. So an apparent reflected neutron is really a proton that kept going straight but changed into a neutron. And the same way for an apparent reflected proton.
5. It can explain why charge independence is less perfect than charge symmetry. A pair of neutrons can only exchange the neutral $\pi^{0}$. Exchange of a charged pion would create a proton and a nucleon with charge -1 . The latter does not exist. (At least not for measurable times, nor at the energies of most interest here.) Similarly, a pair of protons can normally only exchange a $\pi^{0}$. But a neutron and a proton can also exchange charged pions. So pion interactions are not charge independent.
6. The nuclear potential that can be written down analytically based on pion exchange works very well at large nucleon spacings. This potential is called the "OPEP," for One Pion Exchange Potential, \{A.42\}.
There are also drawbacks to the pion exchange approach.
For one, the magnetic moments of the neutron and proton can be reasonably explained by simply adding those of the constituent quarks, [31, pp. 74, 745]. To be sure, that does not directly affect the question whether the pion exchange model is useful. But it does make the dressed nucleon picture look quite con-
trived.
A bigger problem is nucleon spacings that are not so large. One-pion exchange is generally believed to be dominant for nucleon spacings above 3 fm , and reasonable for spacings above 2 fm , [36, p. 135, 159], [5, p. 86, 91]. However, things get much more messy for spacings shorter than that. That includes the vital range of spacings of the primary nucleon attractions and repulsions. For these, two-pion exchange must be considered. In addition, excited pion states and an excited nucleon state need to be included. That is much more complicated. See addendum $\{\mathrm{A} .42\}$ for a brief intro to some of the issues involved.

And for still shorter nucleon spacings, things get very messy indeed, including multi-pion exchanges and a zoo of other particles. Eventually the question must be at what spacing nucleons lose their distinctive character and a model of quarks exchanging gluons becomes unavoidable. Fortunately, very close spacings correspond to very high energies since the nucleons strongly repel each other at close range. So very close spacings may not be that important for most nuclear physics.

Because of the above and other issues, many physicists use a less theoretical approach. The OPEP is still used at large nucleon spacings. But at shorter spacings, relatively simple chosen potentials are used. The parameters of those "phenomenological" potentials are adjusted to match the experimental data.

It makes things a lot simpler. And it is not clear whether the theoretical models used at smaller nucleon spacings are really that much more justified. However, phenomenological potentials do require that large numbers of parameters are fit to experimental data. And they have a nasty habit of not working that well for experimental data different from that used to define their parameters, [32].

Regardless of potential used, it is difficult to come up with an unambiguous probability for the $l=2$ orbital angular momentum. Estimates hover around the $5 \%$ value, but a clear value has never been established. This is not encouraging, since this probability is an integral quantity. If it varies nontrivially from one model to the next, then there is no real convergence on a single deuteron model. Of course, if the proton and neutron are modeled as interacting clouds of particles, it may not even be obvious how to define their orbital angular momentum in the first place, [Phys. Rev. C 19,20 (1979) 1473,325]. And that in turn raises questions in what sense these models are really well-defined two-particle ones.

Then there is the very big problem of generalizing all this to systems of three or more nucleons. One current hope is that closer examination of the underlying quark model may produce a more theoretically justified model in terms of nucleons and mesons, [32].

### 14.10 Draft: Liquid drop model

Nucleons attract each other with nuclear forces that are not completely understood, but that are known to be short range. That is much like molecules in a classical liquid drop attract each other with short-range Van der Waals forces. Indeed, it turns out that a liquid drop model can explain many properties of nuclei surprisingly well. This section gives an introduction.

### 14.10.1 Draft: Nuclear radius

The volume of a liquid drop, hence its number of molecules, is proportional to the cube of its radius $R$. Conversely, the radius is proportional to the cube root of the number of molecules. Similarly, the radius of a nucleus is approximately equal to the cube root of the number of nucleons:

$$
\begin{equation*}
R \approx R_{A} \sqrt[3]{A} \quad R_{A}=1.23 \mathrm{fm} \tag{14.9}
\end{equation*}
$$

Here $A$ is the mass number, equal to the number of protons $Z$ plus the number of neutrons $N$. Also fm stands for "femtometer," equal to $10^{-15}$ meter; it may be referred to as a "fermi" in some older references. Enrico Fermi was a great curse for early nuclear physicists, quickly doing all sorts of things before they could.

It should be noted that the above nuclear radius is an average one. A nucleus does not stop at a very sharply defined radius. (And neither would a liquid drop if it only contained 100 molecules or so.) Also, the constant $R_{A}$ varies a bit with the nucleus and with the method used to estimate the radius. Values from 1.2 to 1.25 are typical. This book will use the value 1.23 stated above.

It may be noted that these results for the nuclear radii are quite solidly established experimentally. Physicists have used a wide variety of ingenious methods to verify them. For example, they have bounced electrons at various energy levels off nuclei to probe their Coulomb fields, and alpha particles to also probe the nuclear forces. They have examined the effect of the nuclear size on the electron spectra of the atoms; these effects are very small, but if you substitute a muon for an electron, the effect becomes much larger since the muon is much heavier. They have dropped pi mesons on nuclei and watched their decay. They have also compared the energies of nuclei with $Z$ protons and $N$ neutrons against the corresponding "mirror nuclei" that have with $N$ protons and $Z$ neutrons. There is good evidence that the nuclear force is the same when you swap neutrons with protons and vice versa, so comparing such nuclei shows up the Coulomb energy, which depends on how tightly the protons are packed together. All these different methods give essentially the same results for the nuclear radii. They also indicate that the neutrons and protons are well-mixed throughout the nucleus, [31, pp. 44-59]

### 14.10.2 Draft: von Weizsäcker formula

The binding energy of nuclei can be approximated by the "von Weizsäcker formula," or "Bethe-von Weizsäcker formula:"

$$
E_{\mathrm{B}, \mathrm{vW}}=C_{v} A-C_{s} A^{2 / 3}-C_{c} \frac{Z\left(Z-C_{z}\right)}{A^{1 / 3}}-C_{d} \frac{(Z-N)^{2}}{A}-C_{p} \frac{o_{Z}+o_{N}-1}{A^{C_{e}}}
$$

where the $C$. are constants, while $o_{Z}$ is 1 if the number of protons is odd and zero if it is even, and similar for $o_{N}$ for neutrons. This book uses values given by [37] for the constants:

$$
\begin{gathered}
C_{v}=15.409 \mathrm{MeV} \quad C_{s}=16.873 \mathrm{MeV} \quad C_{c}=0.695 \mathrm{MeV} \quad C_{z}=1 \\
C_{d}=22.435 \mathrm{MeV} \quad C_{p}=11.155 \mathrm{MeV} \quad C_{e}=0.5
\end{gathered}
$$

where a MeV (mega electron volt) is $1.6021810^{-13} \mathrm{~J}$, equal to the energy that an electron picks up in a one million volt electric field.

Plugged into the mass-energy relation, the von Weizsäcker formula produces the so-called "semi-empirical mass formula:"

$$
\begin{equation*}
m_{\mathrm{nucleus}, \mathrm{SE}}=Z m_{\mathrm{p}}+N m_{\mathrm{n}}-\frac{E_{\mathrm{B}, \mathrm{vW}}}{c^{2}} \tag{14.11}
\end{equation*}
$$

### 14.10.3 Draft: Explanation of the formula

The various terms in the von Weizsäcker formula of the previous subsection have quite straightforward explanations. The $C_{v}$ term is typical for short-range attractive forces; it expresses that the energy of every nucleon is lowered the same amount by the presence of the attracting nucleons in its immediate vicinity. The classical analogue is that the energy needed to boil away a drop of liquid is proportional to its mass, hence to its number of molecules.

The $C_{s}$ term expresses that nucleons near the surface are not surrounded by a complete set of attracting nucleons. It raises their energy. This affects only a number of nucleons proportional to the surface area, hence proportional to $A^{2 / 3}$. The effect is negligible for a classical drop of liquid, which may have a million molecules along a diameter, but not for a nucleus with maybe ten nucleons along it. (Actually, the effect is important for a classical drop too, even if it does not affect its overall energy, as it gives rise to surface tension.)

The $C_{c}$ term expresses the Coulomb repulsion between protons. Like the Coulomb energy of a sphere with constant charge density, it is proportional to the square net charge, so to $Z^{2}$ and inversely proportional to the radius, so to $A^{1 / 3}$. However, the empirical constant $C_{c}$ is somewhat different from that of a constant charge density. Also, a correction $C_{z}=1$ has been thrown in to ensure that there is no Coulomb repulsion if there is just one proton.

The last two terms cheat; they try to deviously include quantum effects in a supposedly classical model. In particular, the $C_{d}$ term adds an energy increasing with the square of the difference in number of protons and neutrons. It simulates the effect of the Pauli exclusion principle. Assume first that the number of protons and neutrons is equal, each $A / 2$. In that case the protons will be able to occupy the lowest $A / 2$ proton energy levels, and the neutrons the lowest $A / 2$ neutron levels. However, if then, say, some of the protons are turned into neutrons, they will have to move to energy levels above $A / 2$, because the lowest $A / 2$ neutron levels are already filled with neutrons. Therefore the energy goes up if the number of protons and neutrons becomes unequal.

The last $C_{p}$ term expresses that nucleons of the same type like to pair up. When both the number of protons and the number of neutrons is even, all protons can pair up, and all neutrons can, and the energy is lower than average. When both the number of protons is odd and the number of neutrons is odd, there will be an unpaired proton as well as an unpaired neutron, and the energy is higher than average.

### 14.10.4 Draft: Accuracy of the formula

Figure 14.9 shows the error in the von Weizsäcker formula as colors. Blue means that the actual binding energy is higher than predicted, red that it is less than predicted. For very light nuclei, the formula is obviously useless, but for the remaining nuclei it is quite good. Note that the error is in the order of MeV , to be compared to a total binding energy of about $8 A \mathrm{MeV}$. So for heavy nuclei the relative error is small.

Near the magic numbers the binding energy tends to be greater than the predicted values. This can be qualitatively understood from the quantum energy levels that the nucleons occupy. When nucleons are successively added to a nucleus, those that go into energy levels just below the magic numbers have unusually large binding energy, and the total nuclear binding energy increases above that predicted by the von Weizsäcker formula. The deviation from the formula therefore tends to reach a maximum at the magic number. Just above the magic number, further nucleons have a much lower energy level, and the deviation from the von Weizsäcker value decreases again.

### 14.11 Draft: Alpha Decay

In alpha decay a nucleus emits an "alpha particle," later identified to be simply a helium-4 nucleus. Since the escaping alpha particle consists of two protons plus two neutrons, the atomic number $Z$ of the nucleus decreases by two and the mass number $A$ by four. This section explains why alpha decay occurs.

Figure 14.9: Error in the von Weizsäcker formula. [pdf][con]

### 14.11.1 Draft: Decay mechanism

Figure 14.10 gives decay data for the nuclei that decay exclusively through alpha decay. Nuclei are much like cherries: they have a variable size that depends mainly on their mass number $A$, and a charge $Z$ that can be shown as different shades of red. You can even define a "stem" for them, as explained later. Nuclei with the same atomic number $Z$ are joined by branches.

Figure 14.10: Half-life versus energy release for the atomic nuclei marked in NUBASE 2003 as showing pure alpha decay with unqualified energies. Top: only the even values of the mass and atomic numbers cherry-picked, omitting ${ }_{4}^{8} \mathrm{Be}$. Inset: really cherry-picking, only a few even mass numbers for thorium and uranium! Bottom: all the nuclei except ${ }_{4}^{8} \mathrm{Be}(67 \mathrm{as}, 0.092 \mathrm{MeV})$. [pdf]

Not shown in figure 14.10 is the unstable beryllium isotope ${ }_{4}^{8} \mathrm{Be}$, which has a half-life of only 67 as, (i.e. $6710^{-18} \mathrm{~s}$ ), and a decay energy of only 0.092 MeV . As you can see from the graph, these numbers are wildly different from the
other, much heavier, alpha-decay nuclei, and inclusion would make the graph very messy.

Note the tremendous range of half-lives in figure 14.10, from mere nanoseconds to quintillions of years. And that excludes beryllium's attoseconds. In the early history of alpha decay, it seemed very hard to explain how nuclei that do not seem that different with respect to their numbers of protons and neutrons could have such dramatically different half-lives. The energy that is released in the decay process does not vary that much, as figure 14.10 also shows.

To add to the mystery in those early days of quantum mechanics, if an alpha particle was shot back at the nucleus with the same energy that it came out, it would not go back in! It was reflected by the electrostatic repulsion of the positively charged nucleus. So, it had not enough energy to pass through the region of high potential energy surrounding the nucleus, yet it did pass through it when it came out.

Gamow, and independently Gurney \& Condon, recognized that the explanation was quantum tunneling. Tunneling allows a particle to get through a potential energy barrier even if classically it does not have enough energy to do so, chapter 7.12.2.

Figure 14.11: Schematic potential for an alpha particle that tunnels out of a nucleus.

Figure 14.11 gives a rough model of the barrier. The horizontal line represents the total energy of the alpha particle. Far from the nucleus, the potential energy $V$ of the alpha particle can be defined to be zero. Closer to the nucleus, the potential energy of the alpha particle ramps up due to Coulomb repulsion. However, right at the outer edge $r=R$ of the nucleus itself, the strong but very short-range attractive nuclear force pops up, and the combined potential energy plummets almost vertically downwards to some low value $V_{n}$. In between the radial position $r_{1} \approx R$ and some larger radius $r_{2}$, the potential energy exceeds the total energy that the alpha particle has available. Classically, the alpha particle cannot penetrate into this region. However, in quantum mechanics it retains a very small probability of doing so.

The region in between $r_{1}$ and $r_{2}$ is called the "Coulomb barrier." It is a poorly chosen name, because the barrier is only a Coulomb one for an alpha particle trying to get in the nucleus. For an alpha particle trying to get out, it is a nuclear force barrier; here the Coulomb force assists the tunneling particle to get through the barrier and escape. The term "nuclear barrier" would avoid this ambiguity. Therefore physicists do not use it.

Now, to get a rough picture of alpha decay, imagine an alpha particle wave packet "rattling around" inside the nucleus trying to escape. Each time it hits the barrier at $r_{1}$, it has a small chance of escaping. Eventually it gets lucky.

Assume that the alpha particle wave packet is small enough that the motion can be assumed to be one-dimensional. Then the small chance of escaping each time it hits the barrier is approximately given by the analysis of chapter 7.13 as

$$
\begin{equation*}
T \approx e^{-2 \gamma_{12}} \quad \gamma_{12}=\frac{1}{\hbar} \int_{r_{1}}^{r_{2}} \sqrt{2 m_{\alpha}(V-E)} \mathrm{d} r \tag{14.12}
\end{equation*}
$$

The fact that this probability involves an exponential is the basic reason for the tremendous range in half-lives: exponentials can vary greatly in magnitude for relatively modest changes in their argument.

### 14.11.2 Draft: Comparison with data

The previous subsection explained alpha decay in terms of an imprisoned alpha particle tunneling out of the nucleus. To verify whether that is reasonable, the next step is obviously to put in some ballpark numbers and see whether the experimental data can be explained.

First, the energy $E$ of the alpha particle may be found from Einstein's famous expression $E=m c^{2}$, section 14.6. Just find the difference between the rest mass of the original nucleus and the sum of that of the final nucleus and the alpha particle, and multiply by the square speed of light. That gives the energy release. It comes out primarily as kinetic energy of the alpha particle, ignoring any excitation energy of the final nucleus. (A reduced mass can be used to allow for recoil of the nucleus.) Note that alpha decay cannot occur if $E$ is negative; the kinetic energy of the alpha particle cannot be negative.

It may be noted that the energy release $E$ in a nuclear process is generally called the " $Q$-value." The reason is that one of the most common other quantities used in nuclear physics is the so-called quadrupole moment $Q$. Also, the total nuclear charge is indicated by $Q$, as is the quality factor of radiation, while projection and rotation operators, and second points are often also indicted by $Q$. The underlying idea is that when you are trying to figure out some technical explanation, then if almost the only mathematical symbol used is $Q$, it provides a pretty strong hint that you are probably reading a book on nuclear physics.

The nuclear radius $R$ approximately defines the start $r_{1}$ of the region that the alpha particle has to tunnel through, figure 14.11. It can be ballparked
reasonably well from the number of nucleons $A$; according to section 14.10 ,

$$
R \approx R_{A} \sqrt[3]{A} \quad R_{A}=1.23 \mathrm{fm}
$$

where f , femto, is $10^{-15}$. That is a lot smaller than the typical Bohr radius over which electrons are spread out. Electrons are "far away" and are not really relevant.

It should be pointed out that the results are very sensitive to the assumed value of $r_{1}$. The simplest assumption would be that at $r_{1}$ the alpha particle would have its center at the nuclear radius of the remaining nucleus, computed from the above expression. But very noticeable improvements are obtained by assuming that at $r_{1}$ the center is already half the radius of the alpha particle outside. (In literature, it is often assumed that the alpha particle is a full radius outside, which means fully outside but still touching the remaining nucleus. However, half works better and is maybe somewhat less implausible.)

The good news about the sensitivity of the results on $r_{1}$ is that conversely it makes alpha decay a reasonably accurate way to deduce or verify nuclear radii, [31, p. 57]. You are hardly likely to get the nuclear radius noticeably wrong without getting into major trouble explaining alpha decay.

The number of escape attempts per unit time is also needed. If the alpha particle has a typical velocity $v_{\alpha}$ inside the original nucleus, it will take it a time of about $2 r_{0} / v_{\alpha}$ to travel the $2 r_{0}$ diameter of the nucleus. So it will bounce against the barrier about $v_{\alpha} / 2 r_{0}$ times per second. That is sure to be a very large number of times per second, the nucleus being so small, but each time it hits the perimeter, it only has a miniscule $e^{-2 \gamma_{12}}$ chance of escaping. So it may well take trillions of years before it is successful anyway. Even so, among a very large number of nuclei a few will get out every time. Remember that a mol of atoms represents in the order of $10^{23}$ nuclei; among that many nuclei, a few alpha particles are likely to succeed whatever the odds against. The relative fraction of successful escape attempts per unit time is by definition the reciprocal of the lifetime $\tau$;

$$
\begin{equation*}
\frac{v_{\alpha}}{2 r_{0}} e^{-2 \gamma_{12}}=\frac{1}{\tau} \tag{14.13}
\end{equation*}
$$

Multiply the lifetime by $\ln 2$ to get the half-life.
The velocity $v_{\alpha}$ of the alpha particle can be ballparked from its kinetic energy $E-V_{n}$ in the nucleus as $\sqrt{2\left(E-V_{n}\right) / m_{\alpha}}$. Unfortunately, finding an accurate value for the nuclear potential $V_{n}$ inside the nucleus is not trivial. But have another look at figure 14.10. Forget about engineering ideas about acceptable accuracy. A $50 \%$ error in half-life would be invisible seen on the tremendous range of figure 14.10 . Being wrong by a factor 10 , or even a factor 100 , two orders of magnitude, is ho-hum on the scale that the half-life varies. So, the potential energy $V_{n}$ inside the nucleus can be ballparked. The current results use the typical value of -35 MeV given in [31, p. 252].

That leaves the value of $\gamma_{12}$ to be found from the integral over the barrier in (14.12). Because the nuclear forces are so short-range, they should be negligible over most of the integration range. So it seems reasonable to simply substitute the Coulomb potential everywhere for $V$. The Coulomb potential is inversely proportional to the radial position $r$, and it equals $E$ at $r_{2}$, so $V$ can be written as $V=E r_{2} / r$. Substituting this in, and doing the integral by making a change of integration variable to $u$ with $r=r_{2} \sin ^{2} u$, produces

$$
\gamma_{12}=\frac{\sqrt{2 m_{\alpha} E}}{\hbar} r_{2}\left[\frac{\pi}{2}-\sqrt{\frac{r_{1}}{r_{2}}\left(1-\frac{r_{1}}{r_{2}}\right)}-\arcsin \sqrt{\frac{r_{1}}{r_{2}}}\right]
$$

The last two terms within the square brackets are typically relatively small compared to the first one, because $r_{1}$ is usually fairly small compared to $r_{2}$. Then $\gamma_{12}$ is about proportional to $\sqrt{E} r_{2}$. But $r_{2}$ itself is inversely proportional to $E$, because the total energy of the alpha particle equals its potential energy at $r_{2}$;

$$
E=\frac{\left(Z-Z_{\alpha}\right) e Z_{\alpha} e}{4 \pi \epsilon_{0} r_{2}} \quad Z_{\alpha}=2
$$

That makes $\gamma_{12}$ about proportional to $1 / \sqrt{E}$ for a given atomic number $Z$.
So if you plot the half-life on a logarithmic scale, and the energy $E$ on an reciprocal square root scale, as done in figure 14.10, they should vary linearly with each other for a given atomic number. This does assume that the variations in number of escape attempts are also ignored. The predicted slope of linear variation is indicated by the "stems" on the cherries in figure 14.10. Ideally, all cherries connected by branches should fall on a single line with this slope. The figure shows that this is quite reasonable for even-even nuclei, considering the rough approximations made. For nuclei that are not even-even, the deviations from the predicted slope are more significant. The next subsection discusses the major sources of error.

The bottom line question is whether the theory, rough as it may be, can produce meaningful values for the experimental half-lives, within reason. Figure 14.12 shows predicted half-lives versus the actual ones. Cherries on the black line indicate that the correct value is predicted. It is clear that there is no real accuracy to the predictions in any normal sense; they are easily off by several orders of magnitude. What can you expect without an accurate model of the nucleus itself? However, the predictions do successfully reproduce the tremendous range of half-lives and they do not deviate from the correct values that much compared to that tremendous range. It is hard to imagine any other theory besides tunneling that could do the same.

The worst performance of the theory is for the ${ }_{83}^{209} \mathrm{Bi}$ bismuth isotope indicated by the rightmost dot in figure 14.12. Its true half-life of 19 Ey, $1910^{18}$ years, is grossly underestimated to be just $9 \mathrm{Py}, 910^{15}$ years. Then again, since the universe has only existed about $1410^{9}$ years, who is going to live long

Figure 14.12: Half-life predicted by the Gamow / Gurney \& Condon theory versus the true value. Top: even-even nuclei only. Bottom: all the nuclei except ${ }_{4}^{8} \mathrm{Be}$ ( 55 as versus 67 as). [pdf]
enough to complain about it? Essentially none of the bismuth-209 that has ever been created in the universe has decayed. It took until 2003 for physicists to observe that bismuth-209 actually did decay; it is still listed as stable in many references. For ${ }_{4}^{8} \mathrm{Be}$, which is not shown in the figure, the predicted half-life is 55 as $\left(5510^{-18} \mathrm{~s}\right)$, versus a true value of 67 as.

### 14.11.3 Draft: Forbidden decays

You may wonder why there is so much error in the theoretical predictions of the half life. Or why the theory seems to work so much better for even-even nuclei than for others. A deviation by a factor 2000 like for bismuth-209 seems an awful lot, rough as the theory may be

Some of the sources of inaccuracy are self-evident from the theoretical description as given. In particular, there is the already mentioned effect of the value of $r_{1}$. It is certainly possible to correct for deviations from the Coulomb potential near the nucleus by a suitable choice of the value of $r_{1}$. However, the precise value that kills off the error is unknown, and unfortunately the results strongly depend on that value. To fix this would require an accurate evaluation of the nuclear force potential, and that is very difficult. Also, the potential of the electrons would have to be included. The alpha particle does reach a distance of the order of a tenth of a Bohr radius from the nucleus at the end of tunneling. The Bohr radius is here taken to be based on the actual nuclear charge, not the hydrogen one.

Also, the picture of a relatively compact wave packet of the alpha particle "rattling around" assumes that that the size of that wave packet is small compared to the nucleus. That spatial localization is associated with increased uncertainty in momentum, which implies increased energy. And the kinetic energy of the alpha particle is not really known anyway, without an accurate value for the nuclear force potential.

A very major other problem is the assumption that the final alpha particle and nucleus end up in their ground states. If either ends up in an excited state, the energy that the alpha particle has available for escape will be correspondingly reduced. Now the alpha particle will most certainly come out in its ground state; it takes over 20 MeV to excite an alpha particle. But for most nuclei, the remaining nucleus cannot be in its ground state if the mechanism is as described.

The main reason is angular momentum conservation. The alpha particle has no net internal angular angular momentum. Also, it was assumed that the alpha particle comes out radially, which means that there is no orbital angular momentum either. So the angular momentum of the nucleus after emission must be the same as that of the nucleus before the emission. That is no problem for even-even nuclei, because it is the same; even-even nuclei all have zero internal
angular momentum in their ground state. So even-even nuclei do not suffer from this problem.

However, almost all other nuclei do. All even-odd and odd-even nuclei and almost all odd-odd ones have nonzero angular momentum in their ground state. Usually the initial and final nuclei have different values. That means that alpha decay that leaves the final nucleus in its ground state violates conservation of angular momentum. The decay process is called "forbidden." The final nucleus must be excited if the process is as described. That energy subtracts from that of the alpha particle. Therefore the alpha particle has less energy to tunnel through, and the true half-life is much longer than computed.

Note in the bottom half of figure 14.12 how many nuclei that are not eveneven do indeed have half-lifes that are orders of magnitude larger than predicted by theory. Consider the example of bismuth-209, with a half-life 2000 times longer than predicted. Bismuth-209 has a spin, i.e. an azimuthal quantum number, of $9 / 2$. However, the decay product thallium-205 has spin $1 / 2$ in its ground state. If you check out the excited states of thallium-205, there is an excited state with spin $9 / 2$, but its excitation energy would reduce the energy of the alpha particle from 3.2 MeV to 1.7 MeV , making the tunneling process very much slower.

And there is another problem with that. The decay to the mentioned exited state is not possible either, because it violates conservation of parity, chapter 7.3 and 7.4. Saying "the alpha particle comes out radially," as done above is not really correct. The proper quantum way to say that the alpha particle comes out with no orbital angular momentum is to say that its wave function varies with angular location as the spherical harmonic $Y_{0}^{0}$, chapter 4.2.3. In spectroscopic terms, it "comes out in an s-wave." Now the initial bismuth atom has odd parity; its complete wave function changes sign if you everywhere replace $\vec{r}$ by $-\vec{r}$. But the alpha particle, the excited thallium state, and the $Y_{0}^{0}$ orbital motion all have even parity; there is no change of sign. That means that the total final parity is even too, so the final parity is not the same as the initial parity. That violates conservation of parity so the process cannot occur.

Thallium- 205 does not have excited states below 3.2 MeV that have been solidly established to have spin $9 / 2$ and odd parity, so you may start to wonder whether alpha decay for bismuth-209 is possible at all. However, the alpha particle could of course come out with orbital angular momentum. In other words it could come out with a wave function that has an angular dependence according to $Y_{l}^{m}$ with the azimuthal quantum number $l$ equal to one or more. These states have even parity if $l$ is even and odd parity when $l$ is odd. Quantum mechanics then allows the thallium-205 excited state to have any spin $j$ in the range $\left|\frac{9}{2}-l\right| \leqslant j \leqslant \frac{9}{2}+l$ as long as its parity is odd or even whenever $l$ is even or odd.

For example, bismuth-209 could decay to the ground state of thallium-205 if the orbital angular momentum of the alpha particle is $l=5$. Or it could decay
to an excited $7 / 2^{+}$state with an excitation energy of 0.9 MeV if $l=1$. The problem is that the kinetic energy in the angular motion subtracts from that available for the radial motion, making the tunneling, once again, much slower. In terms of the radial motion, the angular momentum introduces an additional effective potential $l(l+1) \hbar^{2} / 2 m_{\alpha} r^{2}$, compare the analysis of the hydrogen atom in chapter 4.3.2. Note that this effect increases rapidly with $l$. However, the decay of bismuth-209 appears to be to the ground state anyway; the measured energy of the alpha particle turns out to be 3.14 MeV . The predicted half-life including the effective potential is found to be 4.6 Ey , much better than the one computed in the previous section.

One final source of error should be mentioned. Often alpha decay can proceed in a number of ways and to different final excitation energies. In that case, the specific decay rates must be added together. This effect can make the true half-life shorter than the one computed in the previous subsection. But clearly, this effect should be minor on the scale of half-lifes of figure 14.12. Indeed, while the predicted half-lifes of many nuclei are way below the true value in the figure, few are significantly above it.

### 14.11.4 Draft: Why alpha decay?

The final question that begs an answer is why do so many nuclei so specifically want to eject an helium- 4 nucleus? Why none of the other nuclei? Why not the less tightly bound, but lighter deuteron, or the more tightly bound, but heavier carbon-12 nucleus? The answer is subtle.

To understand the reason, reconsider the analysis of the previous subsection for a more general ejected nucleus. Assume that the ejected particle has an atomic number $Z_{1}$ and mass $m_{1}$. As mentioned, the precise number of escape attempts is not really that important for the half life; almost all the variation in half-life is through the quantity $\gamma_{12}$. Also, to a first approximation the ratio of start to end of the tunneling domain, $r_{1} / r_{2}$, can be ignored. Under those conditions, $\gamma_{12}$ is proportional to

$$
\gamma_{12} \propto \sqrt{\frac{m_{1}}{E}} Z_{1}\left(Z-Z_{1}\right)
$$

It is pretty much all in there.
As long as the ejected particle has about the usual 8 MeV binding energy per nucleon, the square root in the expression above does not vary that much. In such cases the energy release $E$ is about proportional to the amount of nucleons ejected. Table 14.3 gives some example numbers. That makes $\gamma_{12}$ about proportional to $Z_{1}$, and the greatest chance of tunneling out then occurs by far for the lightest nuclei. It explains why the alpha particle tunnels out instead of heavier nuclei. It is not that a heavier nucleus like carbon-14 cannot be emitted, it is just that an alpha particle has already done so long before
carbon-14 gets the chance. In fact, for radium-223 it has been found that one carbon-14 nucleus is ejected for every billion alpha particles. That is about consistent with the computed half-lifes of the events as shown in table 14.3.

But the argument that $Z_{1}$ should be as small as possible should make protons or neutrons, not the alpha particle, the ones that can escape most easily. However, these do not have any binding energy. While protons or neutrons are indeed ejected from nuclei that have a very large proton, respectively neutron excess, normally the energy release for such emissions is negative. Therefore the emission cannot occur. Beta decay occurs instead to adjust the ratio between protons and neutrons to the optimum value. Near the optimum value, you would still think it might be better to eject a deuteron than an alpha. However, because the binding energy of the deuteron is only a single MeV per nucleon, the energy release is again negative. Among the light nuclei, the alpha is unique in having almost the full 8 MeV of binding energy per nucleon. It is therefore the only one that produces a positive energy release.

The final problem is that the arguments above seem to show that spontaneous fission cannot occur. For, is the fission of say fermium- 256 into two tin-128 nuclei not just ejection of a tin-128 nucleus, leaving a tin-128 nucleus? The arguments above say that alpha decay should occur much before this can happen.

The problem is that the analysis of alpha decay is inapplicable to fission. The numbers for fission-scale half-lifes in table 14.3 are all wrong. Fission is indeed a tunneling event. However, it is one in which the energy barrier is disintegrating due to a global instability of the nuclear shape. That instability mechanism strongly favors large scale division over short scale ones. The only hint of this in table 14.3 are the large values of $r_{1} / r_{2}$ for fission-scale events. When $r_{1} / r_{2}$ becomes one, the tunneling region is gone. But long before that happens, the region is so small compared to the size of the ejected nucleus that the basic ideas underlying the analysis have become meaningless. Even ignoring the fact that the nuclear shapes have been assumed spherical and they are not in fission.

Thus, unlike table 14.3 suggests, fermium- 256 does fission. The two fragments are usually of different size, but not vastly so. About $92 \%$ of fermium256 nuclei spontaneously fission, while the other $8 \%$ experience alpha decay. Uranium-238 decays for $99.99995 \%$ through $\alpha$ decay, and for only $0.00005 \%$ through spontaneous fission. Although the amount of fission is very small, it is not by far as small as the numbers in table 14.3 imply. Fission is not known to occur for radium-223; this nucleus does indeed show pure alpha decay except for the mentioned rare carbon-14 emission.

### 14.12 Draft: Shell model

The liquid drop model gives a very useful description of many nuclear properties. It helps understand alpha decay quite well. Still, it has definite limitations. Quantum properties such as the stability of individual nuclei, spin, magnetic moment, and gamma decay can simply not be explained using a classical liquid model with a couple of simple fixes applied.

Historically, a major clue about a suitable quantum model came from the magic numbers. Nuclei tend to be unusually stable if the number of protons and/or neutrons is one of the

$$
\begin{equation*}
\text { magic numbers: } \quad 2,8,20,28,50,82,126, \ldots \tag{14.14}
\end{equation*}
$$

The higher magic number values are quite clearly seen in proton pair and neutron pair removal graphs like figures 14.7 and 14.8 in section 14.8.

If an additional proton is added to a nucleus with a magic number of protons, or an additional neutron to a nucleus with a magic number of neutrons, then that additional nucleon is much more weakly bound.

The doubly magic ${ }_{2}^{4} \mathrm{He}$ helium- 4 nucleus, with 2 protons and 2 neutrons, is a good example. It has more than three times the binding energy of ${ }_{2}^{3} \mathrm{He}$ helium-3 which merely has a magic number of protons. Still, if you try to add another proton or neutron to helium-4, it will not be bound at all, it will be ejected in less than $10^{-21}$ seconds.

That is very reminiscent of the electron structure of the helium atom. The two electrons in the helium atom are very tightly bound, making helium into an inert noble gas. In fact, it takes 25 eV of energy to remove an electron from a helium atom. However, for lithium, with one more electron, the third electron is very loosely bound, and readily given up in chemical reactions. It takes only 5.4 eV to remove the third electron from lithium. Similar effects appear for the other noble gasses, neon with 10 electrons, argon with 18 , krypton with 36 , etcetera. The numbers $2,10,18,36, \ldots$, are magic for electrons in atoms.

For atoms, the unusual stability could be explained in chapter 5.9 by ignoring the direct interactions between electrons. It was assumed that for each electron, the complicated effects of all the other electrons could be modeled by some average potential that the electron moves in. That approximation produced single-electron energy eigenfunctions for the electrons. They then had to occupy these single-electron states one by one on account of Pauli's exclusion principle. Noble gasses completely fill up an energy level, requiring any additional electrons to go into the next available, significantly higher energy level. That greatly decreases the binding energy of these additional electrons compared to those already there.

The similarity suggests that the protons and neutrons in nuclei might be described similarly. There are now two types of particles but in the approximation that each particle is not directly affected by the others it does not make
much of a difference. Also, antisymmetrization requirements only apply when the particles are identical, either both protons or both neutrons. Therefore, protons and neutrons can be treated completely separately. Their interactions occur only indirectly through whatever is used for the average potential that they move in. The next subsections work out a model along these lines.

### 14.12.1 Draft: Average potential

The first step will be to identify a suitable average potential for the nucleons. One obvious difference distinguishing nuclei from atoms is that the Coulomb potential is not going to hack it. In the electron structure of an atom the electrons repel each other, and the only reason the atom stays together is that there is a nucleus to attract the electrons. But inside a nucleus, the nucleons all attract each other and there is no additional attractive core. Indeed, a Coulomb potential like the one used for the electrons in atoms would get only the first magic number, 2 , right, predicting 10, instead of 8 , total particles for a filled second energy level.

A better potential is needed. Now in the center of a nucleus, the attractive forces come from all directions and the net force will be zero by symmetry. Away from the center, the net force will be directed inwards towards the center to keep the nucleons together inside the nucleus. The simplest potential that describes this is the harmonic oscillator one. For that potential, the inward force is simply proportional to the distance from the center. That makes the potential energy $V$ proportional to the square distance from the center, as sketched in figure $14.13 a$.

Figure 14.13: Example average nuclear potentials: (a) harmonic oscillator, (b) impenetrable surface, (c) Woods-Saxon, (d) Woods-Saxon for protons.

The energy eigenvalues of the harmonic oscillator are

$$
\begin{equation*}
E_{n}=\left(n+\frac{1}{2}\right) \hbar \omega \quad n=1,2,3, \ldots \tag{14.15}
\end{equation*}
$$

Also, in spherical coordinates the energy eigenfunctions of the harmonic oscillator can be taken to be of the form, $\{D .76\}$,

$$
\psi_{n l m m_{s}}^{\mathrm{hho}}=R_{n l}^{\mathrm{ho}}(r) Y_{l}^{m}(\theta, \phi) \uparrow \quad \begin{align*}
& l=n-1, n-3, \ldots \geqslant 0  \tag{14.16}\\
& \\
& m=-l,-l+1, \ldots, l-1, l \\
& m_{s}= \pm \frac{1}{2}
\end{align*}
$$

Here $l$ is the azimuthal quantum number that gives the square orbital angular momentum of the state as $l(l+1) \hbar^{2}$; $m$ is the magnetic quantum number that gives the orbital angular momentum in the direction of the arbitrarily chosen $z$-axis as $m \hbar$, and $m_{s}$ is the spin quantum number that gives the spin angular momentum of the nucleon in the $z$-direction as $m_{s} \hbar$. The "spin-up" state with $m_{s}=\frac{1}{2}$ is commonly indicated by a postfix $\uparrow$, and similarly the spin-down one $m_{s}=-\frac{1}{2}$ by $\downarrow$. The details of the functions $R_{n l}^{\mathrm{ho}}$ and $Y_{l}^{m}$ are of no particular interest.
(It may be noted that the above spherical eigenfunctions are different from the Cartesian ones derived in chapter 4.1, except for the ground state. However, the spherical eigenfunctions at a given energy level can be written as combinations of the Cartesian ones at that level, and vice-versa. So there is no fundamental difference between the two. It just works out that the spherical versions are much more convenient in the rest of the story.)

Compared to the Coulomb potential of the hydrogen electron as solved in chapter 4.3, the major difference is in the number of energy states at a given energy level $n$. While for the Coulomb potential the azimuthal quantum number $l$ can have any value from 0 to $n-1$, for the harmonic oscillator $l$ must be odd or even depending on whether $n-1$ is odd or even.

It does not make a difference for the lowest energy level $n=1$; in that case only $l=0$ is allowed for either potential. And since the number of values of the magnetic quantum number $m$ at a given value of $l$ is $2 l+1$, there is only one possible value for $m$. That means that there are only two different energy states at the lowest energy level, corresponding to $m_{s}=\frac{1}{2}$ respectively $-\frac{1}{2}$. Those two states explain the first magic number, 2 . Two nucleons of a given type can occupy the lowest energy level; any further ones of that type must go into a higher level.

In particular, helium-4 has the lowest energy level for protons completely filled with its two protons, and the lowest level for neutrons completely filled with its two neutrons. That makes helium-4 the first doubly-magic nucleus. It is just like the two electrons in the helium atom completely fill the lowest energy level for electrons, making helium the first noble gas.

At the second energy level $n=2$, where the Coulomb potential allows both $l$ $=0$ and $l=1$, only $l=1$ is allowed for the harmonic oscillator. So the number of states available at energy level $n=2$ is less than that of the Coulomb potential. In particular, the azimuthal quantum number $l=1$ allows $2 l+1=3$ values of the magnetic quantum number $m$, times 2 values for the spin quantum number $m_{s}$. Therefore, $l=1$ at $n=2$ corresponds to 3 times 2 , or 6 energy states. Combined with the two $l=0$ states at energy level $n=1$, that gives a total of 8. The second magic number 8 has been explained! It requires 8 nucleons of a given type to fill the lowest two energy levels.

It makes oxygen- 16 with 8 protons and 8 neutrons the second doubly-magic nucleus. Note that for the electrons in atoms, the second energy level would
also include two $l=0$ states. That is why the second noble gas is neon with 10 electrons, and not oxygen with 8 .

Before checking the other magic numbers, first a problem with the above procedure of counting states must be addressed. It is too easy. Everybody can evaluate $2 l+1$ and multiply by 2 for the spin states! To make it more challenging, physicists adopt the so-called "spectroscopic notation" in which they do not tell you the value of $l$. Instead, they tell you a letter like maybe p, and you are then supposed to figure out yourself that $l=1$. The scheme is:

$$
\mathrm{s}, \mathrm{p}, \mathrm{~d}, \mathrm{f}, \mathrm{~g}, \mathrm{~h}, \mathrm{i},[\mathrm{j}], \mathrm{k}, \ldots \quad \Longrightarrow \quad l=0,1,2,3,4,5,6,7,8, \ldots
$$

The latter part is mostly alphabetic, but by convention j is not included. However, my references on nuclear physics do include $\mathbf{j}$; that is great because it provides additional challenge. Using spectroscopic notations, the second energy level states are renotated as

$$
\psi_{21 m m_{s}} \quad \Longrightarrow \quad 2 p
$$

where the 2 indicates the value of $n$ giving the energy level. The additional dependence on the magnetic quantum numbers $m$ and $m_{s}$ is kept hidden from the uninitiated. (To be fair, as long as there is no preferred direction to space, these quantum numbers are physically not of importance. If an external magnetic field is applied, it provides directionality, and magnetic quantum numbers do become relevant.)

However, physicists figured that this would not provide challenge enough, since most students already practiced it for atoms. The above notation follows the one that physicists use for atoms. In this notation, the leading number is $n$, the energy level of the simplest theoretical model. To provide more challenge, for nuclei physicist replace the leading number with a count of states at that angular momentum. For example, physicists denote 2 p above by 1 p, because it is the lowest energy p states. Damn what theoretical energy level it is. For still more challenge, while most physicists start counting from one, some start from zero, making it 0p. However, since it gives the author of this book a headache to count angular momentum states upwards between shells, this book will mostly follow the atomic convention, and the leading digit will indicate $n$, the harmonic oscillator energy level. The "official" eigenfunction designations will be listed in the final results where appropriate. Most but not all references will follow the official designations.

In these terms, the energy levels and numbers of states for the harmonic oscillator potential are as shown in figure 14.14. The third energy level has 23 s states and 103 d states. Added to the 8 from the first two energy levels, that brings the total count to 20 , the third magic number.

Unfortunately, this is where it stops. The fourth energy level should have only 8 states to reach the next magic number 28 , but in reality the fourth

Figure 14.14: Nuclear energy levels for various assumptions about the average nuclear potential. The signs indicate the parity of the states.
harmonic oscillator level has 64 p states and 14 4f ones. Still, getting 3 magic numbers right seems like a good start.

The logical next step is to try to improve upon the harmonic oscillator potential. In an average nucleus, it can be expected that the net force on a nucleon pretty much averages out to zero everywhere except in a very thin layer at the outer surface. The reason is that the nuclear forces are very short range; therefore the forces seem to come equally from all directions unless the nucleon is very close to the surface. Only right at the surface do the particles experience a net inward attraction because of the deficit of particles beyond the surface to provide the full compensating outward force. This suggests a picture in which the nucleons do not experience a net force within the confines of the nucleus. However, at the surface, the potential ramps up very steeply. As an idealization the potential beyond the surface can be taken infinite.

That reasoning results in the "impenetrable-shell" potential shown in figure 14.13. It too is analytically solvable, \{D.77\}. The energy levels are shown in figure 14.14. Unfortunately, it does not help any explaining the fourth magic number 28 .

It does help understand why the shell model works at all, 【15】. That is not at all obvious; for a long time physicists really believed it would not work. For the electrons in an atom, the nucleus at least produces some potential that is independent of the relative positions of the electrons. In a nucleus, there is nothing: the potential experienced by the nucleons is completely dependent on relative nucleon positions and spins. So what reasonable justification could there possibly be to assume that the nucleons act as if they move in an average potential that is independent of the other nucleons? However, first assume that the only potential energy is the one that keeps the nucleons within the experimental nuclear radius. That is the impenetrable shell model. In that case, the energy eigenfunctions are purely kinetic energy ones, and these have a shell structure. Now restore the actual complex interactions between nucleons. You would at first guess that these should greatly change the energy eigenstates. But if they really do that, it would bring in large amounts of unoccupied kinetic energy states. That would produce a significant increase in kinetic energy, and that is not possible because the binding energy is fairly small compared to the kinetic energy. In particular, therefore, removing the last nucleon should not require an energy very different from a shell model value regardless of however complex the true potential energy really is.

Of course, the impenetrable-shell potential too is open to criticism. A nucleus has maybe ten nucleons along a diameter. Surely the thickness of the surface layer cannot reasonably be much less than the spacing between nucleons. Or much less than the range of the nuclear forces, for that matter. Also, the potential should not be infinite outside the nucleus; nucleons do escape from, or enter nuclei without infinite energy. The truth is clearly somewhere in between the harmonic oscillator and impenetrable shell potentials. A more
realistic potential along such lines is the "Woods-Saxon" potential

$$
V=-\frac{V_{0}}{1+e^{(r-a) / d}}+\text { constant }
$$

which is sketched in figure $14.13 c$. For protons, there is an additional repulsive Coulomb potential that will be maximum at the center of the sphere and decreases to zero proportional to $1 / r$ outside the nucleus. That gives a combined potential as sketched in figure 14.13 d . Note that the Coulomb potential is not short-range like the nucleon-nucleon attractions; its nontrivial variation is not just restricted to a thin layer at the nuclear surface.

Typical energy levels are sketched in figure 14.14. As expected, they are somewhere in between the extreme cases of the harmonic oscillator and the impenetrable shell.

The signs behind the realistic energy levels in 14.14 denote the predicted "parity" of the states. Parity is a very helpful mathematical quantity for studying nuclei. The parity of a wave function is "one," or "positive," or "even," if the wave function stays the same when the positive direction of the three Cartesian axes is inverted. That replaces every $\vec{r}$ in the wave function by $-\vec{r}$. The parity is "minus one,", or "negative," or "odd," if the wave function merely changes sign under an exes inversion. Parity is uncertain when the wave function changes in any other way; however, nuclei have definite parity as long as the weak force of beta decay does not play a role. It turns out that $\mathrm{s}, \mathrm{d}, \mathrm{g}, \ldots$ states have positive parity while $\mathrm{p}, \mathrm{f}, \mathrm{h}, \ldots$ states have negative parity, $\{\mathrm{D} .14\}$ or $\{\mathrm{D} .76\}$. Therefore, the harmonic oscillator shells have alternatingly positive and negative parity.

For the wave functions of complete nuclei, the net parity is the product of the parities, (taking them to be one or minus one), of the individual nucleons. Now physicist can experimentally deduce the parity of nuclei in various ways. It turns out that the parities of the nuclei up to the third magic number agree perfectly with the values predicted by the energy levels of figure 14.14. (Only three unstable, artificially created, nuclei disagree.) It really appears that the model is onto something.

Unfortunately, the fourth magic number remains unexplained. In fact, any reasonable spherically symmetric spatial potential will not get the fourth magic number right. There are 64 p states and 144 f ones; how could the additional 8 states needed for the next magic number 28 ever be extracted from that? Twiddling with the shape of a purely spatial potential is not enough.

### 14.12.2 Draft: Spin-orbit interaction

Eventually, Mayer in the U.S., and independently Jensen and his co-workers in Germany, concluded that spin had to be involved in explaining the magic numbers above 20. To understand why, consider the six 4 p and fourteen 4 f energy states at the fourth energy level of the harmonic oscillator model. Clearly,
the six 4 p states cannot produce the eight states of the energy shell needed to explain the next magic number 28. And neither can the fourteen 4 f states, unless for some reason they split into two different groups whose energy is no longer equal.

Why would they split? In nonquantum terms, all fourteen states have orbital and spin angular momentum vectors of exactly the same lengths. What is different between states is only the direction of these vectors. And the absolute directions cannot be relevant since the physics cannot depend on the orientation of the axis system in which it is viewed. What it can depend on is the relative alignment between the orbital and spin angular momentum vectors. This relative alignment is characterized by the dot product between the two vectors.

Therefore, the logical way to get an energy splitting between states with differently aligned orbital and spin angular momentum is to postulate an additional contribution to the Hamiltonian of the form

$$
\Delta H \propto-\widehat{\vec{L}} \cdot \widehat{\vec{S}}
$$

Here $\widehat{\vec{L}}$ is the orbital angular momentum vector and $\widehat{\vec{S}}$ the spin one. A contribution to the Hamiltonian of this type is called an "spin-orbit" interaction, because it couples spin with orbital angular momentum. Spin-orbit interaction was already known from improved descriptions of the energy levels of the hydrogen atom, addendum \{A.39\}. However, that electromagnetic effect is far too small to explain the observed spin-orbit interaction in nuclei. Also, it would get the sign of the correction wrong for neutrons.

While nuclear forces remain incompletely understood, there is no doubt that it is these much stronger forces, and not electromagnetic ones, that provide the mechanism. Still, in analogy to the electronic case, the constant of proportionality is usually taken to include the net force $\partial V / \partial r$ on the nucleon and an additional factor $1 / r$ to turn orbital momentum into velocity. None of that makes a difference for the harmonic oscillator potential, for which the net effect is still just a constant. Either way, next the strength of the resulting interaction is adjusted to match the experimental energy levels.

To correctly understand the effect of spin-orbit interaction on the energy levels of nucleons is not quite trivial. Consider the fourteen $\psi_{43 m m_{s}}$ ff states. They have orbital angular momentum in the chosen $z$-direction $m \hbar$, with $m=$ $-3,-2,-1,0,1,2,3$, and spin angular momentum $m_{s} \hbar$ with $m_{s}= \pm \frac{1}{2}$. Naively, you might assume that the spin-orbit interaction lowers the energy of the six states for which $m$ and $m_{s}$ have the same sign, raises it for the six where they have the opposite sign, and leaves the energy of the two states with $m=0$ the same. That is not true. The problem is that the spin-orbit interaction $\widehat{\vec{L}} \cdot \widehat{\vec{S}}$ involves $\widehat{L}_{x}$ and $\widehat{L}_{y}$, and these do not commute with $\widehat{L}_{z}$ regardless of how you orient the axis system. And the same for $\widehat{S}_{x}$ and $\widehat{S}_{y}$.

With spin-orbit interaction, energy eigenfunctions of nonzero orbital angular momentum no longer have definite orbital momentum $L_{z}$ in a chosen $z$-direction. And neither do they have definite spin $S_{z}$ in such a direction.
Therefore the energy eigenfunctions can no longer be taken to be of the form $R_{n l}(r) Y_{l}^{m}(\theta, \phi) \uparrow$. They have uncertainty in both $m$ and $m_{s}$, so they will be combinations of states $R_{n l}(r) Y_{l}^{m}(\theta, \phi) \downarrow$ with varying values of $m$ and $m_{s}$.

However, consider the net angular momentum operator

$$
\widehat{\vec{J}} \equiv \widehat{\vec{L}}+\widehat{\vec{S}}
$$

If you expand its square magnitude,

$$
\widehat{J}^{2}=(\widehat{\vec{L}}+\widehat{\vec{S}}) \cdot(\widehat{\vec{L}}+\widehat{\vec{S}})=\widehat{L}^{2}+2 \widehat{\vec{L}} \cdot \widehat{\vec{S}}+\widehat{S}^{2}
$$

you see that the spin-orbit term can be written in terms of the square magnitudes of orbital, spin, and net angular momentum operators:

$$
-\widehat{\vec{L}} \cdot \widehat{\vec{S}}=-\frac{1}{2}\left[\widehat{J}^{2}-\widehat{L}^{2}-\widehat{S}^{2}\right]
$$

Therefore combination states that have definite square net angular momentum $J^{2}$ remain good energy eigenfunctions even in the presence of spin-orbit interaction.

Now a quick review is needed of the weird way in which angular momenta combine into net angular momentum in quantum mechanics, chapter 12.7. In classical mechanics, the sum of an angular momentum vector with length $L$ and one with length $S$ could have any combined length $J$ in the range $|L-S| \leqslant J$ $\leqslant L+S$, depending on the angle between the vectors. However, in quantum mechanics, the length of the final vector must be quantized as $\sqrt{j(j+1)} \hbar$ where the quantum number $j$ must satisfy $|l-s| \leqslant j \leqslant l+s$ and must change in integer amounts. In particular, since the spin is given as $s=1 / 2$, the net angular momentum quantum number $j$ can either be $l-1 / 2$ or $l+\frac{1}{2}$. (If $l$ is zero, the first possibility is also ruled out, since square angular momentum cannot be negative.)

For the 4f energy level $l=3$, so the square net angular momentum quantum number $j$ can only be $5 / 2$ or $7 / 2$. And for a given value of $j$, there are $2 j+1$ values for the quantum number $m_{j}$ giving the net angular momentum in the chosen $z$-direction. That means that there are six states with $j=5 / 2$ and eight states with $j=7 / 2$. The total is fourteen, still the same number of independent states at the 4 f level. In fact, the fourteen states of definite net angular momentum $j$ can be written as linear combinations of the fourteen $R_{n l} Y_{l}^{m} \uparrow$ states. (Figure 12.5 shows such combinations up to $l=2$; item 2 in chapter 12.8 gives a general formula.) Pictorially,

$$
74 \mathrm{f} \uparrow \text { and } 74 \mathrm{f} \downarrow \text { states } \quad \Longrightarrow \quad 64 \mathrm{f}_{5 / 2} \text { and } 84 \mathrm{f}_{7 / 2} \text { states }
$$

where the spectroscopic convention is to show the net angular momentum $j$ as a subscript for states in which its value is unambiguous.

The spin-orbit interaction raises the energy of the six $4 \mathrm{f}_{5 / 2}$ states, but lowers it for the eight $4 \mathrm{f}_{7 / 2}$ states. In fact, from above, for any state of definite square orbital and square net angular momentum,

$$
-\widehat{\vec{L}} \cdot \widehat{\vec{S}}=-\frac{1}{2} \hbar^{2}[j(j+1)-l(l+1)-s(s+1)]=\left\{\begin{array}{cl}
\frac{1}{2}(l+1) \hbar^{2} & \text { for } j=l-1 / 2 \\
-\frac{1}{2} l \hbar^{2} & \text { for } j=l+1 / 2
\end{array}\right.
$$

The eight $4 \mathrm{f}_{7 / 2}$ states of lowered energy form the shell that is filled at the fourth magic number 28 .

Figure 14.15: Schematic effect of spin-orbit interaction on the energy levels. The ordering within bands is realistic for neutrons. The designation behind the equals sign is the "official" one. (Assuming counting starts at 1).

Figure 14.15 shows how the spin-orbit splitting of the energy levels gives rise to the remaining magic numbers. In the figure, the coefficient of the spin orbit term was simply taken to vary linearly with the energy level $n$. The details depend on whether it is neutrons or protons, and may vary from nucleus to nucleus. Especially for the higher energy bands the Coulomb repulsion has an increasingly large effect on the energies of protons.

The major shells, terminated by magic numbers, are shown as grey bands. In the numbering system followed here, a subshell with a different number as
the others in the same major shell comes from a different harmonic oscillator energy level. Figure 14.15 also shows the "official" enumeration of the states. You be the judge which numbering system makes the most sense to you.

As sketched in figure 14.15, spin-orbit interaction pushes the $5 g_{9 / 2}$ states down into the band that ends at magic number 50. However, the energy gap between between the $5 g_{9 / 2}$ states and the $4 \ldots$ states in the band is relatively large. That is why you might think of 40 as a semi-magic number if you want. For example, one good reason to consider this is figure 14.19 discussed later.

The detailed ordering of the subshells above 50 varies with author and even for a single author. There is no unique answer, because the shell model is only a simple approximation to a system that does not follow simple rules when examined closely enough. Still, a specific ordering must be adopted if the shell model is to be compared to the data. This book will use the orderings:

$$
\begin{gathered}
\text { protons: } \\
1 \mathrm{~s}_{1 / 2} \\
2 \mathrm{p}_{3 / 2} 2 \mathrm{p}_{1 / 2} \\

\end{gathered}
$$

The ordering for protons follows [36, table 7-1], but not [36, p. 223], to $\mathrm{Z}=92$, and then [31], whose table seems to come from Mayer and Jensen. The ordering for neutrons follows [36], with the subshells beyond 136 taken from【10】. However, the $7 \mathrm{i}_{13 / 2}$ and $6 \mathrm{p}_{1 / 2}$ states were swapped since the shell filling [36, table 7-1] makes a lot more sense if you do. The same swap is also found in [40, p. 255], following Klinkenberg, while [31, p. 155] puts the $7 \mathrm{i}_{13 / 2}$ subshell even farther down below the $6 p_{3 / 2}$ state.

### 14.12.3 Draft: Example occupation levels

The purpose of this section is to explore how the shell model works out for sample nuclei.

Figure 14.16: Energy levels for doubly-magic oxygen-16 and neighbors. [pdf]

Figure 14.16 shows experimental energy spectra of various nuclei at the left. The energy values are in MeV . The ground state is defined to be the zero level of energy. The length and color of the energy lines indicates the spin of the nucleus, and the parity is indicated by a plus or minus sign. Some important spin values are also listed explicitly. Yellow lines indicate states for which no unique spin and/or parity are determined or are established with reservations. At the right in the figure, a sketch of the occupation levels according to the shell model is displayed for easy reference.

The top of the figure shows data for oxygen-16, the normal oxygen that makes up $99.8 \%$ of the oxygen in the atmosphere. Oxygen-16 is a doubly-magic nucleus with 8 protons and 8 neutrons. As the right-hand diagram indicates, these completely fill up the lowest two major shells.

As the left-hand spectrum shows, the oxygen-16 nucleus has zero net spin in the ground state. That is exactly what the shell model predicts. In fact, it is a consequence of quantum mechanics that:

Completely filled subshells have zero net angular momentum.
Since the shell model says all shells are filled, the zero spin follows. The shell model got the first one right. Indeed, it passes this test with flying colors for all doubly-magic nuclei.

Next,

## Subshells with an even number of nucleons have even parity.

That is just a consequence of the fact that even if the subshell is a negative parity one, negative parities multiply out pairwise to positive ones. Since all subshells of oxygen-16 contain an even number of nucleons, the combined parity of the complete oxygen-16 nucleus should be positive. It is. And it is for the other doubly-magic nuclei.

The shell model implies that a doubly-magic nucleus like oxygen-16 should be be particularly stable. So it should require a great deal of energy to excite it. Indeed it does: figure 14.16 shows that exciting oxygen- 16 takes over 6 MeV of energy.

Following the shell model picture, one obvious way to excite the nucleus would be to kick a single proton or neutron out of the $2 \mathrm{p}_{1 / 2}$ subshell into the next higher energy $3 \mathrm{~d}_{5 / 2}$ subshell. The net result is a nucleon with spin $5 / 2$ in the $3 \mathrm{~d}_{5 / 2}$ subshell and one remaining nucleon with spin $1 / 2$ in the $2 \mathrm{p}_{1 / 2}$ subshell. Quantum mechanics allows these two nucleons to combine their spins into a net spin of either $\frac{5}{2}+\frac{1}{2}=3$ or $\frac{5}{2}-\frac{1}{2}=2$. In addition, since the nucleon kicked into the $3 \mathrm{f}_{5 / 2}$ changes parity, so should the complete nucleus. And indeed, there is an excited level a bit above 6 MeV with a spin 3 and odd parity, a $3^{-}$level. It appears the shell model may be onto something.

Still, the exited $0^{+}$state suggests there may be a bit more to the story. In a shell model explanation, the parity of this state would require a pair of nucleons
to be kicked up. In the basic shell model, it would seem that this should require twice the energy of kicking up one nucleon. Not all nuclear excitations can be explained by the excitation of just one or two nucleons, especially if the mass number gets over 50 or the excitation energy high enough. This will be explored in section 14.13. However, before summarily dismissing a shell model explanation for this state, first consider the following sections on pairing and configuration mixing.

Next consider oxygen-17 and fluorine-17 in figure 14.16. These two are examples of so-called "mirror nuclei;" they have the numbers of protons and neutrons reversed. Oxygen- 17 has 8 protons and 9 neutrons while its twin fluorine- 17 has 9 protons and 8 neutrons. The similarity in energy levels between the two illustrates the idea of charge symmetry: nuclear forces are the same if the protons are turned into neutrons and vice versa. (Of course, this swap does mess up the Coulomb forces, but Coulomb forces are not very important for light nuclei.)

Each of these two nuclei has one more nucleon in addition to an oxygen-16 "core". Since the filled subshells of the oxygen-16 core have zero spin, the net nuclear spin should be that of the odd nucleon in the $3 \mathrm{~d}_{5 / 2}$ subshell. And the parity should be even, since the odd nucleon is in an even parity shell. And indeed each ground state has the predicted spin of $5 / 2$ and even parity. Chalk up another two for the shell model.

This is a big test for the shell model, because if a doubly-magic-plus-one nucleus did not have the predicted spin and parity of the final odd nucleon, there would be no reasonable way to explain it. Fortunately, all nuclei of this type pass the test.

For both oxygen-17 and fluorine-17, there is also a low-energy $1 / 2^{+}$excited state, likely corresponding to kicking the odd nucleon up to the next minor shell, the $3 \mathrm{~s}_{1 / 2}$ one. And so there is an excited $3 / 2^{+}$state, for kicking up the nucleon to the $3 \mathrm{~d}_{3 / 2}$ state instead.

However, from the shell model, in particular figure 14.15, you would expect the spacing between the $3 \mathrm{~d}_{5 / 2}$ and $3 \mathrm{~s}_{1 / 2}$ subshells to be more than that between the $3 \mathrm{~s}_{1 / 2}$ and $3 \mathrm{~d}_{3 / 2}$ ones. Clearly it is not. One consideration not in a shell model with a straightforward average potential is that a nucleon in an unusually farout s orbit could be closer to the other nucleons in lower orbits than one in a far-out p orbit; the $s$ orbit has larger values near the center of the nucleus, $\{\mathrm{N} .8\}$. While the shell model gets a considerable number of things right, it is certainly not a very accurate model.

Then there are the odd parity states. These are not so easy to understand: they require a nucleon to be kicked up past a major shell boundary. That should require a lot of energy according to the ideas of the shell model. It seems to make them hard to reconcile with the much higher energy of the $3 / 2^{+}$state. Some thoughts on these states will be given in the next subsection.

The fourth nucleus in figure 14.16 is nitrogen-14. This is an odd-odd nucleus,
with both an odd number of protons and of neutrons. The odd proton and odd neutron are in the $2 \mathrm{p}_{1 / 2}$ shell, so each has spin $1 / 2$. Quantum mechanics allows the two to combine their spins into a triplet state of net spin one, like they do in deuterium, or in a singlet state of spin zero. Indeed the ground state is a $1^{+}$ one like deuterium. The lowest excited state is a $0^{+}$one.

The most obvious way to further excite the nucleus with minimal energy would be to kick up a nucleon from the $2 \mathrm{p}_{3 / 2}$ subshell to the $2 \mathrm{p}_{1 / 2}$ one. That fills the $2 \mathrm{p}_{1 / 2}$ shell, making its net spin zero. However, there is now a "hole," a missing particle, in the $2 \mathrm{p}_{3 / 2}$ shell.

Holes in an otherwise filled subshell have the same possible angular momentum values as particles in an otherwise empty shell.

Therefore the hole must have the spin $3 / 2$ of a single particle. This can combine with the $1 / 2$ of the odd nucleon of the opposite type to either spin 1 or spin 2 . A relatively low energy $1^{+}$state can be observed in the experimental spectrum.

The next higher $0^{-}$state would require a particle to cross a major shell boundary. Then again, the energy of this excited state is quite substantial at 5 MeV . It seems simpler to assume that a $1 \mathrm{~s}_{1 / 2}$ nucleon is kicked to the $2 \mathrm{p}_{1 / 2}$ shell than that a $2 p_{3 / 2}$ nucleon is kicked to the $3 d_{5 / 2}$ one. In the latter case, it seems harder to explain why the four odd nucleons would want to particularly combine their spins to zero. And you could give an argument based on the ideas of the next subsection that 4 odd nucleons is a lot.

### 14.12.4 Draft: Shell model with pairing

This section examines some nuclei with more than a single nucleon in an unfilled shell.

Consider first oxygen-18 in figure 14.17, with both an even number of protons and an even number of neutrons. As always, the filled subshells have no angular momentum. That leaves the two $3 \mathrm{~d}_{5 / 2}$ neutrons. These could have combined integer spin from 0 to 5 if they were distinguishable particles. However, the two neutrons are identical fermions, and the wave function must be antisymmetric with respect to their exchange. It can be seen from chapter 12.8 item 3 , or more simply from table 12.1 , that only the 0,2 , and 4 combined spins are allowed. Still, that leaves three possibilities for the net spin of the entire nucleus.

Now the basic shell model is an "independent particle model:" there are no direct interactions between the particles. Each particle moves in a given average potential, regardless of what the others are doing. Therefore, if the shell model as covered so far would be strictly true, all three spin states 0,2 , and 4 of oxygen- 18 should have equal energy. Then the ground state should be any combination of these spins. But that is untrue. The ground-state has zero spin:

Figure 14.17: Nucleon pairing effect. [pdf]

All even-even nuclei have zero spin and even parity in the ground state.

There are zero known exceptions to this rule among either the stable or unstable nuclei.

So physicists have concluded that besides the average potential included in the shell model, there must be an additional "pairing energy" that makes nucleons of the same type want to combine pairwise into states of zero spin. In order to treat this effect mathematically without losing the basic shell model, the pairing energy must be treated as a relatively small perturbation to the shell model energy. Theories that do so are beyond the scope of this book, although the general ideas of perturbation theories can be found in addendum $\{A .38\}$. Here it must be suffice to note that the pairing effect exists and is due to interactions between nucleons not included in the basic shell model potential.

Therefore the basic shell model will from here on be referred to as the "unperturbed" shell model. The "perturbed shell model" will refer to the shell model in which additional energy corrections are assumed to exist that account for nontrivial interactions between individual nucleons. These corrections will not be explicitly discussed, but some of their effects will be demonstrated by means of experimental energy spectra.

If the pairing energy is a relatively small perturbation to the shell model, then for oxygen-18 you would expect that besides the zero spin ground state, the other possibilities of spin 2 and 4 would show up as low-lying excited states. Indeed the experimental spectrum in figure 14.17 shows $2^{+}$and $4^{+}$states of the right spin and parity, though their energy is obviously not so very low. To put it in context, the von Weizsäcker formula puts the pairing energy at $22 / \sqrt{A} \mathrm{MeV}$, which would be of the rough order of 5 MeV for oxygen-18.

If one neutron of the pair is kicked up to the $3 \mathrm{~s}_{1 / 2}$ state, a $2^{+}$or $3^{+}$state should result. This will require the pair to be broken up and a subshell boundary to be crossed. A potential $2^{+}$candidate is present in the spectrum.

Like for oxygen-16, there is again an excited $0^{+}$state of relatively low energy. In this case however, its energy seems rather high in view that the two $3 \mathrm{~d}_{5 / 2}$ neutrons could simply be kicked up across the minor shell boundary to the very nearby $3 \mathrm{~s}_{1 / 2}$ shell. An explanation can be found in the fact that physicists have concluded that:

The pairing energy increases with the angular momentum of the subshell.

When the neutron pair is kicked from the $3 \mathrm{~d}_{5 / 2}$ shell to the $3 \mathrm{~s}_{1 / 2}$, its pairing energy decreases. Therefore this excitation requires additional energy besides the crossing of the minor shell boundary.

It seems therefore that the perturbed shell model can give a plausible explanation for the various features of the energy spectrum. However, care must be
taken not to attach too much finality to such explanations. Section 14.13 will give a very different take on the excited states of oxygen-18. Presumably, neither explanation will be very accurate. Only additional considerations beyond mere energy levels can decide which explanation gives the better description of the excited states.

The purpose in this section is to examine what features seem to have a reasonable explanation within a shell model context, not how absolutely accurate that explanation really is.

Consider again the $0^{+}$excited state of oxygen-16 in figure 14.16 as discussed in the previous subsection. Some of the energy needed for a pair of $2 \mathrm{p}_{1 / 2}$ nucleons to cross the major shell boundary to the $3 \mathrm{~d}_{5 / 2}$ subshell will be compensated for by the higher pairing energy in the new subshell. It still seems curious that the state would end up below the $3^{-}$one, though.

Similarly, the relatively low energy $1 / 2^{-}$state in oxygen-17 and fluorine-17 can now be made a bit more plausible. To explain the negative parity, a nucleon must be kicked across the major shell boundary from the $2 \mathrm{p}_{1 / 2}$ subshell to the $3 \mathrm{~d}_{5 / 2}$ one. That should require quite a bit of energy, but this will in part be compensated for by the fact that pairing now occurs at higher angular momentum.

So what to make of the next $5 /{ }^{-}$state? One possibility is that a $2 p_{1 / 2}$ nucleon is kicked to the $3 \mathrm{~s}_{1 / 2}$ subshell. The three spins could then combine into $5 / 2$, [31, p. 131]. If true however, this would be a quite significant violation of the basic ideas of the perturbed shell model. Just consider: it requires breaking up the $2 \mathrm{p}_{1 / 2}$ pair and kicking one of the two neutrons across both a major shell boundary and a subshell one. That would require less energy than the $3 / 2^{+}$excitation in which the odd nucleon is merely kicked over two subshell boundaries and no pair is broken up? An alternative that is more consistent with the perturbed shell model ideas would be that the $5 / 2^{-}$excitation is like the $3 / 2^{-}$one, but with an additional partial break up of the resulting pair. The energy seems still low.

How about nuclei with an odd number of neutrons and/or protons in a subshell that is greater than one? For these:

The "odd-particle shell model" predicts that even if the number of nucleons in a subshell is odd, in the ground state all nucleons except the final odd one still combine into spherically symmetric states of zero spin.

That leaves only the final odd nucleon to provide any nonzero spin and corresponding nontrivial electromagnetic properties.

Figure 14.17 shows the example of oxygen-19, with three neutrons in the unfilled $3 \mathrm{~d}_{5 / 2}$ subshell. The odd-particle shell model predicts that the first two
neutrons still combine into a state of zero spin like in oxygen-18. That leaves only the spin of the third neutron. And indeed, the total nuclear spin of oxygen18 is observed to be $5 / 2$ in the ground state, the spin of this odd neutron. The odd-particle shell model got it right.

It is important to recognize that the odd-particle shell model only applies to the ground state. This is not always sufficiently stressed. Theoretically, three $3 \mathrm{~d}_{5 / 2}$ neutrons can combine their spins not just to spin $5 / 2$, but also to $3 / 2$ or $9 / 2$ while still satisfying the antisymmetrization requirement, table 12.1. And indeed, the oxygen-19 energy spectrum in figure 14.17 shows relatively low energy $3 / 2^{+}$and $9 / 2^{+}$states. To explain the energies of these states would require computation using an actual perturbed shell model, rather than just the odd-particle assumption that such a model will lead to perfect pairing of even numbers of nucleons.

It is also important to recognize that the odd-particle shell model is only a prediction. It does fail for a fair number of nuclei. That is true even excluding the very heavy nuclei for which the shell model does not apply period. For example, note in figure 14.17 how close together are the $5 / 2^{+}$and $3 / 2^{+}$energy levels. You might guess that the order of those two states could easily be reversed for another nucleus. And so it can; there are a number of nuclei in which the spins combine into a net spin one unit less than that of the last odd nucleon. While the unperturbed shell model does not fundamentally fail for such nuclei, (because it does not predict the spin at all), the additional odd-particle assumption does.

It should be noted that different terms are used in literature for the oddparticle shell model. The term "shell model with pairing" is accurate and understandable, so that is not used. Some authors use the term "extreme independent particle model." You read that right. While the unperturbed shell model is an independent particle model, the shell model with pairing has become a dependent particle model: there are now postulated direct interactions between the nucleons causing them to pair. So what better way to confuse students than to call a dependent particle model an extreme independent particle model? However, this term is too blatantly wrong even for some physicists. So, some other books use instead "extreme single-particle model," and still others use "one-particle shell model." Unfortunately, it is fundamentally a multipleparticle model. You cannot have particle interactions with a single particle. Only physicists would come up with three different names for the same model and get it wrong in each single case. This book uses the term odd-particle shell model, (with odd in dictionary rather than mathematical sense), since it is not wrong and sounds much like the other names being bandied around. (The official names could be fixed up by adding the word "almost," like in "extreme almost independent particle model." This book will not go there, but you could substitute "asymptotically" for "almost" to sound more scientific.)

While the odd-particle model applies only to the ground state, some excited
states can still be described as purely odd-particle effects. In particular, for the oxygen-19 example, the odd $3 \mathrm{~d}_{5 / 2}$ neutron could be kicked up to the $3 \mathrm{~s}_{1 / 2}$ subshell with no further changes. That would leave the two remaining $3 d_{5 / 2}$ neutrons with zero spin, and the nucleus with the new spin $1 / 2$ of the odd neutron. Indeed a low-lying $12^{+}$state is observed. (Because of the antisymmetrization requirement, this state cannot result from three neutrons in the $3 \mathrm{~d}_{5 / 2}$ subshell.)

It may further be noted that "pairing" is not really the right quantum term. If two nucleons have paired into the combination of zero net spin, the next two cannot just enter the same combination without violating the antisymmetrization requirements between the pairs. What really happens is that all four as a group combine into a state of zero spin. However, everyone uses the term pairing, and so will this book.

Examples that highlight the perturbation effects of the shell model are shown in figure 14.18. These nuclei have unfilled $4 \mathrm{~d}_{7 / 2}$ shells. Since that is a major shell with no subshells, nucleon transitions to different shells require quite a bit of energy.

First observe that all three nuclei have a final odd $4 \mathrm{f}_{7 / 2}$ nucleon and a corresponding ground state spin of $7 / 2$ just like the odd-particle shell model says they should. And the net nuclear parity is negative like that of the odd nucleon. That is quite gratifying.

As far as calcium-41 is concerned, one obvious minimal-energy excitation would be that the odd neutron is kicked up from the $4 \mathrm{f}_{7 / 2}$ shell to the $4 \mathrm{p}_{3 / 2}$ shell. This will produce a $3 / 2^{-}$excited state. Such a state does indeed exist and it has relatively high energy, as you would expect from the fact that a major shell boundary must be crossed.

Another obvious minimal-energy excitation would be that a nucleon is kicked up from the filled $3 \mathrm{~d}_{3 / 2}$ shell to pair up with the odd nucleon already in the $4 \mathrm{f}_{7 / 2}$ shell. This requires again that a major shell boundary is crossed, though some energy can be recovered by the fact that the new nucleon pairing is now at higher spin. Since here a nucleon changes shells from the positive parity $3 \mathrm{~d}_{3 / 2}$ subshell to the negative $4 \mathrm{f}_{7 / 2}$ one, the nuclear parity reverses and the excited state will be a $3 / 2^{+}$one. Such a state is indeed observed.

The unstable mirror twin of calcium-41, scandium-41 has energy levels that are very much the same.

Next consider calcium-43. The odd-particle shell model correctly predicts that in the ground state, the first two $4 \mathrm{f}_{7 / 2}$ neutrons pair up into zero spin, leaving the $7 / 2$ spin of the third neutron as the net nuclear spin. However, even allowing for the antisymmetrization requirements, the three $4 \mathrm{f}_{7 / 2}$ neutrons could instead combine into spin $3 / 2,5 / 2,9 / 2,11 / 2$, or $15 / 2$, table 12.1 . A low-energy $5 / 2-$ excited state, one unit of spin less than the ground state, is indeed observed. A $3 / 2^{-}$state is just above it. On the other hand, the lowest known $9 / 2^{-}$state has more energy than the lowest $11 / 2^{-}$one. Then again, consider the spin values that are not possible for the three neutrons if they stay in the $4 \mathrm{f}_{7 / 2}$ shell. The

Figure 14.18: Energy levels for neighbors of doubly-magic calcium-40. [pdf]
first $13 / 2^{-}$and $17 / 2^{-}$states occur at energies well beyond the $15 / 2^{-}$one, and the first $1 /{ }^{-}$state only appears at 2.6 MeV .

The lowest $3 / 2^{+}$state energy is half that of the one for calcium-41. Apparently, the $3 \mathrm{~d}_{3 / 2}$ neutron would rather pair up with 3 other attracting neutrons in the $4 \mathrm{f}_{7 / 2}$ shell than with just one. That seems reasonable enough. The overall picture seems in encouraging agreement with the perturbed shell model ideas.

Scandium- 43 has one proton and two neutrons in the $4 \mathrm{f}_{7 / 2}$ shells. The oddparticle model predicts that in the ground state, the two neutrons combine into zero spin. However, the antisymmetrization requirement allows excited spins of 2,4 , and 6 without any nucleons changing shells. The lowest excited spin value 2 can combine with the $7 / 2$ spin of the odd proton into excited nuclear states from $3 / 2^{-}$up to $11 / 2^{-}$. Relatively low-lying $3 / 2^{-}, 5 / 2^{-}$, and $7 / 2^{-}$states, but not a $1 / 2^{-}$one, are observed. (The lowest-lying potential $9 / 2^{-}$state is at 1.9 MeV . The lowest lying potential $1 / 2^{-}$state is at 3.3 MeV , though there are 4 states of unknown spin before that.)

Note how low the lowest $3 / 2^{+}$state has sunk. That was maybe not quite unpredictable. Two protons plus two neutrons in the $4 \mathrm{f}_{7 / 2}$ shells have to obey less antisymmetrization requirements than four protons do, while the attractive nuclear forces between the four are about the same according to charge independence.

The difference between the energy levels of scandium-41 versus scandium-43 is dramatic. After all, the unperturbed shell model would almost completely ignore the two additional neutrons that scandium-43 has. Protons and neutrons are solved for independently in the model. It brings up a point that is often not sufficiently emphasized in other expositions of nuclear physics. The oddparticle shell model is not an "only the last odd particle is important" model. It is a "the last odd particle provides the ground-state spin and electromagnetic properties, because the other particles are paired up in spherically symmetric states" model. The theoretical justification for the model, which is weak enough as it is already, only applies to the second statement.

### 14.12.5 Draft: Configuration mixing

To better understand the shell model and its limitations, combinations of states must be considered.

Take once again the excited $0^{+}$state of oxygen- 16 shown in figure 14.16 . To create this state within the shell model picture, a pair of $2 \mathrm{p}_{1 / 2}$ nucleons must be kicked up to the $3 \mathrm{~d}_{5 / 2}$ subshell. Since that requires a major shell boundary crossing by two nucleons, it should take a considerable amount of energy. Some of it will be recovered by the fact that the nucleon pairing now occurs at higher angular momentum. But there is another effect.

First of all, there are two ways to do it: either the $2 \mathrm{p}_{1 / 2}$ protons or the two $2 \mathrm{p}_{1 / 2}$ neutrons can be kicked up. One produces an excited wave function that
will be indicated by $\psi_{2 p}$ and the other by $\psi_{2 n}$. Because of charge symmetry, and because the Coulomb force is minor for light nuclei, these two states should have very nearly the same energy.

Quantum mechanics allows for linear combinations of the two wave functions:

$$
\Psi=c_{1} \psi_{2 p}+c_{2} \psi_{2 n}
$$

Within the strict context of the unperturbed shell model, it does not make a difference. That model assumes that the nucleons do not interact directly with each other, only with an average potential. Therefore the combination should still have the same energy as the individual states.

But now consider the possibility that both the protons and the neutrons would be in the $3 \mathrm{~d}_{5 / 2}$ subshell. In that case, surely you would agree that these four, mutually attracting, nucleons in the same spacial orbits would significantly interact and lower their energy. Even if the unperturbed shell model ignores that.

Of course, the four nucleons are not all in the $3 \mathrm{~d}_{5 / 2}$ state; that would require four major shell crossing and make things worse. Each component state has only two nucleons in the $3 \mathrm{~d}_{5 / 2}$ subshell. However, quantum mechanical uncertainty makes the two states interact through "twilight" terms, chapter 5.3. These act in some sense as if all four nucleons are indeed in the $3 \mathrm{~d}_{5 / 2}$ subshell at the same time. It has the weird effect that the right combination of the states $\psi_{2 p}$ and $\psi_{2 n}$ can have significantly less energy than the lowest of the two individual states. That is particularly true if the two original states have about the same energy, as they have here.

The amount of energy lowering is hard to predict. It depends on the amount of nucleon positions that have a reasonable probability for both states and the amount of interaction of the nucleons. Intuition still suggests it should be quite considerable. And there is a more solid argument. If the strictly unperturbed shell model applies, there should be two $0^{+}$energy states with almost the same energy; one for protons and one for neutrons. However, if there is significant twilight interaction between the two, the energy of one of the pair will be pushed way down and the other way up. There is no known second excited $0^{+}$state with almost the same energy as the first one for oxygen-16.

Of course, a weird excited state at 6 MeV in a nucleus is not such a big deal. But there is more. Consider figure 14.19. It gives the excitation energy of the lowest $2^{+}$state for all even-even nuclei.

For all nuclei except the crossed-out ones, the $2^{+}$state is the lowest excited state of all. That seems curious already. Why would the lowest excited state not be a $0^{+}$one for a lot of even-even nuclei? Based on the shell model you would assume there are two ways to excite an even-even nucleus with minimal energy. The first way would be to kick a pair of nucleons up to the next subshell. That would create a $0^{+}$excited state. It could require very little energy if the subshells are close together.

Figure 14.19: $2^{+}$excitation energy of even-even nuclei. [pdf][con]

The alternative way to excite an even-even nucleus with minimal energy would break up a pair, but leave them in the same subshell. This would at the minimum create a $2^{+}$state. (For partially filled shells of high enough angular momentum, it may also be possible to reconfigure the nucleons into a different state that still has zero angular momentum, but that does not affect the argument.) Breaking the pairing should require an appreciable amount of energy, on the MeV level. So why is the $2^{+}$state almost invariably the lowest energy one?

Then there is the magnitude of the $2^{+}$energy levels. In figure 14.19 the energies have been normalized with the von Weizsäcker value for the pairing energy,

$$
\frac{2 C_{p}}{A^{C_{e}}}
$$

You would expect all squares to have roughly the full size, showing that it takes about the von Weizsäcker energy to break up the pair. Doubly magic nuclei are quite happy to obey. Singly magic nuclei seem a bit low, but hey, the break-up is usually only partial, you know.

But for nuclei that are not close to any magic number for either protons and neutrons all hell breaks loose. Break-up energies one to two orders of magnitude less than the von Weizsäcker value are common. How can the pairing energy just suddenly stop to exist?

Consider a couple of examples in figure 14.20. In case of ruthenium-104, it takes a measly 0.36 MeV to excite the $2^{+}$state. But there are 10 different ways to combine the four $5 \mathrm{~g}_{9.2}$ protons into a $2^{+}$state, table 12.1. Kick up the pair of protons from the $4 \mathrm{p}_{1 / 2}$ shell, and there are another $102^{+}$states. The four $5 g_{7 / 2}$ neutrons can produce another 10 of them. Kick up a pair of neutrons from the $5 d_{5 / 2}$ subshell, and there is 10 more. Presumably, all these states will have similar energy. And there might be many other low-energy ways to create $2^{+}$ states, [31, pp. 135-136].

Consider now the following simplistic model. Assume that the nucleus can be in any of $Q$ different global states of the same energy,

$$
\psi_{1}, \psi_{2}, \psi_{3}, \ldots, \psi_{Q}
$$

Watch what happens when such states are mixed together. The energy follows from the Hamiltonian coefficients

$$
\begin{array}{ccccc}
E_{1} \equiv\left\langle\psi_{1} \mid H \psi_{1}\right\rangle & \varepsilon_{12} \equiv\left\langle\psi_{1} \mid H \psi_{2}\right\rangle & \varepsilon_{13} \equiv\left\langle\psi_{1} \mid H \psi_{3}\right\rangle & \ldots & \varepsilon_{1 Q} \equiv\left\langle\psi_{1} \mid H \psi_{Q}\right\rangle \\
\varepsilon_{12}^{*} \equiv\left\langle\psi_{2} \mid H \psi_{1}\right\rangle & E_{2} \equiv\left\langle\psi_{2} \mid H \psi_{1}\right\rangle & \varepsilon_{23} \equiv\left\langle\psi_{2} \mid H \psi_{3}\right\rangle & \ldots & \varepsilon_{2 Q} \equiv\left\langle\psi_{2} \mid H \psi_{Q}\right\rangle \\
\varepsilon_{13}^{*} \equiv\left\langle\psi_{3} \mid H \psi_{1}\right\rangle & \varepsilon_{23}^{*} \equiv\left\langle\psi_{3} \mid H \psi_{2}\right\rangle & E_{3} \equiv\left\langle\psi_{3} \mid H \psi_{3}\right\rangle & \ldots & \varepsilon_{3 Q} \equiv\left\langle\psi_{3} \mid H \psi_{Q}\right\rangle \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
\varepsilon_{1 Q}^{*} \equiv\left\langle\psi_{Q} \mid H \psi_{1}\right\rangle & \varepsilon_{2 Q}^{*} \equiv\left\langle\psi_{Q} \mid H \psi_{2}\right\rangle & \varepsilon_{3 Q}^{*} \equiv\left\langle\psi_{Q} \mid H \psi_{3}\right\rangle & \ldots & E_{Q} \equiv\left\langle\psi_{Q} \mid H \psi_{Q}\right\rangle
\end{array}
$$

By assumption, the energy levels $E_{1}, E_{2}, \ldots$ of the states are all about the same, and if the unperturbed shell model was exact, the perturbations $\varepsilon_{\text {.. }}$ would all be

Figure 14.20: Collective motion effects. [pdf]
zero. But since the shell model is only a rough approximation of what is going on inside nuclei, the shell model states will not be true energy eigenfunctions. Therefore the coefficients $\varepsilon$.. will surely not be zero, though what they will be is hard to say.

To get an idea of what can happen, assume for now that the $\varepsilon_{\text {.. }}$ are all equal and negative. In that case, following similar ideas as in chapter 5.3, a state of lowered energy exists that is an equal combination of each of the $Q$ individual excited states; its energy will be lower than the original states by an amount $(Q-1) \varepsilon$. Even if $\varepsilon$ is relatively small, that will be a significant amount if the number $Q$ of states with the same energy is large.

Of course, the coefficients $\varepsilon$.. will not all be equal and negative. Presumably they will vary in both sign and magnitude. Interactions between states will also be limited by symmetries. (If states combine into an equivalent state that is merely rotated in space, there is no energy lowering.) Still, the lowest excitation energy will be defined by the largest negative accumulation of shell model errors that is possible.

The picture that emerges then is that the $2^{+}$excitation for ruthenium-104, and most other nuclei in the rough range $50<A<150$, is not just a matter of just one or two nucleons changing. It apparently involves the collaborative motion of a large number of nucleons. This would be quite a challenge to describe in the context of the shell model. Therefore physicists have developed different models, ones that allow for collective motion of the entire nucleus, like in section 14.13 .

When the energy of the excitation hits zero, the bottom quite literally drops out of the shell model. In fact, even if the energy merely becomes low, the shell model must crash. If energy states are almost degenerate, the slightest thing will throw the nucleus from one to the other. In particular, small perturbation theory shows that originally small effects blow up as the reciprocal of the energy difference, addendum $\{\mathrm{A} .38\}$. Physicists have found that nuclei in the rough ranges $150<A<190$ and $A>220$ acquire an intrinsic nonspherical shape, fundamentally invalidating the shell model as covered here. More physically, as figure 14.19 suggests, it happens for pretty much all heavy nuclei except ones close to the magic lines. The energy spectrum of a typical nucleus in the nonspherical range, hafnium-176, is shown in figure 14.20.

### 14.12.6 Draft: Shell model failures

The previous subsection already indicated two cases in which the shell model has major problems with the excited states. But in a number of cases the shell model may also predict an incorrect ground state. Figure 14.21 shows some typical examples.

In case of titanium-47, the shell model predicts that there will be five neutrons in an unfilled $4 \mathrm{f}_{7 / 2}$ subshell. It is believed that this is indeed correct [36,

Figure 14.21: Failures of the shell model. [pdf]
p. 224]. The unperturbed shell model makes no predictions about the nuclear spin. However, the odd-particle shell model says that in the ground state the nuclear spin should be that of the odd neutron, $\frac{7}{2}$. But it is not, the spin is $\frac{5}{2}$. The pairing of the even number of neutrons in the $4 \mathrm{f}_{7 / 2}$ shell is not complete. While unfortunate, this is really not that surprising. The perturbation Hamiltonian used to derive the prediction of nucleon pairing is a very crude one. It is quite common to see subshells with at least three particles and three holes (three places for additional particles) end up with a unit less spin than the odd-particle model predicts. It almost happened for oxygen-19 in figure 14.17.

In fact, 5 particles in a shell in which the single-particle spin is $7 / 2$ can combine their spin into a variety of net values. Table 12.1 shows that $3 / 2,5 / 2,7 / 2,9 / 2,11 / 2$, and $15 / 2$ are all possible. Compared to that, the odd-particle prediction does not seem that bad. Note that the predicted state of spin $7 / 2$ has only slightly more energy than the ground state. On the other hand, other states that might be produced through the combined spin of the five neutrons have much more energy.

Fluorine-19 shows a more fundamental failure of the shell model. The shell model would predict that the odd proton is in the $3 \mathrm{~d}_{5 / 2}$ state, giving the nucleus $\operatorname{spin} 5 / 2$ and even parity. In fact, it should be just like fluorine-17 in figure 14.16. For the unperturbed shell model, the additional two neutrons should not make a significant difference. But the nuclear spin is $1 / 2$, and that means that the odd proton must be in the $3 \mathrm{~s}_{1 / 2}$ state. A look at figure 14.15 shows that the unperturbed shell model cannot qualitatively explain this swapping of the two states.

It is the theoretician's loss, but the experimentalist's gain. The fact that fluorine has spin one-half makes it a popular target for nuclear magnetic resonance studies. Spin one-half nuclei are easy to analyze and they do not have nontrivial electric fields that mess up the nice sharp signals in nuclei with larger spin.

And maybe the theoretician can take some comfort in the fact that this complete failure is rare among the light nuclei. In fact, the main other example is fluorine-19's mirror twin neon-19. Also, there is an excited state with the correct spin and parity just above the ground state. But no funny business here; if you are going to call fluorine-19 almost right, you have to call fluorine17 almost wrong.

Note also how low the $1 / 2^{-}$excited state has become. Maybe this can be somewhat understood from the fact that the kicked-up $2 \mathrm{p}_{1 / 2}$ proton is now in a similar spatial orbit with three other nucleons, rather than just one like in the case of fluorine-17. In any case, it would surely require a rather sophisticated perturbed shell model to describe it, one that includes nucleons of both type in the perturbation.

And note that formulating a perturbed shell model from physical principles is not easy anyway, because the basic shell model already includes the interactions
between nucleons in an average sense. The perturbations must not just identify the interactions, but more importantly, what part of these interactions is still missing from the unperturbed shell model.

For the highly unstable beryllium-11 and nitrogen-11 mirror nuclei, the shell model gets the spin right, but the parity wrong! In shell model terms, a change of parity requires the crossing of a major shell boundary. Beryllium- 11 is known to be a "halo nucleus," a nucleus whose radius is noticeably larger than that predicted by the liquid drop formula (14.9). This is associated with a gross inequality between the number of protons and neutrons. Beryllium-11 has only 4 protons, but 7 neutrons; far too many for such a light nucleus. Beryllium-13 with 9 neutrons presumably starts to simply throw the bums out. Beryllium11 does not do that, but it keeps one neutron at arms length. The halo of beryllium-11 is a single neutron one. (That of its beta-decay parent lithium-11 is a two-neutron one. Such a nucleus is called "Borromean," after the three interlocking rings in the shield of the princes of Borromeo. Like the rings, the three-body system lithium-9 plus two neutrons hangs together but if any of the three is removed, the other two fall apart too. Both lithium-10 and the dineutron are not bound.) Halo nucleons tend to prefer states of low orbital angular momentum, because in classical terms it reduces the kinetic energy they need for angular motion. The potential energy is less significant so far out. In shell model terms, the beryllium- 11 neutron has the $3 \mathrm{~s}_{1 / 2}$ state available to go to; that state does indeed have the $1 / 2$ spin and positive parity observed. Very little seems to be known about nitrogen-11 at the time of writing; no energy levels, no electric quadrupole moment (but neither is there for beryllium-11). It is hard to do experiments at your leisure on a nucleus that lives for less than $10^{-21} \mathrm{~s}$.

For much heavier nuclei, the subshells are often very close together. Also, unlike for the $3 \mathrm{~d}_{5 / 2}$ and $3 \mathrm{~s}_{1 / 2}$ states, the shell model often does not produce an unambiguous ordering for them. In that case, it is up to you whether you want to call it a failure if a particle does not follow whatever ambiguous ordering you have adopted.

Selenium- 77 illustrates a more fundamental reason why the odd particle may end up in the wrong state. The final odd neutron would normally be the third one in the $5 g_{9 / 2}$ state. That would give the nucleus a net spin of $\frac{9}{2}$ and positive parity. There is indeed a low-lying excited state like that. (It is just above a $\frac{7}{2}$ one that might be an effect of incomplete pairing.) However, the nucleus finds that if it promotes a neutron from the $4 \mathrm{p}_{1 / 2}$ shell to the $5 \mathrm{~g}_{9 / 2}$ one just above, that neutron can pair up at higher angular momentum, lowering the overall nuclear energy. That leaves the odd neutron in the $4 \mathrm{p}_{1 / 2}$ state, giving the nucleus a net spin of $1 / 2$ and negative parity. Promotion happens quite often if there are more than 32 nucleons of a given type and there is a state of lower spin immediately below the one being filled.

Tantalum-181 is an example nucleus that is not spherical. For it, the shell
model simply does not apply as derived here. So there is no need to worry about it. Which is a good thing, because it does not seem easy to justify a $7 / 2^{+}$ ground state based on the shell model. As noted in the previous subsection, nonspherical nuclei appear near the stable line for mass numbers of about 150 to 190 and above 220. There are also a few with mass numbers between 20 and 30.

Preston \& Bhaduri [36, p. 224ff] give an extensive table of nucleons with odd mass number, listing shell occupation numbers and spin. Notable is iron57 , believed to have three neutrons in the $4 \mathrm{p}_{3 / 2}$ shell as the shell model says, but with a net nuclear spin of $1 / 2^{-}$. Since the three neutrons cannot produce that spin, in a shell model explanation the 6 protons in the $4 \mathrm{f}_{7 / 2}$ shell will need to contribute. Similarly neodymium-149 with, maybe, 7 neutrons in the $6 \mathrm{f}_{7 / 2}$ shell has an unexpected $5 / 2^{-}$ground state. Palladium- 101 with 5 neutrons in the $5 \mathrm{~d}_{5 / 2}$ shell has an unexpected spin $7 / 2$ according to the table; however, the more recent data of [3] list the nucleus at the expected $5 / 2^{+}$value. In general the table shows that the ground state spin values of spherical nuclei with odd mass numbers are almost all correctly predicted if you know the correct occupation numbers of the shells. However, predicting those numbers for heavy nuclei is often nontrivial.

### 14.13 Draft: Collective Structure

Some nuclear properties are difficult to explain using the shell model approach as covered here. Therefore physicists have developed different models.

For example, nuclei may have excited states with unexpectedly low energy. One example is ruthenium-104 in figure 14.20, and many other even-even nuclei with such energies may be found in figure 14.19. If you try to explain the excitation energy within a shell model context, you are led to the idea that many shell model excitations combine forces, as in section 14.12.5.

Then there are nuclei for which the normal shell model does not work at all. They are called the nonspherical or deformed nuclei. Among the line of most stable nuclei, they are roughly the "rare earth" lanthanides and the extremely heavy actinides that are deformed. In terms of the mass number, the ranges are about $150<A<190$ and $220<A$. (However, various very unstable lighter nuclei are quite nonspherical too. None of this is written in stone.) In terms of figure 14.19, they are the very small squares. Examples are hafnium-176 in figure 14.20 and tantalum-181 in figure 14.21 .

It seems clear that many or all nuclei participate in these effects. Trying to explain such organized massive nucleon participation based on a perturbed basic shell model alone would be very difficult, and mathematically unsound in the case of deformed nuclei. A completely different approach is desirable.

Nuclei with many nucleons and densely spaced energy levels bear some similarity to macroscopic systems. Based on that idea, physicists had another look at the classical liquid drop model for nuclei. That model was quite successful in explaining the size and ground state energy levels of nuclei in section 14.10.

But liquid drops are not necessarily static; they can vibrate. Vibrating states provide a model for low-energy excited states in which the nucleons as a group participate nontrivially. Furthermore, the vibrations can become unstable, providing a model for permanent nuclear deformation or nuclear fission. Deformed nuclei can display effects of rotation of the nuclei. This section will give a basic description of these effects.

### 14.13.1 Draft: Classical liquid drop

This section reviews the mechanics of a classical liquid drop, like say a droplet of water. However, there will be one additional effect included that you would be unlikely to see in a drop of water: it will be assumed that the liquid contains distributed positively charged ions. This is needed to allow for the very important destabilizing effect of the Coulomb forces in a nucleus.

It will be assumed that the nuclear "liquid" is homogeneous throughout. That is a somewhat doubtful assumption for a model of a nucleus; there is no a priori reason to assume that the proton and neutron motions are the same. But a two-liquid model, such as found in [40, p. 183ff], is beyond the current coverage.

It will further be assumed that the nuclear liquid preserves its volume. This assumption is consistent with the formula (14.9) for the nuclear radius, and it greatly simplifies the classical analysis.

The von Weizsäcker formula showed that the nuclear potential energy increases with the surface area. The reason is that nucleons near the surface of the nucleus are not surrounded by a full set of attracting neighboring nucleons. Macroscopically, this effect is explained as "surface tension." Surface tension is defined as increased potential energy per unit surface area. (The work in expanding the length of a rectangular surface area must equal the increased potential energy of the surface molecules. From that it is seen that the surface tension is also the tension force at the perimeter of the surface per unit length.)

Using the surface term in the von Weizsäcker formula (14.10) and (14.9), the nuclear equivalent of the surface tension is

$$
\begin{equation*}
\sigma=\frac{C_{s}}{4 \pi R_{A}^{2}} \tag{14.17}
\end{equation*}
$$

The $C_{d}$ term in the von Weizsäcker formula might also be affected by the nuclear surface area because of its unavoidable effect on the nuclear shape, but to simplify things this will be ignored.

The surface tension wants to make the surface of the drop as small as possible. It can do so by making the drop spherical. However, this also crowds the protons together the closest, and the Coulomb repulsions resist that. So the Coulomb term fights the trend towards a spherical shape. This can cause heavy nuclei, for which the Coulomb term is big, to fission into pieces. It also makes lighter nuclei less resistant to deformation, promoting nuclear vibrations or even permanent deformations. To include the Coulomb term in the analysis of a classical drop of liquid, it can be assumed that the liquid is charged, with total charge $Z e$.

Infinitesimal vibrations of such a liquid drop can be analyzed, \{A.43\}. It is then seen that the drop can vibrate around the spherical shape with different natural frequencies. For a single mode of vibration, the radial displacement of the surface of the drop away from the spherical value takes the form

$$
\begin{equation*}
\delta=\varepsilon l \sin (\omega t-\varphi) \bar{Y}_{l}^{m}(\theta, \phi) \tag{14.18}
\end{equation*}
$$

Here $\varepsilon l$ is the infinitesimal amplitude of vibration, $\omega$ the frequency, and $\varphi$ a phase angle. Also $\theta$ and $\phi$ are the coordinate angles of a spherical coordinate system with its origin at the center of the drop, N.3. The $\bar{Y}_{l}^{m}$ are essentially the spherical harmonics of orbital angular momentum fame, chapter 4.2.3. However, in the classical analysis it is more convenient to use the real version of the $Y_{l}^{m}$. For $m=0$, there is no change, and for $m \neq 0$ they can be obtained from the complex version by taking $Y_{l}^{m} \pm Y_{l}^{-m}$ and dividing by $\sqrt{2}$ or $\sqrt{2} \mathrm{i}$ as appropriate.

Vibration with $l=0$ is not possible, because it would mean that the radius increased or decreased everywhere, $\left(Y_{0}^{0}\right.$ is a constant), which would change the volume of the liquid. Motion with $l=1$ is possible, but it can be seen from the spherical harmonics that this corresponds to translation of the drop at constant velocity, not to vibration.

Vibration occurs only for $l \geqslant 2$, and the frequency of vibration is then, \{A.43\}:

$$
\begin{equation*}
\omega=\sqrt{\frac{E_{s, l}^{2}}{\hbar^{2}} \frac{1}{A}-\frac{E_{c, l}^{2}}{\hbar^{2}} \frac{Z^{2}}{A^{2}}} \tag{14.19}
\end{equation*}
$$

The constants $E_{s, l}$ and $E_{c, l}$ express the relative strengths of the surface tension and Coulomb repulsions, respectively. The values of these constants are, expressed in energy units,

$$
\begin{equation*}
E_{s, l}=\frac{\hbar c}{R_{A}} \sqrt{\frac{(l-1) l(l+2)}{3} \frac{C_{s}}{m_{\mathrm{p}} c^{2}}} \quad E_{c, l}=\frac{\hbar c}{R_{A}} \sqrt{\frac{2(l-1) l}{2 l+1} \frac{e^{2}}{4 \pi \epsilon_{0} R_{A} m_{\mathrm{p}} c^{2}}} \tag{14.20}
\end{equation*}
$$

The most important mode of vibration is the one at the lowest frequency, which means $l=2$. In that case the numerical values of the constants are

$$
\begin{equation*}
E_{s, 2} \approx 35 \mathrm{MeV} \quad E_{c, 2} \approx 5.1 \mathrm{MeV} \tag{14.21}
\end{equation*}
$$

Of course a nucleus with a limited number of nucleons and energy levels is not a classical system with countless molecules and energy levels. The best you may hope for that there will be some reasonable qualitative agreement between the two.

It turns out that the liquid drop model significantly overestimates the stability of nuclei with respect to relatively small deviations from spherical. However, it does much a better job of estimating the stability against the large scale deformations associated with nuclear fission.

Also, the inertia of a nucleus can be quite different from that of a liquid drop, $[36$, p. 345,576$]$. This however affects $E_{s, l}$ and $E_{c, l}$ equally, and so it does not fundamentally change the balance between surface tension and Coulomb repulsions.

### 14.13.2 Draft: Nuclear vibrations

In the previous subsection, the vibrational frequencies of nuclei were derived using a classical liquid drop model. They apply to vibrations of infinitely small amplitude, hence infinitesimal energy.

However, for a quantum system like a nucleus, energy should be quantized. In particular, just like the vibrations of the electromagnetic field come in photons of energy $\hbar \omega$, you expect vibrations of matter to come in "phonons" of energy $\hbar \omega$. Plugging in the classical expression for the lowest frequency gives

$$
\begin{equation*}
E_{\text {vibration }}=\sqrt{E_{s, 2}^{2} \frac{1}{A}-E_{c, 2}^{2} \frac{Z^{2}}{A^{2}}} \quad E_{s, 2} \approx 35 \mathrm{MeV} \quad E_{c, 2} \approx 5.1 \mathrm{MeV} \tag{14.22}
\end{equation*}
$$

That is in the ballpark of excitation energies for nuclei, suggesting that collective motion of the nucleons is something that must be considered.

In particular, for light nuclei, the predicted energy is about $35 / \sqrt{A} \mathrm{MeV}$, comparable to the von Weizsäcker approximation for the pairing energy, $22 / \sqrt{A}$ MeV . Therefore, it is in the ballpark to explain the energy of the $2^{+}$excitation of light even-even nuclei in figure 14.19. The predicted energies are however definitely too high. That reflects the fact mentioned in the previous subsection that the classical liquid drop overestimates the stability of nuclei with respect to small deformations. Note also the big discrete effects of the magic numbers in the figure. Such quantum effects are completely missed in the classical liquid drop model.

It should also be pointed out that now that the energy is quantized, the basic assumption that the amplitude of the vibrations is infinitesimal is violated. A quick ballpark shows the peak quantized surface deflections to be in the fm range, which is not really small compared to the nuclear radius. If the amplitude was indeed infinitesimal, the nucleus would electrically appear as a spherically symmetric charge distribution. Whether you want to call the deviations from
that prediction appreciable, [36, p. 342, 354] or small, [31, p. 152], nonzero values should certainly be expected.

As far as the spin is concerned, the classical perturbation of the surface of the drop is given in terms of the spherical harmonics $Y_{2}^{m}$. The overall mass distribution has the same dependence on angular position. In quantum terms you would associate such an angular dependence with an azimuthal quantum number 2 and even parity, hence with a $2^{+}$state. It all seems to fit together rather nicely.

There is more. You would expect the possibility of a two-phonon excitation at twice the energy. Phonons, like photons, are bosons; if you combine two of them in a set of single-particle states of square angular momentum $l=2$, then the net square angular momentum can be either 0,2 , or 4 , table 12.2 . So you would expect a triplet of excited $0^{+}, 2^{+}$, and $4^{+}$states at roughly twice the energy of the lowest $2^{+}$excited state.

And indeed, oxygen-18 in figure 14.17 shows a nicely compact triplet of this kind at about twice the energy of the lowest $2^{+}$state. Earlier, these states were seemingly satisfactorily explained using single-nucleon excitations, or combinations of a few of them. Now however, the liquid drop theory explains them, also seemingly satisfactory, as motion of the entire nucleus!

That does not necessarily mean that one theory must be wrong and one right. There is no doubt that neither theory has any real accuracy for this nucleus. The complex actual dynamics is quite likely to include nontrivial aspects of each theory. The question is whether the theories can reasonably predict correct properties of the nucleus, regardless of the approximate way that they arrive at those predictions. Moreover, a nuclear physicist would always want to look at the decay of the excited states, as well as their electromagnetic properties where available, before classifying their nature. That however is beyond the scope of this book.

Many, but by no means all, even-even nuclei show similar vibrational characteristics. That is illustrated in figure 14.22. This figure shows the ratio of the second excited energy level $E_{2}$, regardless of spin, divided by the energy $E_{2^{+}}$ of the lowest $2^{+}$excited state. Normally $E_{2^{+}}$is the lowest excited state of all, so $E_{2}$ will be larger, making the ratio greater than one. That are the nuclei we are interested in here. Helium 4, the little black square at the $Z=N=2$ intersection, is of no interest.

Now the theoretically-ideal vibrating nucleus would have a $2^{+}$lowest excited state, corresponding to a single phonon of vibration. It would also have a triplet of states with two phonons, where ideally speaking all three of these states should each have an energy $E_{2}$ that is exactly twice the energy $E_{2^{+}}$of the state with one phonon. That makes the ideal energy ratio $E_{2} / E_{2^{+}}$equal to 2 . The nuclei that do have that energy ratio are shown as bright green squares in figure 14.22. These bright green squares are likely candidates for nuclei with vibrating excited states of low energy. But in addition, for the ideal vibrating nucleus, the

Figure 14.22: An excitation energy ratio for even-even nuclei. [pdf][con]
triplet of exited two-phonon states must consist of exactly one $0^{+}$state, exactly one $2^{+}$state, and exactly one $4^{+}$state, because that are the only three states that the two phonons can produce. The nuclei four which the lowest excited state is $2^{+}$one, and the next three states consist of one $0^{+}$state, one $2^{+}$state, and one $4^{+}$state, are marked with an " V " in figure 14.22. So bright green squares in figure 14.22 with an " V " in them are surely nuclei willing to vibrate. Anything else would be too much of a coincidence to believe. You can see that nuclei with vibrating excited states are quite common below $N=82$ neutrons, or near magic numbers.

Still, many even-even nuclei do not seem to have vibrational excited states. But many of those who do not still have that unexpected lowest exited state that has spin $2^{+}$and very little energy. Obviously, then, liquid-drop vibrations must be only a part of the story.

Figure 14.23: Textbook vibrating nucleus tellurium-120. [pdf]
Much heavier vibrating nuclei than oxygen-18 are tellurium-120 in figure 14.23 as well as the earlier example of ruthenium-104 in figure 14.20. Both nuclei have again a fairly compact $0^{+}, 2^{+}, 4^{+}$triplet at roughly twice the energy of the lowest $2^{+}$excited state. But these more "macroscopic" nuclei also show a nice $0^{+}, 2^{+}, 3^{+}, 4^{+}, 6^{+}$quintuplet at very roughly three times the energy of the lowest $2^{+}$state. Yes, three identical phonons of spin 2 can have a combined spin of $0,2,3,4$, and 6 , but not 1 or 5 (c.f. 12.2).

As subsection 14.13 .1 showed, liquid drops can also vibrate according to spherical harmonics $Y_{l}^{m}$ for $l>2$. The lowest such possibility $l=3$ has spin 3 and negative parity. Vibration of this type is called "octupole vibration," while $l=2$ is referred to as "quadrupole vibration." For very light nuclei, the energy of octupole vibration is about twice that of the quadrupole type. That would put the $3^{-}$octupole vibration right in the middle of the two-phonon quadrupole triplet. However, for heavier nuclei the $3^{-}$state will be relatively higher, since the energy reduction due to the Coulomb term is relatively smaller in the case $l$ $=3$. Indeed, the first $3^{-}$states for tellurium-120 and ruthenium-104 are found
well above the quadrupole quintuplet. The lowest $3^{-}$state for much lighter oxygen-18 is relatively lower.

### 14.13.3 Draft: Nonspherical nuclei

The classical liquid drop model predicts that the nucleus cannot maintain a spherical ground state if the destabilizing Coulomb energy exceeds the stabilizing nuclear surface tension. Indeed, from electromagnetic measurements, it is seen that many very heavy nuclei do acquire a permanent nonspherical shape. These are called "deformed nuclei".

They are roughly the red squares and yellow squares marked with " $R$ " in figure 14.22. Near the stable line, their mass number ranges are from about 150 to 190 and above 220. But many unstable much lighter nuclei are deformed too.

The liquid drop model, in particular (14.19), predicts that the nuclear shape becomes unstable at

$$
\frac{Z^{2}}{A}=\frac{E_{s, 2}^{2}}{E_{c, 2}^{2}} \approx 48
$$

If that was true, essentially all nuclei would be spherical. A mass number of 150 corresponds to about $Z^{2} / A$ equal to 26 . However, as pointed out in subsection 14.13.1, the liquid drop model overestimates the stability with respect to relatively small deformations. However, it does a fairly good job of explaining the stability with respect to large ones. That explains why the deformation of the deformed nuclei does not progress until they have fissioned into pieces.

Physicists have found that most deformed nuclei can be modeled well as spheroids, i.e. ellipsoids of revolution. The nucleus is no longer assumed to be spherically symmetric, but still axially symmetric. Compared to spherical nuclei, there is now an additional nondimensional number that will affect the various properties: the ratio of the lengths of the two principal axes of the spheroid. That complicates analysis. A single theoretical number now becomes an entire set of numbers, depending on the value of the nondimensional parameter. For some nuclei furthermore, axial symmetry is insufficient and a model of an ellipsoid with three unequal axes is needed. In that case there are two nondimensional parameters. Things get much messier still then.

### 14.13.4 Draft: Rotational bands

Vibration is not the only semi-classical collective motion that nuclei can perform. Deformed nuclei can also rotate as a whole. This section gives a simplified semiclassical description of it.

### 14.13.4.1 Draft: Basic notions in nuclear rotation

Classically speaking, the kinetic energy of a solid body due to rotation around an axis is $T_{\mathrm{R}}=\frac{1}{2} \mathcal{I}_{\mathrm{R}} \omega^{2}$, where $\mathcal{I}_{\mathrm{R}}$ is the moment of inertia around the axis and $\omega$ the angular velocity. Quantum mechanics does not use angular velocity but angular momentum $J=\mathcal{I}_{\mathrm{R}} \omega$, and in these terms the kinetic energy is $T_{\mathrm{R}}=$ $J^{2} / 2 \mathcal{I}_{\mathrm{R}}$. Also, the square angular momentum $J^{2}$ of a nucleus is quantized to be $\hbar^{2} j(j+1)$ where $j$ is the net "spin" of the nucleus, i.e. the azimuthal quantum number of its net angular momentum.

Therefore, the kinetic energy of a nucleus due to its overall rotation becomes:

$$
\begin{equation*}
T_{\mathrm{R}}=\frac{\hbar^{2}}{2 \mathcal{I}_{\mathrm{R}}} j(j+1)-\frac{\hbar^{2}}{2 \mathcal{I}_{\mathrm{R}}} j_{\min }\left(j_{\min }+1\right) \quad\left(j_{\min } \neq 1 / 2\right) \tag{14.23}
\end{equation*}
$$

Here $j_{\text {min }}$ is the azimuthal quantum number of the "intrinsic state" in which the nucleus is not rotating as a whole. The angular momentum of this state is in the individual nucleons and not available for nuclear rotation, so it must be subtracted. The total energy of a state with spin $j$ is then

$$
E_{j}=E_{\min }+T_{\mathrm{R}}
$$

where $E_{\min }$ is the energy of the intrinsic state.
Consider now first a rough ballpark of the energies involved. Since $j$ is integer or half integer, the rotational energy comes in discrete amounts of $\hbar^{2} / 2 \mathcal{I}_{\mathrm{R}}$. The classical value for the moment of inertia $\mathcal{I}_{\mathrm{R}}$ of a rigid sphere of mass $m$ and radius $R$ is $\frac{2}{5} m R^{2}$. For a nucleus the mass $m$ is about $A$ times the proton mass and the nuclear radius is given by (14.9). Plugging in the numbers, the ballpark for rotational energies becomes

$$
\frac{35}{A^{5 / 3}}\left[j(j+1)-j_{\min }\left(j_{\min }+1\right)\right] \mathrm{MeV}
$$

For a typical nonspherical nucleus like hafnium-177 in figure 14.24, taking the intrinsic state to be the ground state with $j_{\min }$ equal to $7 / 2$, the state $9 / 2$ with an additional unit of spin due to nuclear rotation would have a kinetic energy of about 0.06 MeV . The lowest excited state is indeed a $9 / 2$ one, but its energy above the ground state is about twice 0.06 MeV . A nucleus is not at all like a rigid body in classical mechanics. It has already been pointed out in the subsection on nuclear vibrations that in many ways a nucleus is much like a classical fluid. Still, it remains true that rotational energies are small compared to typical single-nucleon excitation energies. Therefore rotational effects must be included if the low-energy excited states are to be understood.

To better understand the discrepancy in kinetic energy, drop the dubious assumption that the nuclear material is a rigid solid. Picture the nucleus instead as a spheroid shape rotating around an axis normal to the axis of symmetry. As

Figure 14.24: Rotational bands of hafnium-177. [pdf]
far as the individual nucleons are concerned, this shape is standing still because the nucleons are going so much faster than the nuclear shape. A typical nucleon has a kinetic energy in the order of 20 MeV , not a tenth of a MeV , and it is so much lighter than the entire nucleus to boot. Still, on the larger time scale of the nuclear rotations, the nucleons do follow the overall motion of the nuclear shape, compare chapter 7.1.5. To describe this, consider the nuclear substance to be an ideal liquid, one without internal viscosity. Without viscosity, the nuclear liquid will not pick up the overall rotation of the nuclear shape, so if the nuclear shape is spherical, the nuclear liquid will not be affected at all. This reflect the fact that

## Nuclear rotations can only be observed in nuclei with a nonspherical equilibrium state, [31, p. 142].

But if the rotating nuclear shape is not spherical, the nuclear liquid cannot be at rest. Then it will still have to move radially inwards or outwards to follow the changing nuclear surface radius at a given angular position. This will involve some angular motion too, but it will remain limited. (Technically speaking, the motion will remain irrotational, which means that the curl of the velocity field will remain zero.) In the liquid picture, the moment of inertia has no physical meaning and is simply defined by the relation $T_{\mathrm{R}}=\frac{1}{2} \mathcal{I}_{\mathrm{R}} \omega^{2}$, with $T_{\mathrm{R}}$ the kinetic energy of the liquid. If typical numbers are plugged into this picture, [31, p. 145], you find that the predicted rotational energies are now too high. Therefore the conclusion must be that the nuclear substance behaves like something in between a solid and an ideal liquid, at least as far as nuclear rotations are concerned. Fairly good values for the moment of inertia can be computed by modeling the nucleon pairing effect using a superfluid model, [40, pp. 493ff]

### 14.13.4.2 Draft: Basic rotational bands

Consider the spectrum of the deformed nucleus hafnium-177 in figure 14.24. At first the spectrum seems a mess. However, take the ground state to be an "intrinsic state" with a spin $j_{\min }$ equal to $7 / 2$. Then you would expect that there would also be energy levels with the nucleus still in the same state but additionally rotating as a whole. Since quantum mechanics requires that $j$ increases in integer steps, the rotating versions of the ground state should have spin $j$ equal to any one of $9 / 2,11 / 2,13 / 2, \ldots$ And indeed, a sequence of such excited states can be identified in the spectrum, as shown in the top right of figure 14.24. Such a sequence of energy states is called a "rotational band." Note that all states in the band have the same parity. That is exactly what you would expect based on the classical picture of a rotating nucleus: the parity operator is a purely spatial one, so mere rotation of the nucleus in time should not change it.

How about quantitative agreement with the predicted kinetic energies of rotation (14.23)? Well, as seen in the previous subsubsection, the effective moment of inertia is hard to find theoretically. However, it can be computed from the measured energy of the $9 /{ }^{-}$rotating state relative to the $7 /{ }^{-}$ground state using (14.23). That produces a moment of inertia equal to $49 \%$ of the corresponding solid sphere value. Then that value can be used to compute the energies of the ${ }^{11} /^{-}, 13 / 2^{-}, \ldots$ states, using again (14.23). The energies obtained in this way are indicated by the spin-colored tick marks on the axis in the top-right graph of figure 14.24. The lower energies agree very well with the experimental values. Of course, the agreement of the $7 / 2^{-}$and $9 / 2^{-}$levels is automatic, but that of the higher levels is not.

For example, the predicted energy of the $11 / 2^{-}$state is 0.251 MeV , and the experimental value is 0.250 MeV . That is just a fraction of a percent error, which is very much nontrivial. For higher rotational energies, the experimental energies do gradually become somewhat lower than predicted, but nothing major. There are many effects that could explain the lowering, but an important one is "centrifugal stretching." As noted, a nucleus is not really a rigid body, and under the centrifugal forces of rapid rotation, it can stretch a bit. This increases the effective moment of inertia and hence lowers the kinetic energy, (14.23).

How about all these other excited energy levels of hafnium-177? Well, first consider the nature of the ground state. Since hafnium- 177 does not have a spherical shape, the normal shell model does not apply to it. In particular, the normal shell model would have the hafnium-177's odd neutron alone in the $6 f_{5 / 2}$ subshell; therefore it offers no logical way to explain the $7 / 2$ ground state spin. However, the Schrödinger equation can solved using a nonspherical, but still axially symmetric, potential to find suitable single particle states. Using such states, it turns out that the final odd neutron goes into a state with magnetic quantum number $7 / 22$ around the nuclear axis and odd parity. (For a nonspherical potential, the square angular momentum no longer commutes with the Hamiltonian and both $l$ and $j$ become uncertain.) With rotation, or better, with uncertainty in axial orientation, this state gives rise to the $7 / 2^{-}$ground state of definite nuclear spin $j$. Increasing angular momentum then gives rise to the $9 / 2^{-}, 11 / 2^{-},{ }^{13} / 2^{-}, \ldots$ rotational band build on this ground state.

It is found that the next higher single-particle state has magnetic quantum number $9 / 2$ and even parity. If the odd neutron is kicked into that state, it produces a low-energy $9 / 2^{+}$excited nuclear state. Adding rotational motion to this intrinsic state produces the $9 / 2^{+}, 11 / 2^{+}, 13 / 2^{+}, \ldots$ rotational band shown in the middle left of figure 14.24. (Note that for this band, the experimental energies are larger than predicted. Centrifugal stretching is certainly not the only effect causing deviations from the simple theory.) In this case, the estimated moment of inertia is about $64 \%$ of the solid sphere value. There is no reason to assume that the moment of inertia remains the same if the intrinsic state of the nucleus
changes. However, clearly the value must remain sensible.
The low-lying $5 / 2^{-}$state is believed to be a result of promotion, where a neutron from a $5 / 2^{-}$single-particle state is kicked up to the $7 / 2^{-}$state where it can pair up with the 105th neutron already there. Its rotating versions give rise to the rotational band in the middle right of figure 14.24. The moment of inertia is about $45 \%$ of the solid sphere value. The last two bands have moments of inertia of $54 \%$ and $46 \%$, in the expected ballpark.

The general approach as outlined above has been extraordinarily successful in explaining the excited states of deformed nuclei, [31, p. 156].

### 14.13.4.3 Draft: Bands with intrinsic spin one-half

The semi-classical explanation of rotational bands was very simplistic. While it works fine if the intrinsic spin of the rotating nuclear state is at least one, it develops problems if it becomes one-half or zero. The most tricky case is spin one-half.

Despite less than stellar results in the past, the discussion of the problem will stick with a semi-classical approach. Recall first that angular momentum is a vector. In vector terms, the total angular momentum of the nucleus consists of rotational angular momentum and intrinsic angular momentum of the nonrotating nucleus:

$$
\vec{J}=\vec{J}_{\mathrm{rot}}+\vec{J}_{\mathrm{min}}
$$

Now in the expression for rotational energy, (14.23) it was implicitly assumed that the square angular momentum of the nucleus is the sum of the square angular momentum of rotation plus the square angular momentum of the intrinsic state. But classically the Pythagorean theorem shows that this is only true if the two angular momentum vectors are orthogonal.

Indeed, a more careful quantum treatment, [40, pp. 356-389], gives rise to a semi-classical picture in which the axis of the rotation is normal to the axis of symmetry of the nucleus. In terms of the inviscid liquid model of subsubsection 14.13.4.1, rotation about an axis of symmetry "does not do anything." That leaves only the intrinsic angular momentum for the component of angular momentum along the axis of symmetry. The magnetic quantum number of this component is $j_{\min }$, equal to the spin of the intrinsic state. Correct that: the direction of the axis of symmetry should not make a difference. Therefore, the complete wave function should be an equal combination of a state $\left|j_{\text {min }}\right\rangle$ with magnetic quantum number $j_{\min }$ along the axis and a state $\left|-j_{\min }\right\rangle$ with magnetic quantum $-j_{\text {min }}$.

Next, the kinetic energy of rotation is, since $\vec{J}_{\text {rot }}=\vec{J}-\vec{J}_{\text {min }}$,

$$
\frac{1}{2 \mathcal{I}_{\mathrm{R}}} \vec{J}_{\text {rot }}^{2}=\frac{1}{2 \mathcal{I}_{\mathrm{R}}} \vec{J}^{2}-\frac{1}{\mathcal{I}_{\mathrm{R}}} \vec{J} \cdot \vec{J}_{\min }+\frac{1}{2 \mathcal{I}_{\mathrm{R}}} \vec{J}_{\min }^{2}
$$

As long as the middle term in the right hand side averages away, the normal formula (14.23) for the energy of the rotational states is fine. This happens if there is no correlation between the angular momentum vectors $\vec{J}$ and $\vec{J}_{\text {min }}$, because then opposite and parallel alignments will cancel each other.

But not too quick. There is an obvious correlation since the axial components are equal. The term can be written out in components to give

$$
\frac{1}{\mathcal{I}_{\mathrm{R}}} \vec{J} \cdot \vec{J}_{\text {min }}=\frac{1}{\mathcal{I}_{\mathrm{R}}}\left[J_{x} J_{x, \text { min }}+J_{y} J_{y, \text { min }}+J_{z} J_{z, \text { min }}\right]
$$

where the $z$-axis is taken as the axis of symmetry of the nucleus. Now think of these components as quantum operators. The $z$ components are no problem: since the magnetic quantum number is constant along the axis, this term will just shift the all energy levels in the band by the same amount, leaving the spacings between energy levels the same.

However, the $x$ and $y$ components have the effect of turning a state $\left| \pm j_{\text {min }}\right\rangle$ into some combination of states $\left| \pm j_{\min } \pm 1\right\rangle$, chapter 12.11 . Since there is no rotational momentum in the axial direction, $\vec{J}$ and $\vec{J}_{\text {min }}$ have quite similar effects on the wave function, but it is not the same, for one because $\vec{J}$ "sees" the complete nuclear momentum. If $j_{\min }$ is 1 or more, the effects remain inconsequential: then the produced states are part of a different vibrational band, with different energies. A bit of interaction between states of different energy is usually not a big deal, chapter 5.3. But if $j_{\text {min }}=\frac{1}{2}$ then $\left|j_{\text {min }}-1\right\rangle$ and $\left|-j_{\text {min }}+1\right\rangle$ are part of the state itself. In that case, the $x$ and $y$ components of the $\vec{J} \cdot \vec{J}_{\text {min }}$ term produces a contribution to the energy that does not average out, and the larger $\vec{J}$ is, the larger the contribution.

The expression for the kinetic energy of nuclear rotation then becomes

$$
T_{\mathrm{R}}=\frac{\hbar^{2}}{2 \mathcal{I}_{\mathrm{R}}}\left\{\left[j(j+1)+a(-1)^{j+\frac{1}{2}}(j+1 / 2)\right]-\left[j_{\min }\left(j_{\min }+1\right)-a\right]\right\} \quad j_{\min }=1 / 2
$$

(14.24)
where $a$ is a constant. Note that the additional term is alternatingly positive and negative. Averaged over the entire rotational band, the additional term does still pretty much vanish.

As an example, consider the $1 / 2^{-}$ground state rotational band of tungsten183, figure 14.25. To compute the rotational kinetic energies in the band using (14.24) requires the values of both $\mathcal{I}_{\mathrm{R}}$ and $a$. The measured energies of the $3 / 2^{-}$ and $5 / 2^{-}$states above the ground state can be used to do so. That produces a moment of inertia equal to $45 \%$ of the solid sphere value and a nondimensional constant $a$ equal to 0.19 . Next then the formula can be used to predict the energies of the remaining states in the band. As the axial tick marks in the right graph of figure 14.25 show, the prediction is quite good. Note in particular that the energy interval between the $9 / 2^{-}$and $7 / 2^{-}$states is less than that between

$$
\text { spin: } \quad-0 \quad-\frac{1}{2}-1-\frac{3}{2}-2 \quad-\frac{5}{2}-3-\frac{7}{2}-4-\frac{9}{2}-5 \quad-\frac{11}{2}-6 \quad-\frac{13}{2}-7 \quad-\geqslant \frac{15}{2}->\frac{29}{2}-?
$$

Figure 14.25: Ground state rotational band of tungsten-183. [pdf]
the $7 / 2^{-}$and $5 / 2^{-}$states. Without the alternating term, there would be no way to explain that.

Much larger values of $a$ are observed for lighter nuclei. As an example, consider aluminum- 25 in figure 14.26. This nucleus has been studied in detail, and a number of bands with an intrinsic spin $1 / 2$ have been identified. Particularly interesting is the $1 / 2^{-}$band in the bottom left of figure 14.26 . For this band $a$ $=-3.2$, and that is big enough to change the order of the states in the band! For this nucleus, the moments of inertia are $70 \%, 96 \%, 107 \%, 141 \%$ and $207 \%$ respectively of the solid sphere value.

### 14.13.4.4 Draft: Bands with intrinsic spin zero

The case that the intrinsic state has spin zero is particularly important, because all even-even nuclei have a $0^{+}$ground state. For bands build on a zero-spin intrinsic state, the thing to remember is that the only values in the band are even spin and even parity: $0^{+}, 2^{+}, 4^{+}, \ldots$

This can be thought of as a consequence of the fact that the $\left|j_{\min }\right\rangle$ and $\left|-j_{\min }\right\rangle$ states of the previous subsubsection become equal. Their odd or even combinations must be constrained to prevent them from canceling each other.

As an example, consider erbium-164. The ground state band in the top right of figure 14.27 consists of the states $0^{+}, 2^{+}, 4^{+}, \ldots$ as expected. The energies initially agree well with the theoretical prediction (14.23) shown as tick marks. For example, the prediction for the $4^{+}$level has less than $2 \%$ error. Deviations from theory show up at higher angular momenta, which may have to do with centrifugal stretching.

Other bands have been identified that are build upon vibrational intrinsic states. (A $\beta$ or beta vibration maintains the assumed intrinsic axial symmetry of the nucleus, a $\gamma$ or gamma one does not.) Their energy spacings follow (14.23)

spin: $\quad-0 \quad-\frac{1}{2}-1-\frac{3}{2}-2 \quad-\frac{5}{2}-3 \quad-\frac{7}{2}-4-\frac{9}{2} \quad-5 \quad-\frac{11}{2}-6 \quad-\frac{13}{2}-7 \quad-\geqslant \frac{15}{2}->\frac{29}{2}-?$

Figure 14.28: Ground state rotational band of magnesium-24. [pdf]

Light even-even nuclei can also be deformed and show rotational bands. As an example, figure 14.28 shows the ground state band of magnesium- 24 . The moment of inertia is $75 \%$ of the solid sphere value.

It may also be mentioned that nuclei with intrinsic spin zero combined with an octupole vibration can give rise to bands that are purely odd spin/odd parity ones, $1^{-}, 3^{-}, 5^{-}, \ldots,[40$, p. 368]. The lowest odd parity states for erbium-164 are $1^{-}$and $3^{-}$ones, with no $2^{-}$state in between, for a really high estimated moment of inertia of $148 \%$, and a potential $5^{-}$state at roughly, but not accurately, the predicted position. Anomalous bands that have the parity inverted may also be possible; hafnium-176 is believed to have a couple of excited states like that, $0^{-}$at 1.819 MeV and $2^{-}$at 1.857 MeV , with a moment of inertia of 98\%.

Centrifugal effects can be severe enough to change the internal structure of the nucleus nontrivially. Typically, zero-spin pairings between nucleons may be broken up, allowing the nucleons to start rotating along with the nucleus. That creates a new band build on the changed intrinsic state. Physicists then define the state of lowest energy at a given angular momentum as the "yrast state." The term is not an acronym, but Swedish for "that what rotates more." For a discussion, a book for specialists will need to be consulted.

### 14.13.4.5 Draft: Even-even nuclei

All nuclei with even numbers of both protons and neutrons have a $0^{+}$ground state. For nonspherical ones, the rotational model predicts a ground state band of low-lying $2^{+}, 4^{+}, 6^{+}, \ldots$ states. The ratio of the energy levels of the $4^{+}$and
$2^{+}$states is given by (14.23)

$$
\frac{\hbar^{2}}{2 \mathcal{I}_{\mathrm{R}}} 4(4+1) / \frac{\hbar^{2}}{2 \mathcal{I}_{\mathrm{R}}} 2(2+1)=\frac{10}{3}
$$

For spherical nuclei, the vibrational model also predicts a $2^{+}$lowest excited state, but the $4^{+}$excited state is now part of a triplet, and the triplet has only twice the energy of the $2^{+}$state. Therefore, if the ratio of the energy of the second excited state to the lowest $2^{+}$state is plotted, as done in figure 14.22, then vibrating nuclei should be indicated by a value 2 (green) and rotating nuclei by a value 3.33 (red). If the figure is examined, it may be open to some doubt whether green squares are necessarily vibrational, but the red squares quite nicely locate the rotational ones.

In the figure, nuclei marked with "V" have $0^{+}, 2^{+}$, and a $0^{+}, 2^{+}, 4^{+}$triplet as the lowest 5 energy states, the triplet allowed to be in any order. Nuclei marked with an " R " have the sequence $0^{+}, 2^{+}, 4^{+}$, and $6^{+}$as the lowest four energy states. Note that this criterion misses the light rotational nuclei like magnesium-24; for light nuclei the rotational energies are not small enough to be well separated from shell effects. Near the stable line, rotating nuclei are found in the approximate mass number ranges $20<A<30,150<A<190$, and $220<A$. However, away from the stable line rotating nuclei are also found at other mass numbers.

### 14.13.4.6 Draft: Nonaxial nuclei

While most nuclei are well modeled as axially symmetric, some nuclei are not. For such nuclei, an ellipsoidal model can be used with the three major axes all off different length. There are now two nondimensional axis ratios that characterize the nucleus, rather than just one.

This additional nondimensional parameter makes the spectrum much more complex. In particular, in addition to the normal rotational bands, associated "anomalous" secondary bands appear. The first is a $2^{+}, 3^{+}, 4^{+}, \ldots$ one, the second a $4^{+}, 5^{+}, \ldots$ one, etcetera. The energies in these bands are not independent, but related to those in the primary band.

Figure 14.29 shows an example. The primary ground state band in the top right quickly develops big deviations from the axially symmetric theory (14.23) values (thin tick marks.) Computation using the ellipsoidal model for a suitable value of the deviation from axial symmetry is much better (thick tick marks.) The predicted energy levels of the first anomalous band also agree well with the predicted values. The identification of the bands was taken from [40, p. 416], but since they do not list the energies of the second anomalous band, that value was taken from [36, p. 388].

In the limit that the nuclear shape becomes axially symmetric, the anomalous bands disappear towards infinite energy. In the limit that the nuclear shape

${ }_{76}^{90} \mathrm{Os}$

Figure 14.29: Rotational bands of osmium-190. [pdf]
becomes spherical, all states in the primary bands except the lowest one also disappear to infinity, assuming that the "moment of inertia" becomes zero as the ideal liquid model says.

### 14.14 Draft: Fission

In spontaneous fission, a very heavy nucleus falls apart into big fragments. If there are two fragments, it is called binary fission. In some cases, there are three fragments. That is called ternary fission; the third fragment is usually an alpha particle. This section summarizes some of the basic ideas.

### 14.14.1 Draft: Basic concepts

What makes fission energetically possible is that very heavy nuclei have less binding energy per nucleon than those in the nickel/iron range, as shown earlier in figure 14.4. The main culprit is the Coulomb repulsion between the protons. It has a much longer range than the nuclear attractions between nucleons. Therefore, Coulomb repulsion disproportionally increases the energy for heavy nuclei. If a nucleus like uranium- 238 divides cleanly into two palladium-119 nuclei, the energy liberated is on the order of $200 \mathrm{MeV}(200000000 \mathrm{eV})$. That is obviously a very large amount of energy. Chemical reactions produce maybe a few eV per atom.

The liquid drop model predicts that the nuclear shape will become unstable at $Z^{2} / A$ about equal to 48 . However, only the weirdest nuclei like ${ }_{118}^{293} \mathrm{Ei}$ come close to that value. Below $Z=100$ the nuclei that decay primarily through spontaneous fission are curium-250, with $Z^{2} / A$ equal to 37 and a half life of 8300 years, californium-254, 38 and two months, and fermium-256, 39 and less than 3 hours.

Indeed, while the fission products may have lower energy than the original nucleus, in taking the nucleus apart, the nuclear binding energy must be provided right up front. On the other hand the Coulomb energy gets recovered only after the fragments have been brought far apart. As a result, there is normally a energy barrier that must be crossed for the nucleus to come apart. That means that an "activation energy" must be provided in nuclear reactions, much like in most chemical reactions.

For example, uranium has an activation energy of about 6.5 MeV . By itself, uranium- 235 will last a billion years or so. However, it can be made to fission by hitting it with a neutron that has only a thermal amount of energy. (Zero is enough, actually.) When hit, the nucleus will fall apart into a couple of big pieces and immediately release an average of 2.4 "prompt neutrons." These new neutrons allow the process to repeat for other uranium- 235 nuclei, making a "chain reaction" possible.

In addition to prompt neutrons, fusion processes may also emit a small fraction of "delayed neutrons" neutrons somewhat later. Despite their small number, they are critically important for controlling nuclear reactors because of their slower response. If you tune the reactor so that the presence of delayed neutrons is essential to maintain the reaction, you can control it mechanically on their slower time scale.

Returning to spontaneous fission, that is possible without the need for an activation energy through quantum mechanical tunneling. Note that this makes spontaneous fission much like alpha decay. However, as section 14.11.2 showed, there are definite differences. In particular, the basic theory of alpha decay does not explain why the nucleus would want to fall apart into two big pieces, instead of one big piece and a small alpha particle. This can only be understood qualitatively in terms of the liquid drop model: a charged classical liquid drop is most unstable to large-scale deformations, not small scale ones, subsection 14.13.1.

### 14.14.2 Draft: Some basic features

While fission is qualitatively close to alpha decay, its actual mechanics is much more complicated. It is still an area of much research, and beyond the scope of this book. A very readable description is given by [36]. This subsection describes some of the ideas.

From a variety of experimental data and their interpretation, the following qualitative picture emerges. Visualize the nucleus before fission as a classical liquid drop. It may already be deformed, but the deformed shape is classically stable. To fission, the nucleus must deform more, which means it must tunnel through more deformed states. When the nucleus has deformed into a sufficiently elongated shape, it becomes energetically more favorable to reduce the surface area by breaking the connection between the ends of the nucleus. The connection thins and eventually breaks, leaving two separate fragments. During the messy process in which the thin connection breaks an alpha particle could well be ejected. Now typical heavy nuclei contain relatively more neutrons than lighter ones. So when the separated fragments take inventory, they find themselves overly neutron-rich. They may well find it worthwhile to eject one or two right away. This does not change the strong mutual Coulomb repulsion between the fragments, and they are propelled to increasing speed away from each other.

Consider now a very simple model in which a nucleus like fermium- 256 falls cleanly apart into two smaller nuclear fragments. As a first approximation, ignore neutron and other energy emission in the process and ignore excitation of the fragments. In that case, the final kinetic energy of the fragments can be computed from the difference between their masses and the mass of the original nucleus.

In the fission process, the fragments supposedly pick up this kinetic energy from the Coulomb repulsion between the separated fragments. If it is assumed that the fragments are spherical throughout this final phase of the fission process, then its properties can be computed. In particular, it can be computed at which separation between the fragments the kinetic energy was zero. That is important because it indicates the end of the tunneling phase. Putting in the numbers, it is seen that the separation between the fragments at the end of tunneling is at least $15 \%$ more than that at which they are touching. So the model is at least reasonably self-consistent.

Figure 14.30 shows the energetics of this model. Increasing redness indicates increasing energy release in the fission. Also, the spacing between the squares indicates the spacing between the nuclei at the point where tunneling ends. Note in particular the doubly magic point of 50 protons and 82 neutrons. This point is very neutron rich, just what is needed for fission fragments. And because it is doubly magic, nuclei in this vicinity have unusually high binding energy, as seen from figure 14.9. Indeed, nuclei with 50 protons are seen to have the highest fission energy release in figure 14.30. Also, they have the smallest relative spacing between the nuclei at the end of tunneling, so likely the shortest relative distance that must be tunneled through. The conclusion is clear. The logical thing for fermium-256 to do is to come apart into two almost equal fragments with a magic number of 50 protons and about 78 neutrons, giving the fragments a mass number of 128 . Less plausibly, one fragment could have the magic number of 82 neutrons, giving fragment mass numbers of 132 and 124 . But the most unstable deformation for the liquid drop model is symmetric. And so is a spheroidal or ellipsoidal model for the deformed nucleus. It all seems to add up very nicely. The fragments must be about the same size, with a mass number of 128 .

Except that that is all wrong.
Fermium 258 acts like that, and fermium- 257 also mostly, but not fermium 256. It is rare for fermium- 256 to come apart into two fragments of about equal size. Instead, the most likely mass number of the large fragment is about 140, with only a small probability of a mass number 132 or lower. A mass number of 140 clearly does not seem to make much sense based on figure 14.30.

The precise solution to this riddle is still a matter of current research, but physicists have identified quantum effects as the primary cause. The potential energy barrier that the fissioning nucleus must pass through is relatively low, on the order of say 5 MeV . That is certainly small enough to be significantly affected by quantum shell effects. Based on that idea, you would expect that mass asymmetry would decrease if the excitation energy of the nucleus is increased, and such an effect is indeed observed. Also, the separation of the fragments occurs at very low energy, and is believed to be slow enough that the fragments can develop some shell structure. Physicists have found that for many fissioning nuclei, quantum shell effects can create a relatively stable intermediate state in

Figure 14.30: Simplified energetics for fission of fermium-256. [pdf][con]
the fission process. Such a state produces resonances in response to specific excitation energies of the nucleus. Shell corrections can also lower the energy of asymmetric nuclear fissioning shapes below those of symmetric ones, providing an explanation for the mass asymmetry.

Imagine then a very distorted stage in which a neutron-rich, doubly magic 50/82 core develops along with a smaller nuclear core, the two being connected by a cloud of neutrons and protons. Each could pick up part of the cloud in the final separation process. That picture would explain why the mass number of the large fragment exceeds 132 by a fairly constant amount while the mass number of the smaller segment varies with the initial nuclear mass. Whether or not there is much truth to this picture, at least it is a good mnemonic to remember the fragment masses for the nuclei that fission asymmetrically.

### 14.15 Draft: Spin Data

The net internal angular momentum of a nucleus is called the "nuclear spin." It is an important quantity for applications such as NMR and MRI, and it is also important for what nuclear decays and reactions occur and at what rate. One previous example was the categorical refusal of bismuth-209 to decay at the rate it was supposed to in section 14.11.3.

This section provides an overview of the ground-state spins of nuclei. According to the rules of quantum mechanics, the spin must be integer if the total number of nucleons is even, and half-integer if it is odd. The shell model can do a pretty good job of predicting actual values. Historically, this was one of the major reasons for physicists to accept the validity of the shell model.

### 14.15.1 Draft: Even-even nuclei

For nuclei with both an even number of protons and an even number of neutrons, the odd-particle shell model predicts that the spin is zero. This prediction is fully vindicated by the experimental data, figure 14.31. There are no known exceptions to this rule.

### 14.15.2 Draft: Odd mass number nuclei

Nuclei with an odd mass number $A$ have either an odd number of protons or an odd number of neutrons. For such nuclei, the odd-particle shell model predicts that the nuclear spin is the net angular momentum (orbital plus spin) of the last odd nucleon. To find it, the subshell that the last particle is in must be identified. That can be done by assuming that the subshells fill in the order given in section 14.12.2. This ordering is indicated by the colored lines in figures 14.32 and 14.33. Nuclei for which the resulting nuclear spin prediction is correct

Figure 14.31: Spin of even-even nuclei. [pdf][con]
are indicated with a black check mark. (If the check mark is white rather than black, some reservation was expressed about the measured spin in NUBASE 2003.)

The prediction is correct right off the bat for a considerable number of nuclei. That is very much nontrivial. Still, there is an even larger number for which the prediction is not correct.

One major reason is that many heavy nuclei are not spherical in shape. The shell model was derived assuming a spherical nuclear shape and simply does not apply for such nuclei. These are the nonspherical, rotational nuclei, the ones that are easily excited; the nonsmall squares in 14.45 , the red (or yellow) big " R " squares in figure 14.22 , the small squares in figure 14.19. Their main regions are for neutron number $N$ above 132 and in the deep interior of the $Z$ $<82, N>82$ wedge. For these nuclei, the shell model simply does not work.

For almost all remaining nuclei near the stable line, the spin can be explained in terms of the shell model using various reasonable excuses, [36, p. 224ff]. Some excuses are marked.

In particular, if the subshell with the odd neutron is above a subshell of lower spin, a particle from the lower subshell may be promoted to the higher one. This particle can then pair up at a higher spin, which is believed to be energetically favorable. Since an odd nucleon occurs now in the lower shell, the spin of the nucleus is predicted to be the one of that shell. So the nuclear spin is lowered compared to the bare shell model.

Nuclei for which such spin lowering due to promotion can explain the observed spin are indicated with an "L" or " 1 " in figures 14.32 and 14.33. For the nuclei marked with "L," the odd nucleon cannot be in the normal subshell because the nucleus has the wrong parity for that. Therefore, for these nuclei there is a solid additional reason besides the spin to assume that promotion has occurred.

Promotion was only allowed for subshells immediately above one with lower spin in the same major shell, so the nucleon could only be promoted a single subshell. The idea is that the gained pairing energy should not be big enough to make major modifications to the shell model.

For some nuclei, the basic shell model is valid but the odd-particle assumption fails. The odd particle assumption implies that all nucleons except the odd one pair up in states of zero spin. But sometimes at least three nucleons combine in a state with one unit less spin than the single odd particle would have. This is only possible for subshells with at least three particles and three holes (empty spots for additional nucleons). Nuclei for which this unit spin reduction might to be the case are marked with a minus sign. It is evident, for example, for odd nucleon numbers 23 and 25.

Fluorine-19 and its mirror twin neon-19 are rare outright failures of the shell model, as already discussed in section 14.12.6.

Figure 14.32: Spin of even-odd nuclei. [pdf][con]

Figure 14.33: Spin of odd-even nuclei. [pdf][con]

Among the remaining failures, notable are nuclei with odd proton numbers just above 50 . The $5 \mathrm{~g}_{7 / 2}$ and $5 \mathrm{~d}_{5 / 2}$ subshells are very close together and it depends on the details which one gets filled first.

In a few exceptional cases, like the highly unstable nitrogen-11 and beryl-lium-11 "halo" nuclei, the theoretical model predicted the right spin, but it was not counted as a hit because the nuclear parity was inconsistent with the predicted subshell. In all cases, it was demanded that the nuclear parity, if known, did not conflict with the proposed shell model verification (or explanation) of the spin.

For nuclei marked with a cross, no explanation for the spin using the above rules could be found. In general, you might not want to take nuclei well away from the stable line that serious. For yellow squares, NUBASE 2003 gave either no value for the spin or more than one possible value.

### 14.15.3 Draft: Odd-odd nuclei

If both the number of protons and the number of neutrons is odd, the nuclear spin becomes much more difficult to predict. According to the odd-particle shell model, the net nuclear spin $j_{\mathrm{N}}$ comes from combining the net angular momenta $j^{\mathrm{p}}$ of the odd proton and $j^{\mathrm{n}}$ of the odd neutron. Then according to quantum mechanics, the net nuclear spin $j_{\mathrm{N}}$ can be any integer in the range

$$
\begin{equation*}
\left|j^{\mathrm{p}}-j^{\mathrm{n}}\right| \leqslant j_{\mathrm{N}} \leqslant j^{\mathrm{p}}+j^{\mathrm{n}} \tag{14.25}
\end{equation*}
$$

That gives a total of $2 \min \left(j^{\mathrm{p}}, j^{\mathrm{n}}\right)+1$ different possibilities, or at least two.
That is not very satisfactory of course. You would like to get a specific prediction for the spin, not a range. The so-called "Nordheim rules" attempt to do so. The underlying idea is that nuclei like to align the spins of the odd proton and odd neutron, just like the deuterium nucleus does.

To describe the rules, forget about quantum mechanics for now. Just think of the spin and orbital angular momenta involved as simple vectors that can either point up or down. And take "up" to be the direction that the aligned proton and neutron spin vectors $s^{\mathrm{p}}$ and $s^{\mathrm{n}}$ point. Now suppose first that for both neutron and proton the orbital angular momenta $l^{\mathrm{P}}$ and $l^{\mathrm{n}}$ also point upwards (or are zero). Then for both proton and neutron, the orbital and spin angular momenta add up to a total momentum $j^{\mathrm{p}}=l^{\mathrm{P}}+s^{\mathrm{p}}$ respectively $j^{\mathrm{n}}=l^{\mathrm{n}}+s^{\mathrm{n}}$ that also point upwards. So the sum of the two, the total nuclear spin $j_{\mathrm{N}}$ points upwards and has magnitude $j_{\mathrm{N}}=j^{\mathrm{p}}+j^{\mathrm{n}}$.

Conversely, if both orbital momenta point downwards (and are nonzero), then spin and orbital angular momenta are in opposite directions and subtract. Then proton and neutron have net angular momenta of magnitude $j^{\mathrm{P}}=l^{\mathrm{P}}-s^{\mathrm{P}}$ respectively $j^{\mathrm{n}}=l^{\mathrm{n}}-s^{\mathrm{n}}$ that point downwards. (Recall from quantum mechanics that $l$ is at least 1 if nonzero, so is bigger than the $s=1 / 2$ pointing upwards.)

The combined nuclear angular momentum is then again $j_{\mathrm{N}}=j^{\mathrm{p}}+j^{\mathrm{n}}$ (pointing downwards).

However, if for one nucleon the orbital angular momentum is zero or points in the direction of the spin and the other is nonzero and points in the direction opposite to the spin, then one of $j^{\mathrm{p}}$ and $j^{\mathrm{n}}$ points upwards and the other downwards. That then means that now they are in opposite directions and subtract; $j_{\mathrm{N}}=\left|j^{\mathrm{p}}-j^{\mathrm{n}}\right|$.

That then gives the Nordheim rules as, [36, p. 239]:

1. If for both proton and neutron, $j=l+s$, or for both $j=l-s$, then
the angular momenta of the two add up and $j_{\mathrm{N}}=j^{\mathrm{p}}+j^{\mathrm{n}}$.
2. Otherwise they subtract and $j_{\mathrm{N}}=\left|j^{\mathrm{p}}-j^{\mathrm{n}}\right|$.
3. New and improved version: if number 1 above fails, assume that the two angular momenta are opposite anyway and the spin is $j=$ $\left|j^{\mathrm{p}}-j^{\mathrm{n}}\right|$ like in number 2 .
Of course, the real quantum rules for angular momentum are a lot more complicated than the simplified picture above. Note in particular from the Clebsch-Gordan coefficients in figure 12.5 that if $j=l-s$, then that nucleon cannot be just in the spin-up state. The two nucleons cannot fully align then.

To check those rules is not trivial, because it requires the values of $l$ for the odd proton and neutron. Who will say in what shells the odd proton and odd neutron really are? The simplest solution is to simply take the shells to be the ones that the shell model predicts, assuming the subshell ordering from section 14.12.2. The nuclei that satisfy the Nordheim rules under that assumption are indicated with a check mark in figure 14.34. A blue check mark means that the new and improved version has been used. (Yellow is used if there is uncertainty about the measurement.) It is seen that the rules get a number of nuclei right.

An "L" or " l " indicates that it has been assumed that the spin of at least one odd nucleon has been lowered due to promotion. The rules are the same as in the previous subsection. In case of "L," the Nordheim rules were really verified. More specifically, for these nuclei there was no possibility consistent with nuclear spin and parity to violate the rules. For nuclei with an "1" there was, and the case that satisfied the Nordheim rules was cherry-picked among other otherwise valid possibilities that did not.

A further weakening of standards applies to nuclei marked with "N" or "n." For those, one or two subshells of the odd nucleons were taken based on the spins of the immediately neighboring nuclei of odd mass number. For nuclei marked with "N" the Nordheim rules were again really verified, with no possibility of violation within the now larger context. For nuclei marked " $n$," other possibilities violated the rules; obviously, for these nuclei the standards have become miserably low. Note how many "correct" predictions there are in the regions of nonspherical nuclei in which the shell model is quite meaningless.

Preston and Bhaduri [36, p. 239] suggest that the proton and neutron angular momenta be taken from the neighboring pairs of nuclei of odd mass number.

Figure 14.34: Spin of odd-odd nuclei. [pdf][con]

Figure 14.35: Odd-odd spins predicted using the neighbors. [pdf][con]

Figure 14.35 shows results according to that approach. To minimize failures due to other causes than the Nordheim rules, it was demanded that both spin and parity of the odd-odd nucleus were solidly established. For the two pairs of odd mass nuclei, it was demanded that both spin and parity were known, and that the two members of each pair agreed on the values. It was also demanded that the orbital momenta of the pairs could be confidently predicted from the spins and parities. Correct predictions for these superclean cases are indicated by check marks in figure 14.35 , incorrect ones by an " $E$ " or cross. Light check marks indicate cases in which the spin of a pair of odd mass nuclei is not the spin of the odd nucleon.

Preston and Bhaduri [36, p. 239] write: "When confronted with experimental data, Nordheim's rules are found to work quite well, most of the exceptions being for light nuclei." So be it. The results are definitely better than chance. Below $Z=50$, the rules get 43 right out of 71. It may be noted that if you simply take the shells directly from theory with no promotion, like in figure 14.36, you get only 41 right, so using the spins of the neighbors seems to help. The "Nuclear Data Sheets" policies assume that the (unimproved) Nordheim rules may be helpful if there is supporting evidence.

The nuclei marked with "E" in figure 14.35 are particularly interesting. For these nuclei spin or parity show that it is impossible for the odd proton and neutron to be in the same shells as their neighbors. In four cases, the discrepancy is in parity, which is particularly clear. It shows that for an odd proton, having an odd neutron is not necessarily intermediate between having no odd neutron and having one additional neutron besides the odd one. Or vice-versa for an odd neutron. Proton and neutron shells interact nontrivially.

It may be noted that the unmodified Nordheim rules imply that there cannot be any odd-odd nuclei with $0^{+}$or $1^{-}$ground states. However, some do exist, as is seen in figure 14.34 from the nuclei with spin zero (grey) and blue check marks.

### 14.16 Draft: Parity Data

The parity of a nucleus is even, or one, if its wave function stays the same if the positive direction of all three Cartesian axes is inverted. That replaces every $\vec{r}$ in the wave function by $-\vec{r}$. The parity is odd, or minus one, if the wave function gets multiplied by -1 under axes inversion. Nuclei have definite parity, (as long as the weak force is not an active factor), so one of the two must be the case. It is an important quantity for what nuclear decays and reactions occur and at what rate.

This section provides an overview of the ground-state spins of nuclei. It will be seen that the shell model does a pretty good job of predicting them.

Figure 14.36: Odd-odd spins predicted from theory. [pdf][con]

### 14.16.1 Draft: Even-even nuclei

For nuclei with both an even number of protons and an even number of neutrons, the odd-particle shell model predicts that the parity is even. This prediction is fully vindicated by the experimental data, figure 14.37. There are no known exceptions to this rule.

### 14.16.2 Draft: Odd mass number nuclei

For nuclei with an odd mass number $A$, there is an odd proton or neutron. The odd-particle shell model says that the parity is that of the odd nucleon. To find it, the subshell that the last particle is in must be identified, section 14.12.2 This can be done with a fair amount of confidence based on the spin of the nuclei. Nuclei for which the parity is correctly predicted in this way are shown in green in figures 14.38 and 14.39. Failures are in red. Small grey signs are shell model values if the nucleons fill the shells in the normal order.

The failures above $Z=50$ and inside the $Z<82, N>82$ wedge are expected. The shell model does not apply in these regions, because the nuclei are known to be nonspherical there. Besides that, there are very few failures. Those near the $N=40$ and $N=60$ lines away from the stable line are presumably also due to nonspherical nuclei. The highly unstable nitrogen-11 and beryllium-11 mirror nuclei were discussed in section 14.12.6.

### 14.16.3 Draft: Odd-odd nuclei

For odd-odd nuclei, the odd-particle shell model predicts that the parity is the product of those of the surrounding even-odd and odd-even nuclei. The results are shown in figure 14.40. Hits are green, failures red, and unable-to-tell black. Small grey signs are shell model values for the surrounding even-odd and oddeven nuclei. However actual even-odd and odd-even values were used in the prediction.

Failures for spherical nuclei indicate that sometimes the odd proton or neutron is in a different shell than in the corresponding odd-mass neighbors. A similar conclusion can be reached based on the spin data.

Note that the predictions also do a fairly good job in the regions in which the nuclei are not spherical. The reason is that the predictions make no assumptions about what sort of state, spherical or nonspherical, the odd nucleons are in. It merely assumes that they are in the same state as their neighbors.

### 14.16.4 Draft: Parity Summary

Figure 14.41 shows a summary of the parity of all nuclei together. To identify the type of nucleus more easily, the even-even nuclei have been shown as green

Figure 14.37: Parity of even-even nuclei. [pdf][con]

Figure 14.38: Parity of even-odd nuclei. [pdf][con]

Figure 14.39: Parity of odd-even nuclei. [pdf][con]

Figure 14.40: Parity of odd-odd nuclei. [pdf][con]
check marks. The odd-odd nuclei are found on the same vertical lines as the check marks. The even-odd nuclei are on the same horizontal lines as the check marks, and the odd-even ones on the same diagonal lines.

Parities that the shell model predicts correctly are in green, and those that it predicts incorrectly are in red. The parities were taken straight from section 14.12.2 with no tricks. Note that the shell model does get a large number of parities right straight off the bat. And much of the errors can be explained by promotion or nonspherical nuclei.

For parities in light green and light red, NUBASE 2003 expressed some reservation about the correct value. For parities shown as yellow crosses, no (unique) value was given.

### 14.17 Draft: Electromagnetic Moments

The most important electromagnetic property of nuclei is their net charge. It is what keeps the electrons in atoms and molecules together. However, nuclei are not really electric point charges. They have a small size. In a spatially varying electric field most respond somewhat different than a point charge. It is said that they have an electric quadrupole moment. Also, most nuclei act like little electromagnets. It is said that they have a "magnetic dipole moment." These properties are important for applications like NMR and MRI, and for experimentally examining nuclei.

### 14.17.1 Draft: Classical description

This subsection explains the magnetic dipole and electric quadrupole moments from a classical point of view

### 14.17.1.1 Draft: Magnetic dipole moment

The most basic description of an electromagnet is charges going around in circles. It can be seen from either classical or quantum electromagnetics that the strength of an electromagnet is proportional to the angular momentum $\vec{L}$ of the charges times the ratio of their charge $q$ to their mass $m$, chapter 13.2 or 13.4.

This leads to the definition of the magnetic dipole moment as

$$
\vec{\mu} \equiv \frac{q}{2 m} \vec{L}
$$

In particular, a magnet wants to align itself with an external magnetic field $\overrightarrow{\mathcal{B}}_{\text {ext }}$. The energy involved in this alignment is

$$
-\vec{\mu} \cdot \overrightarrow{\mathcal{B}}_{\mathrm{ext}}
$$

### 14.17.1.2 Draft: Electric quadrupole moment

Consider a nuclear charge distribution with charge density $\rho_{c}$ placed in an external electrical potential, or "voltage" $\varphi$. The potential energy due to the external field is

$$
V=\int \varphi \rho_{c} \mathrm{~d}^{3} \vec{r}
$$

It may be noted that since nuclear energies are of the order of MeV , an external field is not going to change the nuclear charge distribution $\rho$. It would need to have a million volt drop over a couple of femtometers to make a dent in it. Unless you shoot very high energy charged particles at the nucleus, that is not going to happen. Also, the current discussion assumes that the external field is steady or at least quasi-steady. That should be reasonable in many cases, as nuclear internal time scales are very fast.

Since nuclei are so small compared to normal external fields, the electric potential $\varphi$ can be well represented by a Taylor series. That gives the potential energy as

$$
V=\varphi_{0} \int \rho_{c} \mathrm{~d}^{3} \vec{r}+\sum_{i=1}^{3}\left(\frac{\partial \varphi}{\partial r_{i}}\right)_{0} \int r_{i} \rho \mathrm{~d}^{3} \vec{r}+\sum_{i=1}^{3} \sum_{j=1}^{3} \frac{1}{2}\left(\frac{\partial^{2} \varphi}{\partial r_{i} \partial r_{j}}\right)_{0} \int r_{i} r_{j} \rho \mathrm{~d}^{3} \vec{r}
$$

where $\left(r_{1}, r_{2}, r_{3}\right)=(x, y, z)$ are the three components of position and 0 indicates that the derivative is evaluated at the origin, the center of the nucleus.

The first integral in the expression above is just the net nuclear charge $q$. This makes the first term exactly the same as the potential energy of a point charge. The second integral defines the "electric dipole moment" in the $i$-direction. It is nonzero if on average the charge is shifted somewhat towards one side of the nucleus. But nuclei do not have nonzero electric dipole moments. The reason is that nuclei have definite parity; the wave function is either the same or the same save for a minus sign when you look at the opposite side of the nucleus. Since the probability of a proton to be found at a given position is proportional to the square magnitude of the wave function, it is just as likely to be found at one side as the other one. (That should really be put more precisely for the picky. The dipole contribution of any set of positions of the protons is canceled by an opposite contribution from the set of opposite nucleon positions.)

The last integral in the expression for the potential energy defines the quadrupole matrix or tensor. You may note a mathematical similarity with the moment of inertia matrix of a solid body in classical mechanics. Just like there, the quadrupole matrix can be simplified by rotating the coordinate system to principal axes. That rotation gets rid of the integrals $\int r_{i} r_{j} \mathrm{~d}^{3} \vec{r}$ for $i \neq j$, so what is left is

$$
V=V_{\mathrm{pc}}+\frac{1}{2}\left(\frac{\partial^{2} \varphi}{\partial x^{2}}\right)_{0} \int x^{2} \rho \mathrm{~d}^{3} \vec{r}+\frac{1}{2}\left(\frac{\partial^{2} \varphi}{\partial y^{2}}\right)_{0} \int y^{2} \rho \mathrm{~d}^{3} \vec{r}+\frac{1}{2}\left(\frac{\partial^{2} \varphi}{\partial z^{2}}\right)_{0} \int z^{2} \rho \mathrm{~d}^{3} \vec{r}
$$

where the first term is the potential of the point charge.
Note that the average of $x^{2}, y^{2}$, and $z^{2}$ is $\frac{1}{3} r^{2}$. It is convenient to subtract that average in each integral. The subtraction does not change the value of the potential energy. The reason is that the sum of the three second order derivatives of the external field $\varphi$ is zero due to Maxwell"s first equation, chapter 13.2. All that then leads to a definition of an electric quadrupole moment for a single axis, taken to be the $z$-axis, as

$$
Q \equiv \frac{1}{e} \int\left(3 z^{2}-r^{2}\right) \rho \mathrm{d}^{3} \vec{r}
$$

For simplicity, the nasty fractions have been excluded from the definition of $Q$. Also, it has been scaled with the charge $e$ of a single proton.

That gives $Q$ units of square length, which is easy to put in context. Recall that nuclear sizes are of the order of a few femtometer. So the SI unit square femtometer, $\mathrm{fm}^{2}$ or $10^{-30} \mathrm{~m}^{2}$, works quite nicely for the quadrupole moment $Q$ as defined. It is therefore needless to say that most sources do not use it. They use the "barn," a non-SI unit equal to $10^{-28} \mathrm{~m}^{2}$. The reason is historical; during the second world war some physicists figured that the word "barn" would hide the fact that work was being done on nuclear bombs from the Germans. Of course, that did not work since so few memos and reports are one-word ones. However, physicists discovered that it did help confuse students, so the term has become very widely used in the half century since then. Also, unlike a square femtometer, the barn is much too large compared to a typical nuclear cross section, producing all these sophisticated looking tiny decimal fractions.

To better understand the likely values of the quadrupole moment, consider the effect of the charge distribution of a single proton. If the charge distribution is spherically symmetric, the averages of $x^{2}, y^{2}$ and $z^{2}$ are equal, making $Q$ zero. However, consider the possibility that the charge distribution is not spherical, but an ellipsoid of revolution, a "spheroid.". If the axis of symmetry is the $z$ axis, and the charge distribution hugs closely to that axis, the spheroid will look like a cigar or zeppelin. Such a spheroid is called "prolate." The value of $Q$ is then about $\frac{2}{5}$ of the square nuclear radius $R$. If the charge distribution stays close to the $x y$-plane, the spheroid will look like a flattened sphere. Such a spheroid is called "oblate." In that case the value of $Q$ is about $-\frac{2}{5}$ of the square nuclear radius. Either way, the values of $Q$ are noticeably less than the square nuclear radius.

It may be noted that the quadrupole integrals also pop up in the description of the electric field of the nucleus itself. Far from the nucleus, the deviations in its electric field from that of a point charge are proportional to the same integrals, compare chapter 13.3.3.

### 14.17.2 Draft: Quantum description

Quantum mechanics makes for some changes to the classical description of the electromagnetic moments. Angular momentum is quantized, and spin must be included.

### 14.17.2.1 Draft: Magnetic dipole moment

As the classical description showed, the strength of an electromagnet is essentially the angular momentum of the charges going around, times the ratio of their charge to their mass. In quantum mechanics angular momentum comes in units of $\hbar$. Also, for nuclei the charged particles are protons with charge $e$ and mass $m_{\mathrm{p}}$. Therefore, a good unit to describe magnetic strengths in terms of is the so-called "nuclear magneton"

$$
\begin{equation*}
\mu_{\mathrm{N}} \equiv \frac{e \hbar}{2 m_{\mathrm{p}}} \tag{14.26}
\end{equation*}
$$

In those terms, the magnetic magnetic dipole moment operator of a single proton is

$$
\frac{1}{\hbar} \widehat{\vec{L}}_{\mathrm{p}} \mu_{\mathrm{N}}
$$

But quantum mechanics brings in a complication, chapter 13.4. Protons have intrinsic angular momentum, called spin. That also acts as an electromagnet. In addition the magnetic strength per unit of angular momentum is different for spin than for orbital angular momentum. The factor that it is different is called the proton $g$-factor $g_{p}$. That then makes the total magnetic dipole moment operator of a single proton equal to

$$
\begin{equation*}
\widehat{\vec{\mu}_{\mathrm{p}}}=\frac{1}{\hbar}\left(\widehat{\vec{L}}+g_{\mathrm{p}} \widehat{\vec{S}}\right) \mu_{\mathrm{N}} \quad g_{\mathrm{p}} \approx 5.59 \tag{14.27}
\end{equation*}
$$

The above value of the proton $g$-factor is experimental.
Neutrons do not have charge and therefore their orbital motion creates no magnetic moment. However, neutrons do create a magnetic moment through their spin:

$$
\begin{equation*}
\widehat{\vec{\mu}}_{\mathrm{n}}=\frac{1}{\hbar} g_{\mathrm{n}} \widehat{\widehat{S}} \mu_{\mathrm{N}} \quad g_{\mathrm{n}} \approx-3.83 \tag{14.28}
\end{equation*}
$$

The reason is that the neutron consists of three charged quarks; they produce a net magnetic moment even if they do not produce a net charge.

The net magnetic dipole moment operator of the complete nucleus is

$$
\begin{equation*}
\widehat{\vec{\mu}}=\frac{1}{\hbar}\left[\sum_{i=1}^{Z}\left(\widehat{\vec{L}}_{i}+g_{\mathrm{p}} \widehat{\vec{S}}_{i}\right)+\sum_{i=Z+1}^{A} g_{\mathrm{n}} \widehat{\vec{S}}_{i}\right] \mu_{\mathrm{N}} \tag{14.29}
\end{equation*}
$$

where $i$ is the nucleon number, the first $Z$ being protons and the rest neutrons.
Now assume that the nucleus is placed in an external magnetic field $\mathcal{B}$ and take the $z$-axis in the direction of the field. Because nuclear energies are so large, external electromagnetic fields are far too weak to change the quantum structure of the nucleus; its wave function remains unchanged to a very good approximation. However, the field does produce a tiny change in the energy levels of the quantum states. These may be found using expectation values:

$$
\Delta E=\langle\Psi|-\widehat{\mu}_{z} \mathcal{B}|\Psi\rangle
$$

The fact that that is possible is a consequence of small perturbation theory, as covered in addendum $\{\mathrm{A} .38\}$.

However, it is not immediately clear what nuclear wave function $\Psi$ to use in the expectation value above. Because of the large values of nuclear energies, a nucleus is affected very little by its surroundings. It behaves essentially as if it is isolated in empty space. That means that while the nuclear energy may depend on the magnitude of the nuclear spin $\widehat{\vec{J}}$, (i.e. the net nuclear angular momentum), it does not depend on its direction. In quantum terms, the energy does not depend on the component $\widehat{J}_{z}$ in the chosen $z$-direction. So, what should be used in the above expectation value to find the change in the energy of a nucleus in a state of spin $j$ ? States with definite values of $J_{z}$ ? Linear combinations of such states? You get a difference answer depending on what you choose.

Now a nucleus is a composite structure, consisting of protons or neutrons, each contributing to the net magnetic moment. However, the protons and neutrons themselves are composite structures too, each consisting of three quarks. Yet at normal energy levels protons and neutrons act as elementary particles, whose magnetic dipole moment is a scalar multiple $g \mu_{\mathrm{N}}$ of their spin. Their energies in a magnetic field split into two values, one for the state with $J_{z}=$ $\frac{1}{2} \hbar$ and the other with $J_{z}=-\frac{1}{2} \hbar$. One state corresponds to magnetic quantum number $m_{j}=\frac{1}{2}$, the other to $m_{j}=-\frac{1}{2}$.

The same turns out to be true for nuclei; they too behave as elementary particles as long as their wave functions stay intact. In a magnetic field, the original energy level of a nucleus with spin $j$ splits into equally spaced levels corresponding to nuclear magnetic quantum numbers $m_{j}=j, j-1, \ldots,-j$. The numerical value of the magnetic dipole moment $\mu$ is therefore defined to be the expectation value of $\widehat{\mu}_{z}$ in the nuclear state in which $m_{j}$ has its largest value $j$, call it the $|j j\rangle$ state:

$$
\begin{equation*}
\mu \equiv\langle j j| \widehat{\mu}_{z}|j j\rangle \tag{14.30}
\end{equation*}
$$

The fact that nuclei would behave so simple is related to the fact that nuclei are essentially in empty space. That implies that the complete wave function of a nucleus in the ground state, or another energy eigenstate, will vary in a very
simple way with angular direction. Furthermore, that variation is directly given by the angular momentum of the nucleus. A brief discussion can be found in chapter 7.3 and its note. See also the discussion of the Zeeman effect, and in particular the weak Zeeman effect, in addendum \{A.38\}.

The most important consequence of those ideas is that
Nuclei with spin zero do not have magnetic dipole moments.
That is not very easy to see from the general expression for the magnetic moment, cluttered as it is with $g$-factors. However, zero spin means on a very fundamental level that the complete wave function of a nucleus is independent of direction, chapter 4.2.3. A magnetic dipole strength requires directionality, there must be a north pole and a south pole. That cannot occur for nuclei of spin zero.

### 14.17.2.2 Draft: Electric quadrupole moment

The definition of the electric quadrupole moment follows the same ideas as that of the magnetic dipole moment. The numerical value of the quadrupole moment is defined as the expectation value of $3 z^{2}-r^{2}$, summed over all protons, in the state in which the net nuclear magnetic quantum number $m_{j}$ equals the nuclear spin $j$ :

$$
\begin{equation*}
Q \equiv\langle j j| \sum_{i=1}^{Z} 3 z_{i}^{2}-r_{i}^{2}|j j\rangle \tag{14.31}
\end{equation*}
$$

Note that there is a close relation with the spherical harmonics;

$$
\begin{equation*}
3 z^{2}-r^{2}=\sqrt{\frac{16 \pi}{5}} r^{2} Y_{2}^{0} \tag{14.32}
\end{equation*}
$$

That is important because it implies that

> Nuclei with spin zero or with spin one-half do not have electric quadrupole moments.

To see why, note that the expectation value involves the absolute square of the wave function. Now if you multiply two wave functions together that have an angular dependence corresponding to a spin $j$, mathematically speaking you get pretty much the angular dependence of two particles of $\operatorname{spin} j$. That cannot become more than an angular dependence of spin $2 j$, in other words an angular dependence with terms proportional to $Y_{2 j}^{m}$. Since the spherical harmonics are mutually orthonormal, $Y_{2 j}^{m}$ integrates away against $Y_{2}^{0}$ for $j \leqslant \frac{1}{2}$.

It makes nuclei with spin $1 / 2$ popular for nuclear magnetic resonance studies. Without the perturbing effects due to quadrupole interaction with the electric field, they give nice sharp signals. Also of course, analysis is easier with only two spin states and no quadrupole moment.

### 14.17.2.3 Draft: Shell model values

According to the odd-particle shell model, all even-even nuclei have spin zero and therefore no magnetic or electric moments. That is perfectly correct.

For nuclei with an odd mass number, the model says that all nucleons except for the last odd one are paired up in spherically symmetric states of zero spin that produce no magnetic moment. Therefore, the magnetic moment comes from the last proton or neutron. To get it, according to the second last subsubsection, what is needed is the expectation value of the magnetic moment operator $\widehat{\mu}_{z}$ as given there. Assume the shell that the odd nucleon is in has single-particle net momentum $j$. According to the definition of magnetic moment, the magnetic quantum number must have its maximum value $m_{j}=j$. Call the corresponding state the $\psi_{n l j j}$ one because the spectroscopic notation is useless as always. In particular for an odd-even nucleus,

$$
\mu=\frac{1}{\hbar}\left\langle\psi_{n l j j}\right| L_{z}+g_{p} \widehat{S}_{z}\left|\psi_{n l j j}\right\rangle \mu_{\mathrm{N}}
$$

while for an even-odd nucleus

$$
\mu=\frac{1}{\hbar}\left\langle\psi_{n l j j}\right| g_{n} \widehat{S}_{z}\left|\psi_{n l j j}\right\rangle \mu_{\mathrm{N}}
$$

The unit $\mu_{\mathrm{N}}$ is the nuclear magneton. The expectation values can be evaluated by writing the state $\psi_{n l j j}$ in terms of the component states $\psi_{n l m m_{s}}$ of definite angular momentum $\widehat{L}_{z}$ and spin $\widehat{S}_{z}$ following chapter 12.8, 2.

It is then found that for an odd proton, the magnetic moment is

$$
\begin{array}{ll}
j=l-1 / 2: & \mu_{\mathrm{p} 1}=\frac{1}{2} \frac{j}{j+1}\left(2 j+3-g_{p}\right) \mu_{\mathrm{N}}  \tag{14.33}\\
j=l+1 / 2: & \mu_{\mathrm{p} 2}=\frac{1}{2}\left(2 j-1+g_{p}\right) \mu_{\mathrm{N}}
\end{array}
$$

while for an odd neutron

$$
\begin{array}{ll}
j=l-1 / 2: & \mu_{\mathrm{n} 1}=-\frac{1}{2} \frac{j}{j+1} g_{n} \mu_{\mathrm{N}}  \tag{14.34}\\
j=l+1 / 2: & \mu_{\mathrm{n} 2}=\frac{1}{2} g_{n} \mu_{\mathrm{N}}
\end{array}
$$

These are called the "Schmidt values."
Odd-odd nuclei are too messy to be covered here, even if the Nordheim rules would be reliable.

For the quadrupole moments of nuclei of odd mass number, filled shells do not produce a quadrupole moment, because they are spherically symmetric. Consider now first the case that there is a single proton in an otherwise empty shell with single-particle momentum $j$. Then the magnetic moment of the nucleus can be found as the one of that proton:

$$
Q=Q_{\mathrm{p}}=\left\langle\psi_{n l j j}\right| 3 z^{2}-r^{2}\left|\psi_{n l j j}\right\rangle
$$

Evaluation, $\{\mathrm{D} .78\}$, gives

$$
\begin{equation*}
Q_{\mathrm{p}}=-\frac{2 j-1}{2 j+2}\left\langle r^{2}\right\rangle \tag{14.35}
\end{equation*}
$$

where $\left\langle r^{2}\right\rangle$ is the expectation value of $r^{2}$ for the proton. Note that this is zero as it should if the spin $j=\frac{1}{2}$. Since the spin $j$ must be half-integer, zero spin is not a consideration. For all other values of $j$, the one-proton quadrupole moment is negative.

The expectation value $\left\langle r^{2}\right\rangle$ can hardly be much more than the square nuclear radius, excepting maybe halo nuclei. A reasonable guess would be to assume that the proton is homogeneously distributed within the nuclear radius $R$. That gives a ballpark value

$$
\left\langle r^{2}\right\rangle \approx \frac{3}{5} R^{2}
$$

Next consider the case that there are not one but $I \geqslant 3$ protons in the unfilled shell. The picture of the odd-particle shell model as usually painted is: the first $I-1$ protons are pairwise combined in spherically symmetric states and the last odd proton is in a single particle state, blissfully unaware of the other protons in the shell. In that case, the quadrupole moment would self evidently be the same as for one proton in the shell. But as already pointed out in section 14.12.4, the painted picture is not really correct. For one, it does not satisfy the antisymmetrization requirement for all combinations on protons. There really are $I$ protons in the shell sharing one wave function that produces a net spin equal to $j$.

In particular consider the case that there are $2 j$ protons in the shell. Then the wave function takes the form of a filled shell, having no quadrupole moment, plus a "hole", a state of angular momentum $j$ for the missing proton. Since a proton hole has minus the charge of a proton, the quadrupole moment for a single hole is opposite to that of one proton:

$$
\begin{equation*}
Q_{2 j \mathrm{p}}=-Q_{\mathrm{p}} \tag{14.36}
\end{equation*}
$$

In other words, the quadrupole moment for a single hole is predicted to be positive. For $j=\frac{1}{2}$, a single proton also means a single hole, so the quadrupole moment must, once more, be zero. It has been found that the quadrupole moment changes linearly with the odd number of protons, [31, p, 129]. Therefore for shells with more than one proton and more than one hole, the quadrupole moment is in between the one-proton and one-hole values. It follows that the one-proton value provides an upper bound to the magnitude of the quadrupole moment for any number of protons in the shell.

Since neutrons have no charge, even-odd nuclei would in the simplest approximation have no quadrupole moment at all. However, consider the odd neutron and the spherical remainder of the nucleus as a two-body system going
around their common center of gravity. In that picture, the charged remainder of the nucleus will create a quadrupole moment. The position vector of the remainder of the nucleus is about $1 / A$ times shorter than that of the odd neutron, so quadratic lengths are a factor $1 / A^{2}$ shorter. However, the nucleus has $Z$ times as much charge as a single proton. Therefore you expect nuclei with an odd neutron to have about $Z / A^{2}$ times the quadrupole moment of the corresponding nucleus with an odd proton instead of an odd neutron. For heavy nuclei, that would still be very much smaller than the magnetic moment of a similar odd-even nucleus.

### 14.17.2.4 Draft: Values for deformed nuclei

For deformed nuclei, part of the angular momentum is due to rotation of the nucleus as a whole. In particular, for the ground state rotational band of deformed even-even nuclei, all angular momentum is in rotation of the nucleus as a whole. This is orbital angular momentum. Protons with orbital angular momentum produce a magnetic dipole moment equal to their angular momentum, provided the dipole moment is expressed in terms of the nuclear magneton $\mu_{\mathrm{N}}$. Uncharged neutrons do not produce a dipole moment from orbital angular momentum. Therefore. the magnetic dipole moment of the nucleus is about

$$
\begin{equation*}
\text { even-even, ground state band: } \quad \mu=g_{\mathrm{R}} j \mu_{\mathrm{N}} \quad g_{\mathrm{R}} \approx \frac{Z}{A} \tag{14.37}
\end{equation*}
$$

where the $g$-factor reflects the relative amount of the nuclear angular momentum that belongs to the protons. This also works for vibrational nuclei, since their angular momentum too is in global motion of the nucleus.

If a rotational band has a minimum spin $j_{\min }$ that is not zero, the dipole moment is, [40, p. 392],

$$
\begin{equation*}
\mu=\left[g_{\mathrm{R}} j+\frac{j_{\min }^{2}}{j+1}\left(g_{\mathrm{int}}-g_{\mathrm{R}}\right)\right] \mu_{\mathrm{N}} \quad g_{\mathrm{R}} \approx \frac{Z}{A} \quad j_{\min } \neq 1 / 2 \tag{14.38}
\end{equation*}
$$

where $g_{\text {int }} j_{\min } \mu_{\mathrm{N}}$ reflects an internal magnetic dipole strength. If $j_{\min }=\frac{1}{2}$, the top of the first ratio has an additional term that has a magnitude proportional to $2 j+1$ and alternates in sign.

The quadrupole moment of deformed nuclei is typically many times larger than that of a shell model one. According to the shell model, all protons except at most one are in spherical orbits producing no quadrupole moment. But if the nucleus is deformed, typically into about the shape of some spheroid instead of a sphere, then all protons contribute. Such a nucleus has a very large "intrinsic" quadrupole moment $Q_{\mathrm{int}}$.

However, that intrinsic quadrupole moment is not the one measured. For example, many heavy even-even nuclei have very distorted intrinsic shapes but
all even-even nuclei have a measured quadrupole moment that is zero in their ground state. That is a pure quantum effect. Consider the state in which the axis of the nucleus is aligned with the $z$-direction. In that state a big quadrupole moment would be observed due to the directional charge distribution. But there are also states in which the nucleus is aligned with the $x$-direction, the $y$-direction, and any other direction for that matter. No big deal classically: you just grab hold of the nucleus and measure its quadrupole moment. But quantum mechanics makes the complete wave function a linear combination of all these different possible orientations; in fact an equal combination of them by symmetry. If all directions are equal, there is no directionality left; the measured quadrupole moment is zero. Also, directionality means angular momentum in quantum mechanics; if all directions are equal the spin is zero. "Grabbing hold" of the nucleus means adding directionality, adding angular momentum. That creates an excited state.

A simple known system that shows such effects is the hydrogen atom. Classically the atom is just an electron and a proton at opposite sides of their center of gravity. If they are both on the $z$-axis, say, that system would have a nonzero quadrupole moment. But such a state is not an exact energy eigenstate, far from it. It interacts with states in which the direction of the connecting line is different. By symmetry, the ground state is the one in which all directions have the same probability. The atom has become spherically symmetric. Still, the atom has not become intrinsically spherically symmetric; the wave function is not of a form like $\psi_{1}\left(r_{\mathrm{e}}\right) \psi_{2}\left(r_{\mathrm{p}}\right)$. The positions of electron and proton are still correlated, $\{$ A. 5$\}$.

A model of a spheroidal nucleus produces the following relationship between the intrinsic quadrupole moment and the one that is measured:

$$
\begin{equation*}
Q=\frac{3 j_{\min }^{2}-j(j+1)}{(j+1)(2 j+3)} Q_{\mathrm{int}} \tag{14.39}
\end{equation*}
$$

where $j_{\min }$ is the angular momentum of the nucleus when it is not rotating. Derivations may be found in [40] or [36]. It can be seen that when the nucleus is not rotating, the measured quadrupole moment is much smaller than the intrinsic one unless the angular momentum is really large. When the nucleus gets additional rotational angular momentum, the measured quadrupole moment decreases even more and eventually ends up with the opposite sign.

### 14.17.3 Draft: Magnetic moment data

Figure 14.42 shows ground state magnetic moments in units of the nuclear magneton $\mu_{\mathrm{N}}$. Even-even nuclei do not have magnetic moments in their ground state, so they are not shown. The red and blue horizontal lines are the Schmidt values predicted by the shell model. They differ in whether spin subtracts from
or adds to the net angular momentum $j$ to produce the orbital momentum $l$. Red dots should be on the red lines, blue dots on the blue lines. For black dots, no confident prediction of the orbital angular momentum could be made. The values have an error of no more than about $0.1 \mu_{\mathrm{N}}$, based on a subjective evaluation of both reported errors as well as differences between results obtained by different studies for the same number. These differences are often much larger than the reported errors for the individual numbers.

One good thing to say about it all is that the general magnitude is well predicted. Few nuclei end up outside the Schmidt lines. (Rhodium-103, a stable odd-even $1 / 2^{-}$nucleus, is a notable exception.) Also, some nuclei are actually on their line. And the others tend to at least be on the right side of the cloud. The bad news is, of course, that the agreement is only qualitatively.

The main excuses that are offered are:

1. The $g$-factors $g_{\mathrm{p}}$ and $g_{\mathrm{n}}$ describe the effectiveness of proton and neutron spins in generating magnetic moments in free space. They may be reduced when these nucleons are inside a nucleus. Indeed, it seems reasonable enough to assume that the motion of the quarks that make up the protons and neutrons could be affected if there are other quarks nearby. Reduction of the $g$-factors drives the Schmidt lines towards each other, and that can clearly reduce the average errors. Unfortunately, different nuclei would need different reductions to obtain quantitative agreement.
2. Collective motion. If some of the angular momentum is into collective motion, it tends to drift the magnetic moment towards about $\frac{1}{2} j \mu_{\mathrm{N}}$, compare (14.38). To compute the effect requires the internal magnetic moment of the nucleus to be known. For some nuclei, fairly good magnetic moments can be obtained by using the Schmidt values for the internal magnetic moment, [40, p. 393].
For odd-odd nuclei, the data average out to about $0.5 j$ nuclear magnetons, with a standard deviation of about one magneton. These average values are shown as yellow lines in figure 14.42. Interestingly enough, the average is like a collective rotation, (14.37).

According to the shell model, two odd particles contribute to the spin and magnetic moment of odd-odd nuclei. So they could have significantly larger spins and magnetic moments than odd mass nuclei. Note from the data in figure 14.42 that that just does not happen.

Even-even nuclei do not have magnetic moments in their ground state. Figure 14.43 shows the magnetic moments of the first exited $2^{+}$state of these nuclei. The values are in fairly good agreement with the prediction (14.37) of collective motion that the magnetic moment equals $Z j / A$ nuclear magnetons. Bright green squares are correct. Big deviations occur only near magic numbers. The maximum error in the shown data is about a quarter of a nuclear magneton, subjectively evaluated.

### 14.17.4 Draft: Quadrupole moment data

If you love the shell model, you may want to skip this subsection. It is going to get a beating.

The prediction of the shell model is relatively straightforward. The electric quadrupole moment of a single proton in an unfilled shell of high angular momentum can quite well be ballparked as

$$
Q_{\mathrm{p} \text { ballpark }} \sim \frac{3}{5} R^{2}
$$

where $R$ is the nuclear radius computed from (14.9). This value corresponds to the area of the square marked "a proton's" in the legend of figure 14.44. As discussed in subsection 14.17.2.3, if there are more protons in the shell, the magnitude is less, though the sign will eventually reverse. If the angular momentum is not very high, the magnitude is less. If there is no odd proton, the magnitude will be almost zero. So, essentially all squares in figure 14.44 must be smaller, most a lot smaller, and those on lines of even $Z$ very much smaller, than the single proton square in the legend...

Well, you might be able to find a smaller square somewhere. For example, the square for lithium-6, straight above doubly-magic ${ }_{2}^{4} \mathrm{He}$, has about the right size and the right color, blue. The data shown have a subjectively estimated error of up to $40 \%$, [sic], and the area of the squares gives the scaled quadrupole moment. Nitrogen-14, straight below doubly-magic ${ }_{8}^{16} \mathrm{O}$, has a suitably small square of the right color, red. So does potassium-39 with one proton less than doubly-magic ${ }_{20}^{40} \mathrm{Ca}$. Bismuth-209, with one more proton than ${ }_{82}^{208} \mathrm{~Pb}$ has a relatively small square of the right color. Some nuclei on magic proton number lines have quite small scaled quadrupole moments, though hardly almost zero as they should. Nuclei one proton above magic proton numbers tend to be of the right color, blue, as long as their squares are small. Nuclei one proton below the magic proton numbers should be red; however, promotion can mess that up.

Back to reality. Note that many nuclei in the $Z<82, N>82$ wedge, and above $Z=82$, as well as various other nuclei, especially away from the stable line, have quadrupole moments that are very many times larger than the ballpark for a single proton. That is simply not possible unless many or all protons contribute to the quadrupole moment. The odd-particle shell model picture of a spherically symmetric nuclear core plus an odd proton, and maybe a neutron, in nonspherical orbits hanging on is completely wrong for these nuclei These nuclei have a global shape that simply is not spherical. And because the shell model was derived based on a spherical potential, its results are invalid for these nuclei. They are the deformed nuclei that also showed up in figures 14.19 and 14.22. It is the quadrupole moment that shows that it was not just an empty excuse to exclude these nuclei in shell model comparisons. The measured quadrupole moments show without a shadow of a doubt that the shell model cannot be valid

Figure 14.44: Electric quadrupole moment. [pdf][con]

You might however wonder about the apparently large amount in random scatter in the quadrupole moments of these nuclei. Does the amount of deformation vary that randomly? Before that can be answered, a correction to the data must be applied. Measured quadrupole moments of a deformed nucleus are often much too small for the actual nuclear deformation. The reason is uncertainty in the angular orientation of these nuclei. In particular, nuclei with spin zero have complete uncertainty in orientation. Such nuclei have zero measured quadrupole moment regardless how big the deformation of the nucleus is. Nuclei with spin one-half still have enough uncertainty in orientation to measure as zero.

Figure 14.45 shows what happens if you try to estimate the "intrinsic" quadrupole moment of the nuclei in absence of uncertainty in angular orientation. For nuclei whose spin is at least one, the estimate was made based on the measured value using (14.39), with both $j_{\min }$ and $j$ equal to the spin. This assumes that the intrinsic shape is roughly spheroidal. For shell-model nuclei, this also roughly corrects for the spin effect, though it overcorrects to some extent for nuclei of low spin.

To estimate the intrinsic quadrupole moment of nuclei with zero ground state spin, including all even-even nuclei, the quadrupole moment of the lowest excited $2^{+}$state was used, if it had been measured. For spin one-half the lowest $3 / 2$ state was used. In either case, $j_{\min }$ was taken to be the spin of the ground state and $j$ that of the excited state. Regrettably, these estimates do not make much sense if the nucleus is not a rotating one.

Note in figure 14.45 how much more uniform the squares in the regions of deformed nuclei have become. And that the squares of nuclei of spin zero and one-half have similar sizes. These nuclei were not really more spherical; it was just hidden from experiments.

The observed intrinsic quadrupole moments in the regions of deformed nuclei correspond to roughly $20 \%$ radial deviation from the spherical value. Clearly, that means quite a large change in shape.

It may be noted that figure 14.44 leaves out magnesium-23, whose reported quadrupole moment of 1.25 barn is far larger that that of similar nuclei. If this value is correct, clearly magnesium- 23 must be a halo nucleus with two protons outside a neon- 21 core.

### 14.18 Draft: Isospin

Isospin is another way of thinking about the two types of nucleons. It has proved quite useful in understanding nuclei, as well as elementary particles.

### 14.18.1 Draft: Basic ideas

Normally, you think of nuclei as consisting of protons and neutrons. But protons and neutrons are very similar in properties, if you ignore the Coulomb force. They have almost the same mass. Also, according to charge independence, the nuclear force is almost the same whether it is protons or neutrons.

So suppose you define only one particle, called nucleon. Then you can give that particle an additional property called "nucleon type." If the nucleon type is $\frac{1}{2}$, it is a proton, and if the nucleon type is $-\frac{1}{2}$ it is a neutron. That makes nucleon type a property that is mathematically much like the spin $S_{z}$ of a nucleon in a chosen $z$-direction. But of course, there is no physical "nucleontype axis." Therefore nucleon type is conventionally indicated by the symbol $T_{3}$, not $T_{z}$, with no physical meaning attached to the 3 -axis. In short, nucleon type is defined as:

$$
\begin{equation*}
\text { proton: } T_{3}=\frac{1}{2} \quad \text { neutron: } T_{3}=-\frac{1}{2} \tag{14.40}
\end{equation*}
$$

So far, all this it may seem like a stupid mathematical trick. And normally it would be. The purpose of mathematical analysis is to understand systems, not to make them even more incomprehensible.

But to the approximation that the nuclear force is charge-independent, nucleon type is not so stupid after all. If the nuclear force is charge-independent, and the Coulomb force is ignored, you can write down nuclear wave functions without looking at the nucleon type. Now suppose that in doing so, you find some energy eigenfunction of the form

$$
\psi_{\mathrm{A}}=\psi_{\mathrm{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|11\rangle
$$

This is a wave function for two nucleons labeled 1 and 2. Assume here that the spatial part $\psi_{\mathrm{s}}$ is unchanged under nucleon exchange (swapping the nucleons):

$$
\psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)=\psi_{\mathbf{s}}\left(\vec{r}_{1}-\vec{r}_{2}\right)
$$

(This is equivalent to assuming that the wave function has even parity.) Further recall from chapter 5.5.6 that the triplet spin state $|11\rangle$ is unchanged under nucleon exchange too. So the total wave function $\psi_{\mathrm{A}}$ above is unchanged under nucleon exchange.

That is fine if nucleon 1 is a proton and nucleon 2 a neutron. Or vice-versa. But it is not OK if both nucleons are protons, or if they are both neutrons. Wave functions must change sign if two identical fermions are exchanged. That is the antisymmetrization requirement. The wave function above stays the same. So it is only acceptable for the deuteron, with one proton and one neutron.

Next suppose you could find a different wave function of the form

$$
\psi_{\mathrm{B}}=\psi_{\mathrm{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle
$$

(Here $\psi_{s}$ is not necessarily the same as before, but assume it still has even parity.) The singlet spin state $|00\rangle$ changes sign under nucleon exchange. Then so does the entire wave function $\psi_{\mathrm{B}}$. And that then means that $\psi_{\mathrm{B}}$ is acceptable even if the nucleons are both protons or both neutrons. This wave function works not just for the deuteron, but also for the "diproton" and the "dineutron." (The prefix "di" means two.)

That would give nontrivial insight in nuclear energy levels. It would mean physically that the diproton, the dineutron, and the deuteron can be in an identical energy state. Such identical energy states, occurring for different nuclei, are called "isobaric analog (or analogue) states." Or "charge states." Or "isobaric multiplets." Or "T-multiplets." Hey, don't blame the messenger.

Disappointingly, in real life there is no bound state of the form $\psi_{\mathrm{B}}$. Still the bottom line stays:

Within the approximations of charge independence and negligible Coulomb effects, whether a given state applies to a given set of nucleon types depends only on the antisymmetrization requirements.

Now for bigger systems of nucleons, the antisymmetrization requirements get much more complex. A suitable formalism for dealing with that has already been developed in the context of the spin of systems of identical fermions. It is convenient to adopt that formalism also for nucleon type.

As an example, consider the above three hypothetical isobaric analog states for the diproton, dineutron, and deuteron. They can be written out separately as, respectively,
$\psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle \Uparrow_{1} \Uparrow_{2} \quad \psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle \Downarrow_{1} \Downarrow_{2} \quad \psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle \frac{\Uparrow_{1} \Downarrow_{2}+\Downarrow_{1} \Uparrow_{2}}{\sqrt{2}}$
Here $\Uparrow$ means the nucleon is a proton and $\Downarrow$ means it is a neutron. If you want, you can write out the above wave functions explicitly in terms of the nucleon type $T_{3}$ as

$$
\begin{gathered}
\psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle\left(\frac{1}{2}+T_{31}\right)\left(\frac{1}{2}+T_{32}\right) \\
\psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle\left(\frac{1}{2}-T_{31}\right)\left(\frac{1}{2}-T_{32}\right) \\
\psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle \frac{\left(\frac{1}{2}+T_{31}\right)\left(\frac{1}{2}-T_{32}\right)+\left(\frac{1}{2}-T_{31}\right)\left(\frac{1}{2}+T_{32}\right)}{\sqrt{2}}
\end{gathered}
$$

Note, for example, that the first wave function is zero if either $T_{31}$ or $T_{32}$ is equal to $-\frac{1}{2}$. So it is zero if either nucleon is a neutron. The only way to get something nonzero is if both nucleons are protons, with $T_{31}=T_{32}=\frac{1}{2}$. Similarly, the second wave function is only nonzero if both nucleons are neutrons, with $T_{31}=T_{32}=-\frac{1}{2}$.

The third wave function represents something of a change in thinking. It requires that one nucleon is a proton and the other a neutron. So it is a wave function for the deuteron. But the actual wave function above is a superposition of two states. In the first state, nucleon 1 is the proton and nucleon 2 the neutron. In the second state, nucleon 1 is the neutron and nucleon 2 the proton. In the combined state the nucleons have lost their identity. It is uncertain whether nucleon 1 is the proton and nucleon 2 the neutron, or vice-versa.

Within the formalism of identical nucleons that have an additional nucleontype property, this uncertainty in nucleon types is unavoidable. The wave function would not be antisymmetric under nucleon exchange without it. But if you think about it, this may actually be an improvement in the description of the physics. Protons and neutrons do swap identities. That happens if they exchange a charged pion. Proton-neutron scattering experiments show that they can do that. For nucleons that have a probability of swapping type, assigning a fixed type in energy eigenstates is not right. Energy eigenstates must be stationary. And having a better description of the physics can affect what sort of potentials you would want to write down for the nucleons.
(You might think that without charge independence, the additional antisymmetrization requirement for identical nucleons would change the physics. But actually, it does not. The antisymmetrization requirement can be accomodated by uncertainty in which nucleon you label 1 and which 2. Consider some completely general proton-neutron wave function $\Psi\left(\vec{r}_{\mathrm{p}}, S_{z \mathrm{p}}, \vec{r}_{\mathrm{n}}, S_{z \mathrm{n}}\right)$, one that would not be the same if you swap the proton and neutron. It might be a subsystem in some larger nucleus for which charge-independence is not a good approximation. The antisymmetrized identical-nucleon wave function is

$$
\begin{equation*}
\frac{1}{\sqrt{2}} \Psi\left(\vec{r}_{1}, S_{z 1}, \vec{r}_{2}, S_{z 2}\right) \Uparrow_{1} \Downarrow_{2}-\frac{1}{\sqrt{2}} \Psi\left(\vec{r}_{2}, S_{z 2}, \vec{r}_{1}, S_{z 1}\right) \Downarrow_{1} \Uparrow_{2} \tag{14.41}
\end{equation*}
$$

This is a superposition of two parts. In the first part the proton is labeled 1 and the neutron 2. In the second part, the proton is labeled 2 and the neutron 1. The physics has stayed exactly the same. What has changed is that there is now confusion about whether the particle labeled 1 is the proton or the neutron. This illustrates that without charge independence, the mathematical trickery employed here is not really wrong. But it is "entirely useless," as Wigner was the first to point out, [50, p. 4].)

Now compare the trailing nucleon-type factors in the three hypothetical isobaric analog states above with the possible combined spin states of two spin $1 / 2$ fermions. It is seen that the nucleon-type factors take the exact same form as the so-called "triplet" spin states, (5.26). So define similarly

$$
\begin{equation*}
\Uparrow_{1} \Uparrow_{2} \equiv|11\rangle_{T} \quad \Downarrow_{1} \Downarrow_{2} \equiv|1-1\rangle_{T} \quad \frac{\Uparrow_{1} \Downarrow_{2}+\Downarrow_{1} \Uparrow_{2}}{\sqrt{2}} \equiv|10\rangle_{T} \tag{14.42}
\end{equation*}
$$

In those terms, the isobaric analog states are all three of the form

$$
\psi_{\mathbf{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|00\rangle\left|1 m_{T}\right\rangle_{T}
$$

where $m_{T}$ is $1,-1$, or 0 for the diproton, dineutron, and deuteron respectively. Note that that is just the sum of the $T_{3}$ values of the two nucleons,

$$
m_{T}=T_{31}+T_{32}
$$

Now reconsider the wave function for two nucleons that was written down first. The one that was only acceptable for the deuteron. In the same terminology, it can be written as

$$
\psi_{\mathrm{s}}\left(\vec{r}_{2}-\vec{r}_{1}\right)|11\rangle|00\rangle_{T} \quad|00\rangle_{T} \equiv \frac{\Uparrow_{1} \Downarrow_{2}-\Downarrow_{1} \Uparrow_{2}}{\sqrt{2}}
$$

The formalism of identical nucleons with nucleon type forces again uncertainty in the nucleon types. But now there is a minus sign. That makes the nucleontype state a singlet state in the terminology of spin.

Of course, all this raises the question what to make of the leading 0 in the singlet state $|00\rangle_{T}$, and the leading 1 in the triplet states $\left|1 m_{T}\right\rangle$ ? If this was spin angular momentum, the 0 or 1 would indicate the quantum number $s$ of the square spin angular momentum. Square spin angular momentum is the sum of the square spin components in the $x, y$, and $z$ directions. But at first that seems to make no sense for nucleon type. Nucleon type is just a simple number, not a vector. While it has been formally associated with some abstract 3 -axis, there are no " $T_{1}$ " and " $T_{2}$ " components.

However, it is possible to define such components in complete analogy with the $x$ and $y$ components of spin. In quantum mechanics the components of spin are the eigenvalues of operators. And using advanced concepts of angular momentum, chapter 12 , the operators of $x$ and $y$ angular momenta can be found without referring explicitly to their axes. The same procedure can be followed for nucleon type.

To do so, first an operator $\widehat{T}_{3}$ for the nucleon type $T_{3}$ is defined as

$$
\begin{equation*}
\widehat{T}_{3} \Uparrow=\frac{1}{2} \Uparrow \quad \widehat{T}_{3} \Downarrow=-\frac{1}{2} \Downarrow \tag{14.43}
\end{equation*}
$$

In words, the proton state is an eigenstate of this operator with eigenvalue $\frac{1}{2}$. The neutron state is an eigenstate with eigenvalue $-\frac{1}{2}$. That follows the usual rules of quantum mechanics; observable quantities, (here nucleon type), are the eigenvalues of Hermitian operators.

Next a "charge creation operator" is defined by

$$
\begin{equation*}
\widehat{T}^{+} \Downarrow=\Uparrow \quad \widehat{T}^{+} \Uparrow=0 \tag{14.44}
\end{equation*}
$$

In words, it turns a neutron into a proton. In effect it adds a unit of charge to it. Since a nucleon with two units of charge does not exist, the operator needs to turn a proton state into zero. Similarly a "charge annihilation operator" is defined by

$$
\begin{equation*}
\widehat{T}^{-} \Uparrow=\Downarrow \quad \widehat{T}^{-} \Downarrow=0 \tag{14.45}
\end{equation*}
$$

Operators for nucleon type in the 1 and 2 directions can now be defined as

$$
\begin{equation*}
\widehat{T}_{1}=\frac{1}{2} \widehat{T}^{+}+\frac{1}{2} \widehat{T}^{-} \quad \widehat{T}_{2}=-\frac{1}{2} \mathrm{i} \widehat{T}^{+}+\frac{1}{2} \mathrm{i} \widehat{T}^{-} \tag{14.46}
\end{equation*}
$$

The eigenvalues of these operators are by definition the values of $T_{1}$ respectively $T_{2}$.

With these operators, square nucleon type can be defined just like square spin. All the mathematics has been forced to be the same.

The quantum number of square nucleon type will be indicated by $t_{T}$ in this book. Different sources use different notations. Many sources swap case, using lower case for the operators and upper case for the quantum numbers. Or they use lower case if it is for a single nucleon and upper case for the entire nucleus. They often do the same for angular momentum. Some sources come up with $I$ for the square nucleon type quantum number, using $J$ for the angular momentum one. However, this book cannot adopt completely inconsistent notations just for nuclear physics. Especially if there is no generally agreed-upon notation in the first place.

In any case there are three scaled operators whose definition and symbols are fairly standard in most sources. These are defined as

$$
\begin{equation*}
\tau_{1}=2 \widehat{T}_{1} \quad \tau_{2}=2 \widehat{T}_{2} \quad \tau_{3}=2 \widehat{T}_{3} \quad \tau^{+}=2 \widehat{T}^{+} \quad \tau^{-}=2 \widehat{T}^{-1} \tag{14.47}
\end{equation*}
$$

The first three are the direct equivalents of the famous Pauli spin matrices, chapter 12.10 . Note that they simply scale away the factors $\frac{1}{2}$ in the nucleon type. The Pauli spin matrices also scale away the factor $\hbar$ that appears in the values of spin.

### 14.18.2 Draft: Heavier nuclei

Now consider an example of isobaric analog states that actually exist. In this case the nucleons involved are carbon-14, nitrogen-14, and oxygen-14. All three have 14 nucleons, so they are isobars. However, carbon- 14 has 6 protons and 8 neutrons, while oxygen- 14 has 8 protons and 6 neutrons. Such pairs of nuclei, that have their numbers of protons and neutrons swapped, are called "conjugate" nuclei. Or "mirror" nuclei. Nitrogen-14 has 7 protons and 7 neutrons and is called "self-conjugate."

Since $T_{3}$ values add up, carbon-14 with 6 protons at $\frac{1}{2}$ each and 8 neutrons at $-\frac{1}{2}$ each has net $T_{3}=-1$. Similarly, nitrogen-14 has $T_{3}=0$, as any selfconjugate nucleus, while oxygen-14 has $T_{3}=1$. In general,

$$
\begin{equation*}
T_{3}=\frac{1}{2}(Z-N) \tag{14.48}
\end{equation*}
$$

where $Z$ is the number of protons and $N$ the number of neutrons. Note that the value of $T_{3}$ is fixed for a given nucleus. It is minus half the neutron excess of the nucleus.

In general, 14 nucleons can have a maximum $T_{3}=7$, if all 14 are protons. The minimum is -7 , if all 14 are neutrons.

Here is where the analogy with spin angular momentum gets interesting. Angular momentum is a vector. A given angular momentum vector can still have different directions. And different directions means different values of the $z$-component of its spin $S_{z}$. In particular, the quantum numbers of the possible $z$ components are

$$
